RF treatment is frequently performed for various forms of spinal pain, although scientific evidence for this intervention remains controversial. The first controlled study was published by Gallagher and coworkers in 1994. The authors selected 41 patients with chronic low back pain who responded with some relief to diagnostic intra-articular injections and randomized them to receive either “sham” or true RF treatment of the medial branches. The two study groups were then subdivided into patients who obtained good relief from the test blocks and those who did not. In a well-designed placebo-controlled study, van Kleef and associates demonstrated good results after RF treatment that lasted up to 12 months. Leclaire and colleagues did not find a therapeutic effect of RF treatment in a placebo-controlled trial, but this study has been criticized because the criterion for a positive “diagnostic” block was relief of pain for 24 hours or longer after lidocaine infiltration, which is inconsistent with the drug’s pharmacokinetics. In addition, 94% of the screened patients with back pain were selected for participation, which is much greater than the presumed prevalence of lumbar facetogenic pain (17% to 30%) in this cohort. For this reason this study is judged to have major methodologic flaws. van Wijk and coworkers also found no difference between the treatment and control groups with regard to VAS pain score, medication use, and function. However, the RF group in this study did report a 50% or greater reduction in complaints significantly more often (62% vs. 39%) than in those who received a sham procedure. The evaluation method, though, was subject to discussion. Finally, in the most recent RCT undertaken in 40 patients who obtained significant pain relief following three diagnostic blocks, a significantly greater improvement in pain symptoms, global perception of improvement, and quality of life was observed after 6 months in subjects allocated to RF treatment.

In two randomized studies comparing PRF and conventional RF treatment of facetogenic pain, both showed conventional RF to be superior. From these seven controlled and a multitude of uncontrolled studies, one can
conclude that RF treatment of the facet joints can provide intermediate-term benefit in carefully selected patients.

Another prospective study, though not an RCT, is of additional importance when estimating the efficacy of RF facet treatment. Dreyfuss and associates\(^{128}\) found that 60% of patients (\(n = 9\)) obtained at least a 90% reduction in pain at 12 months and 87% obtained at least 60% pain relief with RF facet treatment. Relief was associated with treatment of the multifidus muscle.\(^{128}\) This study differs in three important aspects from all previous studies of RF facet treatment. First, the authors used a different protocol for the diagnostic blocks. Although Lord and coworkers\(^{60}\) initially advocated the use of double-blind, placebo-controlled blocks to reach a precise diagnosis of “cervical” facet pain, Dreyfuss and colleagues used a modified comparative block protocol and omitted saline injections. For the first diagnostic nerve block, 0.5 mL of 2% lidocaine was injected. Patients reporting at least 80% pain relief for longer than 1 hour returned for confirmatory blocks with 0.5% bupivacaine. Patients exhibiting at least 80% pain relief for longer than 2 hours were then offered RF treatment. Second, this study used a different operative technique for RF facet treatment. Differences in comparison to other studies included the type of electrode (16-gauge Ray electrode), preoperative access to the target nerve, and coagulation of the targeted nerve 8 to 10 mm along its length, which entailed multiple lesioning. The meaning of multifidus stimulation and denervation is unclear and is still a subject of discussion.\(^{129,130}\)

**Procedure**

The patient assumes a prone position on the fluoroscopic table. A pillow is placed under the abdomen to diminish the physiologic lumbar lordosis. First, targeted levels are identified and a straight AP projection is obtained. The C-arm is then rotated cranially or caudally until no double contours are visible on the caudal end plate of the middle vertebra. The middle vertebra of the levels to be treated is used as the reference point before the searching for the optimal position of the C-arm. Subsequently, the C-arm is rotated to an approximately 15-degree oblique view until the spinous processes are projecting over the midline but well inside the contralateral facet joints. The entry point should then be marked over the target point, which is the junction of the superior articular process and transverse process. To perform a diagnostic block, the target point should be approximately 1 mm under this junction to avoid unwanted spread of local anesthetic to segmental nerves and false-positive results. After injection of local anesthetic (1% lidocaine) into the skin, the needle is inserted at the entry point and slowly advanced via a tunnel vision technique until the tip makes contact with...
bone. For a diagnostic block the position of the needle is checked on the lateral view and should be at the level of the inferior part of the intervertebral foramen, in line with the facet joint column. When accurate positioning is confirmed and after negative aspiration, 1 mL of local anesthetic (1% lidocaine) is injected at each level. To perform RF lesioning of the medial branch, after making bone contact with the tip of the needle, the needle is redirected slightly more cephalad until bone contact is lost, and the cannula is advanced 1 to 2 mm farther anteriorly over the superior margin of the transverse process (Figs. 62.19 and 62.20).

The C-arm is rotated into the lateral view to check the position of the needle tip, which should be in line with the facet joint column and at the level of the inferior part of the intervertebral foramen about 1 mm dorsal to the level of a line connecting the posterior aspects of the intervertebral foramina. It should be a little deeper and more cranial than the position of the needle for a diagnostic block. When this position is confirmed, stimulation at 50 Hz is conducted. The patient should feel new pressure or tingling in the back at less than 0.5 V. If sensations are felt in the ipsilateral extremity, the tip of the needle is too close to the segmental nerve. It is imperative that the needle be withdrawn slightly and stimulation checked again at 50 Hz. Subsequently, stimulation at 2 Hz is performed. The patient should experience localized contractions of the multifidus muscle and not of muscles of the leg. These local contractions can be palpated by the operator. Similarly, any contractions that occur in the leg may be detected by the operator or the assistant if a hand is placed over the muscles innervated by the exiting nerve root. If the patient perceives pain or contractions in the extremity or if muscular contractions are detected by the operator, the needle must be repositioned. After accurate positioning of the tip of the needle, 1 mL of local anesthetic (1% lidocaine) is injected at each level. RF lesioning at 67° C is performed for 60 seconds.

The fluoroscopic view for the L5-S1 facet joint and thus the medial branch of L5 is different from that for the other lumbar levels because of the difference in anatomy. The L5 medial branch lies at the junction between the superior sacral articular process and the upper border of the sacrum. Because there is no pedicle at this level to use as a radiologic landmark, the C-arm is positioned so that the junction is seen as a round curved transition. The C-arm is rotated slightly obliquely (about 15 degrees). The identified target point is the curve of the transition and is the same as the entry point. The needle is inserted via a tunnel view. The depth of the needle is checked on a lateral radiograph to ensure that the tip projects over the posterior border of the facet column. Thereafter, the rest of the procedure is the same as described before. A 22-gauge, 10-cm SMK needle with a 5-mm active tip can be used to perform RF lesioning.

After the procedure the patient is allowed to go home, but driving a car or handling dangerous machinery is prescribed for 24 hours. In some cases there will be transient numbness of the ipsilateral extremity because of overflow of local anesthetic into the intervertebral foramen.

Side Effects and Complications
A retrospective analysis of the incidence of complications associated with fluoroscopically guided percutaneous RF treatment of the lumbar facet joints yielded a 1% overall incidence of minor complications per lesion site. With a total of 616 RF facet treatments, three cases of localized pain lasting longer than 2 weeks (0.5%) and three cases of neuritic pain lasting less than 2 weeks (0.5%) were noted. No cases of infection, new motor deficits, or new sensory deficits were identified.

LUMBAR RADICULAR PAIN
Percutaneous RF-DRG was developed in the 1980s as an alternative to surgical rhizotomy for chronic refractory pain. Although surgical rhizotomy initially led to
impressive short-term pain relief in patients with various pain syndromes, in the long term a dramatic loss of efficacy occurred, accompanied by severe adverse effects if substantial denervation had been carried out.

The rationale for use of RF-DRG for lumbosacral radicular pain is based on the concept that nociceptive input at the level of the primary sensory neuron might be reduced by coagulation of a small part of the DRG without causing a sensory deficit. It has been stressed that RF-DRG should be restricted to “high-input” nociceptive spinal pain syndromes. In the presence of deafferentation symptoms, RF-DRG might lead to aggravation of the pain complaints. Moreover, mechanical entrapment of the nerve with combined back pain and radiculopathy must be excluded as a contributing factor before proceeding with RF-DRG. To minimize the risk for deafferentation pain, an RF-DRG heat lesion should not be used if neurologic deficits are present (i.e., reflexes, sensibility, and motor function). Thus, if diagnostic sleeve root injections were beneficial and surgical interventions are not indicated, RF-DRG can be considered.

**Procedure for Radiofrequency Treatment of the Dorsal Root Ganglion**

RF-DRG is aimed at creating a minimal lesion near the DRG for treating nerve root pain without causing neurologic deficits. For this purpose, at the lumbar level a 10-cm electrode (22 gauge, 5-mm active tip) is placed in the dorsal cranial quadrant of the intervertebral foramen (lateral view) and introduced with its tip between a third and about halfway across the midfacetal column on the AP projection (Fig. 62.21).

Sensory and motor stimulation is applied at 50 and 2 Hz. The position of the electrode is adjusted if necessary to reach a sensory stimulation threshold of between 0.5 and 1.0 V. The motor stimulation threshold is required to be at least 1.5 times the sensory stimulation threshold. A final check of the electrode’s position is made by injecting radiopaque contrast dye to visualize the nerve root and ganglion. Subsequently, a local anesthetic is injected through the cannula to achieve dense anesthesia. RF treatment is usually performed at 65° C to 67° C for 90 seconds. At the sacral level the position of the DRG is first visualized with radiopaque contrast dye injected through a 22-gauge needle placed in the dorsal sacral foramen of the corresponding nerve root. Subsequently, a small hole is drilled with a Kirschner wire and a pneumatic drill through the overlying sacral bone to obtain access to the dorsal ganglion. The remainder of the procedure is identical to that at the lumbar level.

**Evidence for Radiofrequency Treatment of the Dorsal Root Ganglion**

In patients with radiating lower limb pain, one prospective and several retrospective studies reported beneficial effects of lumbosacral RF-DRG in 32% to 76% of cases. In a previous retrospective study, 279 patients underwent RF-DRG because of chronic spinal pain radiating to the leg, and an initial success rate of approximately 60% was reported. In successful patients, the mean duration of reduction in pain was 3.7 years. One sham lesion–controlled RCT to assess the efficacy of RF-DRG for lumbosacral radicular pain has been performed. In this study, lumbosacral RF-DRG failed to show advantage over sham treatment with local anesthetics. Since there is no clear evidence of the efficacy of RF-DRG treatment and it might be contraindicated in patients with a neuropathic component, we therefore prefer PRF-DRG.

**Pulsed Radiofrequency Treatment of the Dorsal Root Ganglion**

PRF-DRG uses intermittent high-frequency current, thus avoiding a rise in temperature above the critical level of 42° C, which is described as the temperature that causes neuronal damage. Therefore, PRF-DRG is considered to be safer than conventional RF-DRG. Since the introduction of PRF-DRG in 1998, no neurologic complications have been reported, only minor postprocedural discomfort.

**Procedure.** The approach is identical to that described for RF-DRG; however, the threshold for sensory stimulation should be less than 0.5 V to maximally reach the DRG. If this is obtained, a pulsed current (routinely a 20-msec current and 480 msec without current) is applied for 120 seconds with an output of 45 V. During this procedure the temperature at the tip of the electrode should not surpass 42° C.

**Radiofrequency Treatment of the Sacroiliac Joint**

SI joint pain may result from sacroiliitis (Bechterew’s disease), infections, spondyloarthropathy, pyogenic or crystal arthropathy, fracture of the sacrum and pelvis, and dias-tasis. Primary pain emanating from the SI joint in the absence of demonstrable pathology is thought to be of mechanical origin and is termed “sacroiliac syndrome.” Fifteen percent to 25% of low back pain originates from the SI joints.

Patients with SI joint pain may have one-sided or two-sided low back pain below the level of L5. Generally, it is localized to the gluteal region (94%). The typical radiation pattern of SI joint pain is illustrated in Figure 62.22. Clinical suspicion for this syndrome may increase when three of five provocative tests for SI joint pain during physical examination are positive. The lateral branches of the L4-S3 dorsal rami are cited as the major innervation of the posterior SI joint. Other investigators claim that L3 and S4 contribute to the posterior nerve supply. Innervation of the anterior joint is similarly ambiguous. Currently, the diagnosis can be confirmed by means of at least one diagnostic nerve block of L4 and L5 and lateral branch blocks of S1-3. Dreyfuss demonstrated the superiority of multisite, multidepth sacral lateral blocks over single-site, single-depth blocks.

**Evidence**

Numerous uncontrolled studies and one controlled study have been published on RF treatment of the SI joint. However, these studies are characterized by wide disparities in technique, selection criteria, and standards of success. The one RCT consisted of 28 patients and sham treatment in the control group and showed significant improvement in pain and function in the treatment group. In this study cooled RF treatment was used. Although these results seem promising, the efficacy of RF treatment of the SI joint for SI syndrome remains to be reproduced by larger RCTs.
Cooled Radiofrequency Treatment

The theoretical advantage of cooled RF electrodes is that they create larger lesions than conventional RF electrodes do. L\(^{154}\) Larger lesions may overcome anatomic variation in the targeted nerves and are more likely to interrupt the afferent lateral branches. Such lesions are created by circulation of cooling water during the delivery of RF current. The circulating water removes heat from tissue adjacent to the electrode, thereby allowing power delivery to be increased without causing high impedance and tissue charring around the electrode.\(^{134-156}\)

As stated earlier, there are reports in favor of cooled RF over “classic” RF techniques for the treatment of SI joint pain, but larger, multicenter studies with long-term follow-up and comprehensive outcome measures are needed to confirm these findings. Furthermore, the additional cost of the disposable components needed for a cooled RF procedure should be taken into consideration.\(^{157}\)

Procedure

Because of variable and extensive innervations of the dorsal SI joint, targeting the nerves innervating the joint with RF methods is sometimes difficult with single-lesion techniques.\(^{132}\) We use the following technique. In patients with a positive diagnostic block, RF treatment is performed

---

**Figure 62.21** A, Lateral view of the needle in the superior part of the intervertebral foramen of L5. B, Slightly oblique view of the position of the needle for lumbar radiofrequency treatment adjacent to the dorsal root ganglion of L5. C, Anteroposterior view of pulsed radiofrequency treatment adjacent to the dorsal root ganglion. Note the spread of contrast medium.
under fluoroscopic guidance. With the C-arm intensifier positioned to confer either a slightly oblique view (L4 dorsal ramus), AP view (L5 dorsal ramus and lateral branches), or cephalocaudad view (lateral branches), 22-gauge SMK-C10 cannulas with 5-mm active tips are inserted until bone contact is made at the location of the target nerve. Correct placement is confirmed by electrostimulation at 50 Hz, with concordant pain being noted at or below 0.6 V at all levels from L4 to S2.

With right-sided lateral branch blocks at the S1-2 levels, the optimum stimulation pattern is found anywhere between the 1:00- and 5:30-o’clock position directly outside the posterior foramen on the surface of the sacrum. For left-sided blocks, optimum stimulation was usually found between 7:00 and 11:00 o’clock. In some patients a concordant stimulation pattern cannot be obtained at less than 0.8 V for the S3 lateral branch. In such cases, two empirically made lesions are recommended, at 2:30 and 4:30 o’clock for rightsided S3 lateral branch blocks and at 7:30 and 9:30 o’clock for left-sided lateral branch blocks. Before lesioning, the absence of contractions in leg muscles was verified at three times the stimulation threshold. When fluoroscopic images and stimulation parameters indicate correct electrode placement, 0.3 mL of 2% lidocaine is injected through each cannula for local anesthesia. The RF probe is then reinserted, and a 90-second 80°C lesion is made. Needle placement for the RF SI procedure is illustrated in Figure 62.23.

**CONCLUSION**

RF treatment of chronic pain syndromes has seen a remarkable evolution over the past decade; RF current can now be applied in continuous and pulsed fashion. The former application method generates heat lesions, whereas the latter induces changes in nerve cells. Besides studies on efficacy and safety, computer modeling and in vitro and animal experiments have begun to shed light on the potential mode of action of PRF. Evidence from good-quality studies demonstrates that continuous RF and PRF can be applied to effectively treat some chronic pain syndromes. When performed in well-selected patients, who often suffer pain refractory to conventional treatment, the degree of pain relief can be higher than with conventional treatment. Moreover, in contrast to drug studies, the follow-up period is much longer and thus provides proof of long-term efficacy. RF treatment can produce minor, immediate side effects that typically resolve spontaneously within a short time. Major neurologic complications are rare but have been reported with conventional heat lesioning, though not with PRF. Because of the low neurodestructive potential, PRF is our choice for treatment of the DRG. A randomized-controlled trial comparing PRF with sham intervention adjacent to the cervical DRG for cervical radicular pain showed a higher success rate in the PRF group at 3 months. These encouraging results point to the urgent need for further studies on this promising nondestructive mode of treatment. In future studies attempts should be made to assess a homogeneous patient population with specified pathology.
KEY POINTS

- Radiofrequency (RF) treatment consists of the application of a high-frequency current by a needle to specific anatomic structures. RF current heats the tissue surrounding the tip of the needle. In interventional pain procedures, these small heat lesions cause selective denervation.
- A new development is pulsed RF (PRF). Application of PRF reduces heat and probably works by creating electrical fields. Indications are neuropathic pain syndromes. Other indications are subject to research.
- An accepted indication for RF treatment of the head region is trigeminal neuralgia (RF of the gasserian ganglion). Neurologic evaluation is mandatory to exclude red flags for treatment. The first step in treatment is medication. RF treatment of the pterygopalatine ganglion can be used for cluster headache and some atypical facial syndromes.
- Indications for RF treatment of the medial branches of the cervical facet joints include degenerative and post-traumatic neck pain. RF treatment of the (higher) cervical facet joints for cervicogenic headache awaits further research. RF facet joint treatment is usually performed at two or three segmental levels since there is overlap in innervation of the facet joints.
- Segmental pain in the upper extremity can be caused by spinal nerve irritation. The involved spinal level can be estimated by the dermatome in which the pain is radiating and can be confirmed by diagnostic nerve blocks. PRF treatment of the dorsal root ganglion (DRG) is safer and has fewer side effects than RF treatment does.
- Thoracic pain may have an underlying pathology. When thoracic spinal pain becomes chronic and resistant to conservative treatment, minimally invasive treatment modalities, including RF lesioning of the facet joints, can be considered. We perform RF treatment on three levels because of the multisegmental innervation of the facet joints. Obtaining a fluoroscopic view is difficult because of overprojection of the ribs and the prominent transverse process.
- Percutaneous RF treatment adjacent to the thoracic DRG has been described for segmental nerve pain. A prognostic blockade is essential before RF treatment. PRF treatment of the DRG is preferred in cases of thoracic segmental radicular pain for which treatment of the DRG might be considered. An important potential complication is the possibility of damage to the nerve root or spinal cord during placement of the needle.
- The diagnosis of lumbar facet joint pain has to be confirmed by a diagnostic local anesthetic nerve block of the medial branch innervating the lumbar facet joints. Conventional RF, in contrast to PRF, can provide intermediate-term benefit in carefully selected patients.
- Mechanical entrapment of the segmental nerve in patients with combined back pain and radiculopathy must be excluded as a contributing factor before proceeding with RF treatment of the DRG. If diagnostic sleeve root injections were beneficial and surgical interventions are not indicated, RF treatment of the DRG can be considered. There is no clear evidence of the efficacy of RF treatment of the DRG, and it might be contraindicated in patients with a neuropathic component; PRF treatment of the DRG is preferred in these instances.
- The diagnosis of sacroiliac joint pain can be confirmed by means of at least one diagnostic nerve block of L4 and L5 and lateral branch blocks of S1-3. Because of variable and extensive innervations of the dorsal sacroiliac joint, RF methods are sometimes difficult with single-lesion techniques. There are reports in favor of cooled RF over “classic” RF techniques because they create larger lesions than conventional RF does.

REFERENCES

The pathologic conditions that affect the sacroiliac (SI) joint are myriad, including inflammatory, degenerative, traumatic, metabolic, infectious, neoplastic, and iatrogenic conditions, as well as sacroiliac joint syndrome. *Sacroiliac joint dysfunction*, or *SI joint syndrome*, is pain originating in the sacroiliac joint (SIJ) without a demonstrable anatomic lesion and presumed to be due to a biochemical abnormality. Predisposing factors include conditions that cause unusual stress on the joint such as spinal deformity, previous spinal surgery, and leg length discrepancy. Pathology and pain from surrounding structures, such as intervertebral disks and lumbar facet joints, can result in SI joint pain caused by postural changes with resulting increased stress on the SI joint. Pregnancy also predisposes to SI joint pain, which is thought to result from ligament laxity mediated by the hormone relaxin. Patients may report a history of minor trauma, such as lifting a heavy object while in a twisted position, or mis-stepping off a curb. The incidence of SI joint dysfunction in patients with back pain ranges from 15% to 30%.

Symptoms of SI joint dysfunction include pain in the superior medial quadrant of the buttock, the lateral buttock, and inferior to the posterosuperior iliac spine, with radiation to the greater trochanter, upper lateral thigh, and groin. Less commonly, the pain may radiate to the posterior thigh and leg below the knee. Two distinguishing features of the pain from SI joint dysfunction are the presence of groin pain and the absence of pain above the level of L5. In contrast to the pain distribution of SI joint dysfunction, the typical pattern of pain from facet joint syndrome includes the low back with radiation to the posterior thigh down to the knee, whereas the pain from a herniated disk usually extends to the leg and foot. Bending, sitting, and riding typically aggravate pain in sacroiliac joint dysfunction, and walking or standing relieves it.

Physical examination of the patient with SI joint syndrome usually reveals tenderness over the posterior aspect of the joint and the sacral sulcus. There are no neurologic symptoms such as numbness or weakness. There are several provocative maneuvers designed to stress the SI joint and elicit concordant pain, including the FABER (flexion, abduction, and external rotation)-Patrick’s test, Gaenslen’s test, Yeoman’s (extension) test,7,8 sacroiliac or posterior shear test, and Gillet’s test.3,8,9

**Sacroiliac Joint Syndrome:** Sacroiliac Joint Injections and Block/Radiofrequency of the Lateral Branches

Ashley Agerson | Honorio T. Benzon | Khalid Malik

---

**SACROILIAC JOINT SYNDROME**

**FABER-PATRICK’S TEST (LEFT SACROILIAC JOINT DYSFUNCTION) (FIG. 63.2)**
- Patient is supine.
- Left leg, near the ankle, is placed in front of the right thigh above the knee.
- The physician places one hand over the right iliac crest while the other hand pushes over the medial aspect of the left knee.
- Positive test: Pain over sacroiliac joint region (also back, buttock, groin).
- Comments: Test stresses sacroiliac and hip joint.

**GAENSLEN’S TEST (LEFT SACROILIAC JOINT DYSFUNCTION) (FIG. 63.3)**
- Patient is supine.
- Left lower thigh and leg hang over the examination table.
- The examiner flexes right hip and right knee (i.e., hip joint is maximally flexed). The examiner presses downward over the left thigh (hip joint is hyperextended).
- Positive test: Pain in the left sacroiliac joint.
- Comments: Test stresses both sacroiliac joints simultaneously by counter-rotation at the extreme range of motion of the joint. Test also stresses the hip joint and stretches the femoral nerve (examiner should ensure the absence of hip pathology or conditions affecting the femoral nerve to diagnose sacroiliac joint syndrome).

**YEOMAN’S TEST (ALSO CALLED EXTENSION TEST (FIG. 63.4)**
- Patient is prone.
- Examiner places one hand above the anterior aspect of the knee and elevates it slightly; the other hand presses downward over the crest of the ilium.
- Positive test: Pain over the posterior sacroiliac joint.
• Comments: The hip is extended and the ipsilateral ilium is rotated. Test stresses the sacroiliac joint; it also extends the lumbar spine and stresses the femoral nerve. More specific and reliable compared to the other tests.

GILLET’S TEST (FIG. 63.5)
• Patient is standing.
• One of the examiner’s thumbs is placed on the second sacral spinous process; the other thumb is placed on the posterior superior iliac spine (PSIS).
• Normal sacroiliac joint: When the patient maximally flexes the hip, the PSIS moves inferior to the S2 spinous process.
• Dysfunctional or fixed sacroiliac joint: PSIS remains at the level of the S2 spinous process or moves superior to the sacrum.

SACROILIAC SHEAR TEST (FIG. 63.6)
• Patient is prone.
• Palm of the examiner’s hand is placed over the posterior iliac wing. Shear thrust is directed inferiorly, producing a shearing force across the sacroiliac joint.
• Positive test: Pain in dysfunctional sacroiliac joint.

Pain secondary to SI joint syndrome is difficult to isolate, making these tests neither highly sensitive nor specific. The FABER-Patrick’s test also stresses the hip joint, Gaenslen’s test stresses the hip joint and stretches the femoral nerve, and Gillet’s test can be difficult to perform. Although the Yeoman’s test stretches the femoral nerve and extends the lumbar spine, it appears to be a more specific and reliable maneuver. Some experts require the presence of three positive screening tests to confirm SI joint dysfunction.

The tests do not by themselves suggest the presence of SI joint dysfunction. Indeed, up to 2% of asymptomatic patients were found to have positive findings in one or more of these tests. Rather, the diagnosis of SI joint dysfunction is made based on the combination of history, symptoms, and physical examination findings. The maneuvers are of added value in confirming the diagnosis when the symptoms suggest SI joint syndrome and other causes of pain have been eliminated. The presence of tenderness over the sacral sulcus, pain over the SI joint, buttock pain, and the patient pointing to the posterior superior iliac spine as the main source of pain showed better sensitivity than the other tests evaluated.1

Radiographic evaluation of the joint rarely aids diagnosis. Diagnostic local anesthetic block of the joint is considered
to be the standard criterion for SI joint pain, although prov-
ocation of pain on injection of the SI joint is not a suitable
criterion of SI joint dysfunction.5

ANATOMY

The sacroiliac (SI) joint is considered a diarthrodial joint
because it contains synovial fluid, the articulating bones have
ligamentous connections, the outer fibrous joint capsule has
an inner synovial lining, and the cartilaginous surfaces allow
motion to occur.2 The sacral side of the joint is thicker and
made up of hyaline cartilage, whereas the iliac side is made
up of thin fibrocartilage. The adult joint has irregular and
coarse surfaces that increase with age, reflecting the stress
to which the joint is exposed.10 The irregular contour of the
joint contributes to its stability; the function of the joint is to
transmit or dissipate the loading of the trunk to the lower
extremities.

The ligaments of the SI joint include the anterior sacroiliac
ligament, intersosseous ligament, and posterior sacroiliac
ligament (Fig. 63.7). The anterior sacroiliac ligament tra-
verses the ilium to the sacrum, and the posterior sacroiliac
ligament traverses the posterior iliac ridge to the sacrum.
The interosseous ligament is responsible for the stability of
the joint. The sacrotuberous ligament, which is superficial to
the posterior SI ligament, has multiple muscle attachments
including the gluteus maximus, piriformis, and long head
of the biceps femoris. These multiple muscle attachments
provide stability during activities such as sitting, walking,
and standing, which stress the sacroiliac joint.2 The sacro-
iliac joint is innervated at its anterior and posterior aspects.
Its variable and extensive innervation accounts for the mul-
tiple presentations and variable referred pain patterns of
sacroiliac joint pain.7 Posteriorly, the joint is innervated by
the lateral branches of the posterior primary rami of the
L4 to S4 dorsal rami.11,12 The predominant innervation is
from the dorsal ramus of S1,13 and there are isolated dorsal
innervations from S1-4.14 The anterior innervation is from
the ventral rami of the L5 to S2 and via branches from the
sacral plexus.11 The blood supply of the joint is from the
anastomosis between the median sacral artery and lateral
sacral branches from the internal iliac artery.

TECHNIQUE OF SACROILIAC JOINT INJECTION

For diagnostic injections, patients are asked to stop their
pain medication on the day of the procedure. Sedation is
usually not required but light sedation (1 to 2 mg intrave-
nous midazolam) may be given in a nervous patient.
Contraindications to the injection include infection in the area and bleeding diathesis. Allergy to contrast media may require pretreatment with H1 and H2 antagonists, whereas allergy to local anesthetics may require identification of the appropriate local anesthetic to be used for the procedure. The use of imaging is recommended during SI joint injection to ensure intra-articular needle placement, as blind injections rarely result in correct needle positioning.15

**FLUOROSCOPY-GUIDED SACROILIAC JOINT INJECTION**

The patient is positioned prone on the table, with the head turned to one side. A pillow is placed under the abdomen to flex the spine. Under a straight anteroposterior (AP) view, the SI joint presents several lines that course caudocranially in a semiparallel fashion. The lateral line represents the ventral or anterior margin of the joint, and the medial line represents the dorsal or posterior margin of the joint.16,17 The C-arm is initially rotated approximately 30 degrees caudal to the axial plane to better visualize the area underneath the posterior superior iliac spine and iliac crest. The C-arm is then angled obliquely to the contralateral side until the inferior joint space is clearly demarcated, usually between 5 and 20 degrees. The target point lies along the inferoposterior aspect of the joint, in the area 1 to 2 cm cephalad from its most caudal end.16

The area is prepped and draped in the usual sterile fashion. The skin is anesthetized with 1 to 2 mL 1% lidocaine via a 25-gauge needle. A 22-gauge spinal needle is advanced coaxially toward the inferior pole of the sacroiliac joint with intermittent images obtained at regular intervals (every 2- to 4-mm advancement of the needle) to confirm trajectory. When the posterior surface of the sacroiliac joint is contacted, the needle is advanced to just penetrate the joint capsule. A change in resistance is commonly felt as the needle passes through the capsular tissue, and the needle tip is often deflected slightly as it traces the surface of the ilium. Some patients have significant osteoarthritic changes that preclude needle entry into the joint, making periarticular infiltration necessary. Once the needle is within the joint, a small amount of contrast is injected to demonstrate intra-articular spread (Fig. 63.8). The response of the patient to the injection of contrast media is noted as either “no pain,” “unfamiliar pain,” or “similar pain” in comparison with the pain complaint.16 After appropriate contrast spread, a solution of steroid and local anesthetic (40 to 60 mg of methylprednisolone or triamcinolone with 1 to 2 mL of 0.5% bupivacaine or ropivacaine) is injected. Because the capacity of the sacroiliac joint is small and distension may exacerbate pain, a maximum volume of 2 to 2.5 mL has been recommended for SI joint injections.16,18 Spillage of injectate outside the SI joint is acceptable because some of the pain receptors are located outside the joint. Nociceptive fibers and receptors containing calcitonin gene-related peptide (CGRP) and substance P immunoreactive free nerve endings have been noted in the interosseous and anterior

ligaments of the SI joint by Szadek and colleagues.\textsuperscript{19} In view of their findings, the authors recommended extra- as well as intra-articular approaches to diagnostic SI joint injection.

Other approaches include placement of the needle at the inferior end where the posterior and anterior joints overlap, if a markedly lucent zone is noted in that area.\textsuperscript{16} The midportion of the joint also can be cannulated. With 20 to 30 degrees of contralateral obliquity, the medial and lateral planes of the joint overlap. The needle entry is at the most lucent zone of the joint space; a 20- to 30-degree medial to lateral and 10- to 20-degree inferior direction of the needle approach has been recommended to gain entry into the midportion of the joint.\textsuperscript{20} Finally, the superior aspect of the joint can be accessed with a cephalocaudal approach.

Directly after the procedure the patient should be observed for 15 to 30 minutes to determine analgesic response and to monitor for complications. The local anesthetic has an immediate effect, but the anti-inflammatory effect of the steroid develops over 3 to 5 days. A greater than 75\% reduction of pain over the SI joint is considered to be a positive response.\textsuperscript{6} Provocative maneuvers can be repeated to assess improvement. Transient weakness in the ipsilateral leg is due to spillage of local anesthetic onto the sacral nerve roots or the sciatic nerve. Other complications include bleeding, infection, exacerbation of pain, fever, transient difficulty voiding, and allergic reaction to components of the prep solution or injectate.\textsuperscript{17}

**ULTRASOUND-GUIDED SACROILIAC JOINT INJECTION**

The feasibility of ultrasound-guided SI joint injections was initially shown by Pekkafahli and associates\textsuperscript{21} and was further described by Harmon and O’Sullivan.\textsuperscript{22} The patient is positioned prone with a pillow underneath the abdomen. A curvilinear low-frequency transducer (4 to 6 MHz) is placed perpendicular to the skin over the distal sacrum in the midline in a cross-sectional view (short axis) to identify the sacral hiatus. The probe is moved laterally until the lateral edge of the sacrum comes in view, then moved cephalad to find the medial aspect of the iliac bone. At this site the SIJ appears as a hypoechoic wedge-shaped structure (Fig. 63.9). The target area for injection is at the level of the second sacral foramen, which is approximately 2 to 3 cm above the caudal pole of the SI joint. Lidocaine 1\% is injected subcutaneously at the medial edge of the probe. A 22-gauge needle is inserted and advanced in-plane with a lateral and anterior trajectory into the joint. After the needle is deep to the iliac bone it is no longer visible on ultrasound. A pop is felt once the synovial joint is penetrated. Visible spread of injectate outside of the joint indicates periarticular rather than intra-articular placement.

The accuracy of this technique has been assessed. Pekkafahli and coworkers noted marked improvement with operator experience, from a 60\% success rate in their first 30 injections to a 94\% success rate in their second 30 injections.\textsuperscript{21} Klausler and colleagues evaluated ultrasound-guided SI joint injection in cadavers at two levels of the joint by comparing approaches at the level of the first sacral foramen versus those at the second sacral foramen.\textsuperscript{23} Computed tomography (CT) examination showed 90\% of the needles at the lower level to be within the SIJ versus 70\% in the upper level. The same procedure resulted in an intra-articular placement rate of 100\% in both locations (eight in the lower and two in the upper site) when performed in live patients.

**COMPUTED TOMOGRAPHY–GUIDED SACROILIAC JOINT INJECTION**

Injection of the SI joint has been described under computed tomography (CT) guidance.\textsuperscript{24-26} The patient is positioned prone and the SI joint scanned. The best access point to the joint is determined and the gluteal injection point selected. The needle is inserted into the joint and steroid or local anesthetic is injected. Success rates from CT-guided injections range from 75\% to 92\%,\textsuperscript{24} with the duration of relief lasting 14 days\textsuperscript{26} to 10 months.\textsuperscript{24} The increased radiation exposure and lack of availability of CT in pain clinics restrict a wider application of this approach.

**EFFICACY OF SACROILIAC JOINT INJECTIONS**

The efficacy of sacroiliac joint injections has been examined in studies, meta-analyses, and reviews with discordant results. Multiple uncontrolled studies indicate that corticosteroid SIJ injections are helpful. Liliang and colleagues reported a prospective observational study of 39 patients with SIJ pain confirmed by two diagnostic SIJ injections.\textsuperscript{27} Triamcinolone injection into the SI joint resulted in 67\% of the patients having significant pain reduction for an average of 37 weeks (Table 63.1). Other studies also showed positive results in patients without spondyloarthropathies.\textsuperscript{28-31} Bollow and associates studied CT-guided SI corticosteroid injections in 66 patients with back pain and known spondyloarthropathies; 92\% had significant relief (average visual analog scale [VAS] reduction of 5 points) for a mean duration of 10 months.\textsuperscript{24} Similarly, Braun and colleagues showed significant reduction in VAS score 5 months after CT-guided SIJ injection with triamcinolone in 25 of 30 patients with spondyloarthropathies and low back pain.\textsuperscript{32} Fischer and coworkers performed corticosteroid SI joint injections in 56 children...
with spondyloarthropathy whose pain was unresponsive to nonsteroidal anti-inflammatory drugs (NSAIDs).

87.5% of the patients who received injections had an improvement in pain scores that lasted 12 ± 6 months.

There have been three randomized, controlled trials that investigated corticosteroid SI joint injections; all demonstrated some benefit. Maugars and colleagues compared steroid and local anesthetic injection with saline in 13 joints (10 patients) with spondyloarthropathy without response to NSAIDs. They noted improved pain control at 1 month compared to placebo (5/6 versus 1/7) and continued analgesia at 3 and 6 months. Luukkainen and associates compared periarticular injections of local anesthetic and corticosteroid with local anesthetic and saline in 20 patients with juvenile spondyloarthropathy and demonstrated significantly reduced VAS scores in the steroid group, but not the saline group, at 2 months. The same investigators compared steroid and local anesthetic versus saline and local anesthetic in 24 patients with clinical sacroiliac joint dysfunction but without radiographic findings. Again, they noted that the pain scores decreased significantly more in the steroid group than the local anesthetic group. These studies are limited by their small sample size, which reduced the ability to find significant differences in medication usage and functional status. In addition, all have a relatively short period of follow-up.

**BLOCKADE OF THE L4 AND L5 DORSAL RAMUS AND LATERAL BRANCHES OF S1-S3**

As noted, the posterior margin of the SIJ is innervated by the L5 dorsal ramus and the lateral branches of S1, S2, and...
S3, with possible contributions from the L4 dorsal ramus. Blockade of these structures can be a diagnostic tool and is employed by some practitioners to predict response to radiofrequency (RF) ablation of the same nerves. The patient is positioned prone and the fluoroscopic C-arm is either positioned AP or angled slightly cephalocald to optimize the appearance of the sacral foramina. After skin infiltration, 22-gauge spinal needles are advanced coaxially to a point 5 mm lateral to each foramen between the 2 and 5 o'clock positions on the right side and the 7 and 10 o'clock positions on the left side. This corresponds to the path of the lateral branch as it travels laterally and enters the ligaments of the joint. The L5 dorsal ramus is blocked at the junction of the ala and the articular process of the sacrum. If L4 blockade is desired, the C-arm is rotated obliquely to block the L4 dorsal ramus at the junction of the transverse process of L5 and the superior articulating process. Once the position of the needle tips is confirmed, 0.5 mL of 0.5% bupivacaine is injected. The patient is instructed to keep a pain diary to monitor pain relief.

**Radiofrequency Denervation of the Sacroiliac Joint**

Transient pain relief from intra-articular steroid injections may require more permanent denervation of the nerve supply of the SI joint. Although chemical neurolysis with phenol can be performed, such intervention is rarely used because of possible spillage of the agent with unintended neurolysis of other structures. RF ablation of the nerves results in a more restricted neurolysis; RF ablation may target the small, terminal sensory fibers at the posterior aspect of the joint itself (strip lesioning) or the nerve supply to the joint.

**Stripping Lesioning of the Sacroiliac Joint**

RF ablation of the terminal fibers supplying the posterior SIJ can result in analgesia in patients who previously responded to diagnostic intra-articular injections. The technique of thermal RF denervation of the SI joint utilizes two probes to create a bipolar strip lesion. The joint is visualized with the fluoroscopic C-arm as described for SIJ injection, then the first RF needle (5- to 10-mm active tip) is inserted at the inferior margin of the joint. A second RF needle is placed more cephalad, at a distance of less than 1 cm from the first probe. After anesthetizing the tissue with lidocaine, the RF probe is inserted and heated to 80°C for 90 seconds. Successive probes are placed less than 1 cm cephalad from the previous probe, and multiple lesions are created in a repetitive “leapfrog” manner as high in the joint as possible, creating a strip lesion in the posterior joint. The posterior superior iliac spine obscures access to the superior portion of the joint, making only the lower third, or at most half, of the joint accessible to the lesioning. Some clinicians lesion the whole posterior border of the joint under heavy sedation.

Using this technique, Ferrante and colleagues reported a series of 50 SIJ denervations performed in 33 patients; 12 (36%) reported at least a 50% decrease in their visual analog pain scores for at least 6 months. Although it was a retrospective study, it showed the efficacy of the technique.

Pino and colleagues studied the ideal distance of the two probes to create a continuous strip lesion. They compared the lesions created by two needles placed at 2, 4, 6, 8, and 10 mm from each other; egg white was used as the protein medium for easy visualization and measurement of the lesions. The temperatures of the probes were raised from 40°C to 90°C and held at 90°C for 190 seconds. They noted that contiguous strip lesions were produced when the cannulas were spaced 6 mm or less apart—unipolar lesions resulted when the lesions were spaced more than 6 mm apart (Fig. 63.11). Ninety percent of the final lesion area was reached by 120 seconds with the final lesions reached by 150 seconds. They concluded that the probes should be placed between 4 and 6 mm apart to maximize the surface area of the thermal lesion and that the treatment duration should be between 120 and 150 seconds at 90°C.

The size of the monopolar lesion can be increased by injecting fluid before the RF lesion is applied. Using ex vivo chicken samples, Provenzano noted that preinjection of fluid other than water increased the lesion size. Hydroxyethyl starch caused the largest lesion, followed by 0.9% NaCl and lidocaine. Increasing the volume from 0.5 mL to 3 mL did not significantly change the size of the lesion. The same findings were noted with bipolar lesioning. Three percent NaCl appears to be ideal in that it increased the size of the lesion between the electrodes while diminishing the spread of tissue destruction beyond the electrodes.

**Radiofrequency Lesioning of the Lateral Branches**

This technique has been performed with traditional thermal RF, as well as water-cooled RF (Table 63.2). The patient is positioned prone and the C-arm is aligned for an anteroposterior image. To target the L5 dorsal rami, an RF cannula is placed at the lateral margin of the superior articular process where it meets the sacral ala, as described previously.

---

**Figure 63.10** Schematic drawing showing the S1-S3 lateral branches innervating the SI joint and overlying ligaments. The needles depict the approximate location for the diagnostic lateral branch blocks (LBB). (From Cohen SP, Abdi S. Lateral branch blocks as a treatment for sacroiliac joint pain: a pilot study. Reg Anesth Pain Med. 2003;28:113-119.)
for the diagnostic block. Because the lesion created by conventional RF is smaller and is positioned along the active tip of the probe, the needle trajectory must preferably be parallel to the path of the nerve to maximize the chances of the neural destruction when using conventional RF. On the lateral fluoroscopic image, the needle tip should be no further anterior than the anterior third of the superior articulating process (SAP). When using cooled RF, the lesion is larger and the tip should be no more anterior than the midpoint of the SAP to avoid lesioning the segmental nerve root. It should be noted that some practitioners favor the use of conventional RF for the dorsal rami of L4 and L5 because the more compact lesion size seems less likely to damage the spinal nerve. This was investigated by Kapural and associates, who retrospectively reviewed 100 cases of RF ablation of the SIJ. Of these patients, 82 had cooled RF of the L5 dorsal

SIJ, sacroiliac joint; ODI, Oswestry disability index; VAS, visual analog scale; NRS, numeric rating scale; RF, radiofrequency.
ramus, whereas others had conventional RF. The rate of acute complications was not higher in the water-cooled RF group.

For the S1-S3 lateral branches, the water-cooled RF needles are placed lateral to the sacral foramina. Three lesions are created at S1 and S2; the needles are ideally placed at 2:30, 4, and 5:30 o’clock positions on the right, and at 6:30, 8, and 9:30 o’clock positions on the left. At S3, two lesions are made at 2:30 and 4 o’clock positions on the right, and at 9:30 and 8 o’clock positions on the left (Fig. 63.12). On lateral fluoroscopic images, the needle tip should not be anterior to the posterior sacrum to avoid intraforaminal positioning. Prior to lesioning at all levels, sensory nerve stimulation is applied at 50 Hz with the goal of concordant pain being reproduced below 0.6 volts. Motor stimulation is applied at 2 Hz at 2 volts, or three times the sensory threshold, to verify the absence of muscle contraction in a radicular distribution. Once the stimulation pattern is acceptable, the sites are anesthetized with 0.5 mL 1% lidocaine and lesioning begins at 80° C for 90 seconds (conventional RF) or 60° C for 150 seconds (water-cooled RF). It is customary to inject 0.5 mL of a mixture of local anesthetic (e.g., bupivacaine) and steroid (e.g., 8 mg/mL triamcinolone) after the lesioning for postoperative analgesia and to prevent neuritis.

**EFFICACY OF THERMAL RF OF THE LATERAL BRANCHES**

Two retrospective studies showed the efficacy of thermal RF lesioning of the lateral branches of the posterior primary ramus of the L4 to S3 dorsal rami in the treatment of SI joint syndrome. In Cohen and Abdi’s study, 18 patients with SI joint pain had nerve blocks of the L4-5 primary dorsal rami and SI-3 lateral branches. Thirteen of the 18 patients obtained approximately 50% relief, 2 of the 13 had relief that lasted several months, 9 of the 13 patients underwent RF lesioning (80° C for 90 seconds), and 8 of the 9 patients who had the RF denervation experienced greater than 50% relief that persisted for at least 9 months. In Yin and colleagues’ study, 9 of 14 (64%) patients experienced a successful outcome (defined as > 60% patient-perceived improvement with concurrent > 50% decrease in pain score for 6 months); 5 patients (36%) had complete relief at 6 months after thermal RF of the lateral branches of S1-3. Prior to the RF lesion, the patients had reproducible and consistent relief of their pain after two SI joint local anesthetic injections. Yin and associates also performed cadaver studies to follow the course of lateral branches. They noted that the lateral branches were located at the 2 to 6 o’clock positions at the right side and at the 6 to 10 o’clock positions on the left side.

The unpredictable course of the lateral branches at the S1-S3 foramina led to the recommendation of bipolar RF strip lesions at these levels. In this technique, bipolar strip lesions are created approximately 5 mm lateral to the edge of the lateral half of the dorsal sacral foramina of S1, S2, and S3 by placing two 20-gauge, 10-mm exposed curved-tip RF cannulas 4 to 6 mm apart. Several sequential bipolar lesions are created by the “leapfrog” technique of moving the two cannulas along the joint edge. Initial results showed eight of nine patients had significant reductions in the severity and frequency of their back pain, as well as their analgesia requirements. Bipolar strip lesioning is an alternative to making several unipolar lesions with thermal RF needles, as the burn area with thermal RF is small. It is not necessary with the water-cooled RF because the lesions created are bigger.

Complete pain relief after lesioning of the lateral branches at the posterior aspect of the SI joint has been questioned because innervation of the ventral aspect of the joint is not destroyed. However, Yin and associates as well as others noted the predominant dorsal innervation of the SI joint. A combined RF lesioning of the SI joint and the dorsal branch of L5 under CT guidance has been described. The authors also lesioned the ventral and dorsal aspects of the joint. However, only an area of the joint and one nerve were lesioned. They reported that 34% of their patients had complete relief at 3 months and 32% had substantial pain reduction.
EFFICACY OF WATER-COOLED RADIOFREQUENCY

In an observational study, Karaman and colleagues investigated water-cooled RF of the L5 dorsal ramus and S1-S3 lateral branches in 15 patients. The presence of SIJ pain was diagnosed by dual intra-articular blocks. They showed a significant reduction in pain scores and disability scores at 1, 3, and 6 months.

Randomized, blinded, placebo-controlled studies investigated the effect of denervation. Patel and associates reported 51 patients with SIJ pain diagnosed by positive responses to two sets of local anesthetic blocks of the L5 dorsal ramus and the S1-S3 lateral branches. Either water-cooled RF or a sham procedure was performed and the patients were followed for 9 months. At 3 months, the patients were unblinded and patients who had the sham procedure were allowed to cross over. At 3 months, there was a statistically significant improvement in pain scores (an average 2.4-point decrease on the numeric rating scale in the procedure group versus a 0.8-point decrease in the sham group) as well as in the disability index (a mean 11-point decrease in Oswestry disability index in the procedure group versus a 2-point increase in the sham group). Patient-reported scores remained improved at the 9-month follow-up.

Cohen and coworkers reported a randomized, blinded, placebo-controlled pilot study that compared the efficacy of conventional RF of the L4 and L5 dorsal rami and water-cooled RF of the lateral branches of S1 to S3 to placebo. Twenty-eight patients with SIJ pain confirmed by intra-articular local anesthetic injection were randomized and followed for 12 months. Baseline pain scores averaged 6.1 in the treatment group and 6.5 in the placebo group. At 1, 3, and 6 months, the pain scores in the intervention group were 2.4, 2.4, and 2.6, respectively. This was significantly better than the average pain score in the sham group, which was 6.3 at 1 month, after which patients were allowed to cross over. At 12 months only 14% of patients in the RF group continued to experience improvement.

In a follow-up retrospective study, Cohen and colleagues investigated the factors associated with success of RF ablation of the lateral branches. Success was defined as a 50% reduction in pain lasting more than 6 months and a positive global perceived effect. Secondary outcomes included disability markers, medication reduction, and active duty status. Fifty-two percent of patients who underwent SIJ denervation had successful results. Pre-procedural pain intensity, pain radiating below the knee, and age over 55 were independent predictors of failure, and there was a trend toward failure in patients who were taking opioids. Water-cooled RF was associated with a higher success rate than conventional RF.

CONCLUSION

Sacroiliac joint syndrome is a common cause of buttock pain. The clinician should know the symptoms as well as the physical examination findings that help to make the diagnosis. RF lesioning of the lateral branches that innervate the SI joint, especially the water-cooled technique, may result in long-term relief.

KEY POINTS

- The pain of sacroiliac (SI) joint syndrome is felt in the SI joint area and usually radiates to the groin, lateral thigh, posterior thigh, and leg.
- The common tests that confirm the presence of SI joint syndrome include the FABER-Patrick’s, Gaenslen’s, Yeoman’s, shear, and Gillet’s tests.
- The diagnosis of SI joint syndrome is based on the patient’s history, symptoms, positive confirmatory tests, elimination of the other causes of buttock pain, and a positive response to an SI joint injection.
- Relief from SI joint injection with local anesthetic and steroid can be temporary. More prolonged relief can be obtained by thermal RF lesioning of the SI joint or the lateral branches of the primary ramus of the L5-S3 nerves. Continuous RF lesions can be obtained by performing bipolar strip lesions. The use of water-cooled radiofrequency lesioning, with its larger lesions, obviates the need for bipolar strip lesions.

OVERVIEW OF MYOFASCIAL INJECTIONS

Myofascial pain is a common source of pain in the neck, low back region, and other areas of the body. The term “myofascial pain” encompasses muscle strain, myofascial trigger points, and specific muscle pain syndromes, including piriformis syndrome, iliopsoas-related pain, and pain related to compression of the brachial plexus by the scalene muscles (neurogenic thoracic outlet syndrome).

RELEVANT ANATOMY

Skeletal muscle consists of muscle fibers under somatic nervous control. Each nerve root innervates a muscle or group of muscles known as a myotome. The muscle belly of skeletal muscles is connected by tendons to the bone. Trigger points occur in the body of the muscle, most often located in the center of the muscle.

TRIGGER POINT INJECTIONS

Trigger points are nodules found in taut bands in skeletal muscle that often produce characteristic patterns of referred pain provoked by palpation. A trigger point may occur in isolation, concomitantly as part of a regional myofascial pain syndrome, or as an effect of other pain syndromes through either segmental effects or biomechanical changes. Trigger points are diagnosed by the history and physical examination. A patient will complain of a localized pain or regional pain in or around skeletal muscle or replicated by palpation of a skeletal muscle. The muscles commonly involved are the trapezius, splenii, cervical and lumbar paraspinal, and quadratus lumborum. On examination, localized taut bands of muscle are noted and palpation produces characteristic nondermatomal referral patterns. Trigger points may be active or latent. Active trigger points produce spontaneous pain and are painful on palpation, whereas latent trigger points produce pain only when palpated. Trigger points may result from trauma, overload or overuse injury, or a prolonged period during which the muscle is in a shortened position. The pathophysiology of trigger points is not fully understood, although multiple lines of relevant research support their existence. Peripheral sensitization and central sensitization both appear to contribute to the pain from trigger points. There is also evidence of an alteration in blood flow at trigger points.

Imaging studies have only recently demonstrated anatomic changes associated with trigger points. Ultrasound (US) examination in combination with Doppler blood flow has been reported to allow visualization of trigger points, and US imaging can help direct muscle injection techniques (see later). Recently developed techniques using magnetic resonance and US elastography purport to reveal changes in intramuscular signal consistent with trigger points, but this technology has not yet been validated.

Treatment of trigger points commonly includes physical therapy (manual release techniques, stretching and strengthening, conditioning, therapeutic modalities), trigger point injections (TPIs), dry needling and acupuncture, and transcutaneous electrical nerve stimulation. A broad range of treatment modalities have been reported, but weak research methodology continues to limit interpretation of the results. Regarding medications, tizanidine, but not cyclobenzaprin, was noted to be efficacious for acute skeletal muscle spasms. Diazepam, amitriptyline, and lidocaine patch were found to be effective, but literature support for the use of anticonvulsants in treating myofascial pain syndrome is limited. Although clonazepam appears to be effective, its use is limited by the side effects of depression, liver dysfunction, and difficulty weaning the patient from this drug. Nonsteroidal anti-inflammatory drugs (NSAIDs), specifically ibuprofen, appear to be effective when given with other agents, but not as monotherapy.

TPIs are intramuscular injections of local anesthetic with or without corticosteroid. Some practitioners perform dry needling (needle penetration without infiltration of medication), and there is evidence that dry needling can be as effective as TPI but may cause more muscle soreness. The response to TPI or dry needling is more effective when a muscle twitch reaction is elicited with needle penetration of the trigger point. Some authors have suggested that botulinum toxin or tropisetron (a serotonin 5-HT3 receptor antagonist) can be used for TPI, but the superiority of alternatives over more conventional injectants has not been consistently demonstrated.

CONTRAINdications

The following conditions are contraindications to TPI: (1) infection, systemic or localized; (2) coagulopathy; (3) distorted or complicated anatomy; and (4) patient refusal.
TECHNIQUE AND FOLLOW-UP

After informed consent, the muscle is palpated and the trigger points are identified and marked. The area is prepared in sterile fashion and a 25-gauge, 1.5-inch needle is inserted into the trigger point. A local twitch may be elicited at this time or the patient verbally identifies the painful area. After negative aspiration, 0.25% bupivacaine, 0.02% ropivacaine, or 1% lidocaine is injected with or without steroid, either dexamethasone (4 mg in a 30-mL bottle of local anesthetic) or a low dose of particulate steroid (e.g., 20 to 40 mg of methylprednisolone or triamcinolone diluted in the local anesthetic solution).

Possible complications include bleeding, hematoma, nerve block, and infection. The patient should be monitored closely for bleeding, development of neurologic symptoms (numbness or weakness, urinary or bowel incontinence), or signs of infection. Depending on the location of the injection, the patient should be instructed on the signs and symptoms of pneumothorax (from neck, shoulder, thoracic, and anterior chest wall injections) or local nerve blockade (for example, inadvertent median nerve block with injection of the flexor carpi ulnaris).

The success of the procedure is dependent on the diagnosis and localization of the trigger point. Patients with chronic widespread pain or psychological disorders are less likely to respond to TPI only. Patients who have focal muscle pain with the characteristics of myofascial pain can achieve significant relief for days to months with a well-performed TPI. Success of TPI is often dependent on subsequent stretching and strengthening and neuromuscular education of the muscle.1 The most effective treatment of myofascial pain syndrome is often a multidisciplinary approach tailored to the individual needs of the patient that incorporates TPI with physical therapy and medication as noted earlier. Practitioners are counseled to provide appropriate follow-up after TPI and encourage patients to address other factors that perpetuate chronic pain (coping, employment, decreased social activity).11,14

ULTRASOUND-GUIDED TECHNIQUES

US guidance provides several theoretical advantages over blind needle insertion. As stated, it allows visualization of the trigger point (Fig. 64.1). The practitioner is ensured that the needle is penetrating muscle tissue, which may be of use in patients with considerable adipose tissue, and can avoid local anatomic structures that are sensitive to needle penetration or local anesthetic infiltration (i.e., neurovascular structures or viscera).15 US imaging also allows visualization of the muscle twitch response with needle penetration, especially in muscles that are deep or small.16 An additional use of US is to confirm local anesthetic infiltration between fascial planes.17 It also aids in blocking the spinal accessory nerve for diagnosis of trapezius muscle–related myofascial pain.18

RESULTS OF TREATMENT

Research on treatment outcomes of myofascial pain has been limited by poor study methodology and reporting, inconsistent outcome selection, small sample sizes, heterogeneous patient populations, and the absence of standardized diagnostic criteria (with the exception of validated diagnostic criteria for myofascial pain of the muscles of the jaw).19 Overall, evidence from systematic reviews supports the finding that TPI (regardless of the injectant) and dry needling of trigger points provide a benefit alone and in addition to stretching and strengthening.9,20 Deep dry needling appears to be more effective than superficial dry needling.21-23

Several well-designed studies have evaluated the use of botulinum toxin for the treatment of myofascial pain, but with conflicting conclusions: although some found positive results, the preponderance did not find statistically significant effects of botulinum toxin over saline or local anesthetic. In fact, a qualitative review of published trials on botulinum toxin for myofascial TPI noted its lack of efficacy.13 Tropisetron, a 5-HT3 receptor antagonist, may offer longer analgesic effect than occurs with local anesthetic.12

Combining medication management with physical therapy and injection therapy can often offer the best opportunity for treatment. Treatment with amitriptyline, benzodiazepines, and ibuprofen (in combination with other agents) appears to be effective, and preliminary data support topical rubefacient patches, diclofenac patches, and lidocaine patches.9 Duloxetine has recently been given an indication for musculoskeletal pain; it will probably be commonly used for the treatment of myofascial pain. The prescription of benzodiazepines must be brief and goal directed, with due diligence to minimize misuse, addiction, and diversion.

Factors associated with a lower therapeutic effect of TPI include poor coping, employment issues, decreased social activity, duration of the pain syndrome, high levels of pain, constant pain (as opposed to intermittent pain), and unresponsiveness of the pain to analgesic medication.14

Novel applications of ultrasound technology to visualize and characterize myofascial trigger points and surrounding soft tissue. Arch Phys Med Rehabil. 2009;90:1829-1838, with permission.)
PIRIFORMIS INJECTIONS

Piriformis syndrome consists of pain in the buttock with or without radiation in the distribution of the ipsilateral sciatic nerve. It may contribute up to 8% of buttock pain. The syndrome can be a consequence of an abnormal relationship between the sciatic nerve and the piriformis muscle that results in irritation of the sciatic nerve. A hypertrophic muscle, infection, or invasion of the muscle by tumor can cause pressure or irritation on the nerve.\textsuperscript{24,25} In 78% to 84% of the population, the sciatic nerve passes in front of the muscle. In 12% to 21% of individuals, the divided nerve passes through or posterior to the piriformis and is exposed to muscle contractions, which trigger sciatic symptoms.\textsuperscript{24} Piriformis syndrome is a diagnosis of exclusion since there are no standardized diagnostic criteria for it. The syndrome should be considered in patients who have buttock pain, tenderness to palpation over the piriformis muscle, and a positive response to provocative maneuvers, including the following:

1. Pace’s sign: pain and weakness with seated abduction of the hip against resistance
2. Lasègue’s sign (also known as the straight-leg raise test): pain with unresisted flexion, adduction, and internal rotation of the flexed hip
3. Freiberg’s sign: pain with forced (i.e., against resistance) internal rotation of the extended hip\textsuperscript{24}

Because of its small size in comparison to the gluteus muscles, its proximity to neurovascular structures, and its deep location, the piriformis muscle is usually injected under radiographic or US guidance. Piriformis injections under computed tomography (CT) or electromyographic guidance have also been described.\textsuperscript{26-29} Contraindications under computed tomography (CT) or electromyographic guidance are the same as those noted in the section on TPI.

ULTRASOUND-GUIDED TECHNIQUE

The US-guided technique not only permits a direct view of the piriformis muscle but can also be used to examine its relationship to the sciatic nerve and rule out any anatomic variation. The patient is placed in the prone position with the US machine on the side opposite the operator. A curved, low-frequency US probe (2 to 6 MHz) is used to scan a wider and deeper area. The US machine should have Doppler to help identify the inferior gluteal artery medial to the sciatic nerve and anterior to the piriformis. A 20- to 22-gauge, 10- to 12-cm-long needle is recommended.

One technique involves positioning the transducer in short axis (transverse) over the sacroiliac joint, where medially the sacrum will be visible and laterally the ilium/gluteus maximus muscle complex will be observed.\textsuperscript{29} While keeping the sacroiliac joint in the center of the screen, the transducer is moved caudally until the lateral view of the ilium is lost, which indicates that the transducer is over the greater sciatic notch. In this position the operator will see the hyperechoic lateral portion of the sacrum medially. In the center of the image the following are visualized: skin and fat in the near field and then the gluteus maximus muscle. Deeper to the gluteus maximus and originating from the anterior and lateral sacral edge is the piriformis muscle with its typical longitudinal fibers (Fig. 64.3). By moving the transducer slightly lower and mildly rotating the left gluteal area clockwise (counterclockwise on the right side), the sciatic nerve becomes visible deeper in the medial aspect of the piriformis. The ischium initially appears as a curved hyperechoic line (posterior acetabulum); more caudally it becomes a flat line deeper to the piriformis. Another way to find the piriformis is to place the transducer over the line between the greater trochanter and ischial tuberosity. Once the sciatic nerve is identified, it is followed cephalad until the piriformis and gluteus maximus muscles are seen over the sciatic nerve.
To confirm the view of the piriformis muscle, flex the patient’s knee 90 degrees and rotate the hip internally and externally. During this maneuver the piriformis will slide over the ischium while the position of the gluteus maximus remains stable. While observing the sciatic notch it is useful to identify the ischial spine since other muscles that are in similar position as the piriformis insert in the area (i.e., the gemelli and obturator muscles) and should be differentiated from it.

The piriformis runs almost horizontal between the sacrum and the femur. A lateral-to-medial, in-plane approach is ideal to maximize visualization of the needle; the needle enters the skin 3 to 4 cm lateral to the lateral edge of the transducer. The needle should cross the skin and fat in a lateral-to-medial, posterior-to-anterior direction and enter the gluteus maximus and then the piriformis in its medial half. Hydrodissection with normal saline (or a nonelectrolyte solution such as 5% dextrose if stimulation is planned) may help confirm the position of the tip of the needle. The steroid (methylprednisolone or triamcinolone) plus local anesthetic (bupivacaine or lidocaine) is then injected. After injecting the piriformis muscle, to decrease sciatic nerve irritation, the needle can be advanced and positioned between the piriformis and the sciatic nerve to create a layer of local anesthetic with steroid. Five to 8 mL of the mixture is usually adequate.

POSTPROCEDURE FOLLOW-UP

The patient should be monitored closely for the following: (1) bleeding and bruising, (2) local infection, and (3) neurologic symptoms (leg numbness and weakness, urinary or bowel incontinence). It is not uncommon for weakness or numbness to develop in the distribution of the sciatic nerve for the expected duration of the local anesthetic.

RESULTS OF TREATMENT

Injection of the piriformis may improve pain-related outcomes for several months. However, the published studies are limited by poor study methodology and reporting, inconsistent outcome selection, small sample sizes, heterogeneous patient populations, and the absence of standardized diagnostic criteria.

A retrospective study noted that 76% of patients treated with physical therapy and local anesthetic/steroid injection had greater than 50% improvement at an average 10.5-month follow-up.30 The combination of a sciatic nerve conduction study with the flexion, abduction, internal rotation (FAIR) test may predict those who will respond to physical therapy.30 A prospective study noted better outcomes with local anesthetic/steroid injection than with medication and physical therapy alone that were sustained for 1 year.31 Several uncontrolled studies have evaluated the use of botulinum toxin, often in combination with physical therapy, and reported high rates of success that lasted for months (Table 64.1).27,32-39 A controlled study demonstrated superiority of botulinum toxin over placebo injection for 10 weeks.35 Other controlled studies have reported that the efficacy of botulinum toxin is superior to that of local anesthetic/steroid or normal saline injections for the treatment of piriformis syndrome when combined with physical therapy.26,40 One study found good results using clonidine.41

ILIOPSOAS INJECTIONS

Pain emanating from the iliopsoas muscle is relatively uncommon but can be a cause of low back, hip, or inguinal pain. Patients typically have unilateral low back or anterior hip pain, although the pain can frequently be referred to the thigh or inguinal area. Patients can vary widely, from young and active athletes, particularly in hockey, soccer, and dance, to older and more sedentary individuals who spend the majority of their time sitting, such as office workers and drivers. Myofascial pain arising from the iliopsoas muscle itself is distinct from that caused by iliopsoas bursitis or tendonitis (coxa saltans or “snapping hip syndrome”), although these causes are frequently included in the differential diagnosis. In addition, other causes such as lumbar spinal stenosis, iliotibial band syndrome, osteoarthritis or joint infection, inguinal hernia, and nerve entrapment syndromes should be considered.42

On physical examination an antalgic gait as a result of a shortened stride on the affected side may be noted as the patient enters the examination room. The patient may also have pain or weakness when squatting to sit or when transitioning from a seated position to a standing one. The psoas muscle can be palpated deep in the abdomen, medial to the anterior superior iliac spine, when the ipsilateral hip is flexed. Pain on palpation while flexing the hip against resistance is an excellent tool for diagnosing psoas major myopathy but may be uncomfortable for the patient. Provocative tests are not specific for the iliopsoas muscle but can be used to aid in the diagnosis via active and passive extension of a painful muscle.43

- Thomas’s test—The patient is supine and unable to completely extend the affected hip with the contralateral hip fully flexed; this is due to tightened hip flexors.
- Yeoman’s test—The patient is prone and experiences pain with passive extension of the affected hip, typically a sacroiliac joint test but can cause anterior hip pain with passive iliopsoas extension.
Gaenslen’s test—The patient is supine and feels pain with extension of the affected hip (leg hanging off the examination table) while the contralateral hip is flexed (knee held to the chest), typically a sacroiliac joint test but can cause anterior hip pain with passive iliopsoas extension.

• FABER test—The patient is supine and experiences pain with flexion, abduction, and external rotation of the affected hip.

• Snapping hip test—“Snapping” or “clicking” is heard when the hip is rotated from flexion and abduction to extension and adduction—this rules out coxa saltans.

### RELEVANT ANATOMY

The psoas major muscle is located in the retroperitoneal space and consists of a deep layer that originates from the transverse processes of L1-5 and a superficial layer that originates from the lateral portions of T12-L4. The lumbar plexus is located between these two layers of muscle. The psoas major also has fibrous attachments to all the lumbar disks except L5-S1. According to their position, the attachments are categorized as either “anterior” or “posterior.” The attachments located on the vertebral bodies and intervertebral disks are referred to as anterior fascicles, whereas those located on the transverse processes are known as the posterior fascicles.

The psoas joins the iliacus muscle, which arises from the ilium, to form the iliopsoas muscle within the iliac fascia. This muscle then runs anterolaterally through the iliopubic (iliopectineal) eminence and the muscular lacuna beneath the inguinal ligament, next forms a tendon that sits anterior to the hip joint, and finally inserts onto the lesser trochanter of the femur. The psoas muscles are usually asymmetrical in size, with the right side larger than the left. Innervation of the psoas muscle is achieved via the lumbar plexus from the ventral rami of L1-3, whereas the iliacus muscle is innervated by the femoral nerve from the ventral rami of L1-4.

Occasionally, a psoas minor muscle is present and arises from T12-L1. It follows the medial border of the psoas major and inserts into the iliopectineal eminence of the innominate bone and the ili fascia at the pelvic brim. The psoas minor is absent in 40% of adults and can therefore be mistaken for lymphadenopathy on imaging studies. This muscle is considered a weak flexor of the spine and is innervated by the ventral rami of L1.

Although it is widely accepted that the iliopsoas muscle aids in flexion and external rotation of the hip, there is controversy surrounding the muscle’s other functions. Other electromyographic studies have demonstrated varying degrees of activation of the iliopsoas muscle during hip rotation, adduction, and abduction, as well as during lumbar spine stabilization, flexion, and lateral flexion. As a result of these investigations, the iliopsoas muscle is thought to be “dynamically active” in that it adjusts its function according to spinal position and loading.

To reduce friction between the bone and muscle, a large synovial-lined bursa with only a trace amount of fluid is located at the level of the iliopubic eminence. The bursa

Note: For botulinum toxin injection of myofascial trigger points, the preponderance of studies showed a lack of efficacy.13

*The Botox injection was combined with physical therapy.

EMG, electromyographic; SF-36, 36-Item Short-Form Medical Survey.
IMAGING

Iliopsoas syndrome can be confirmed via the history and physical examination alone, without the aid of special imaging. However, diagnostic imaging may be required because of the uncommon nature of the syndrome, and the diagnosis is frequently based on incidental findings. Multiple imaging modalities, including US, CT, and MRI, can be useful in providing rapid and accurate information. CT can be used to outline the extent of affected tissue and may provide a diagnosis, such as infection or tumor. MRI can be used selectively in cases in which spinal canal or vertebral involvement is suspected. 46

US has evolved to become a very useful modality for both diagnosis and treatment of iliopsoas-associated disorders. Specifically, US can be used to quickly assess for the presence of fluid in the muscle (e.g., abscess, hematoma) and also to identify abnormal motion of the tendon. Other advantages to using US include the ability to easily scan the hip for assessment of symmetry and to direct injections into the muscle, tendon, or bursa. 49

TECHNIQUE

BASIC CONSIDERATIONS

The same concerns that apply to any myofascial injection apply to iliopsoas injections as well. Care must also be taken to ensure that the muscle is free of tumor, abscess, or hematoma before proceeding with an injection.

FLUOROSCOPIC TECHNIQUE

Proper monitoring is applied; the patient lies prone with pillows placed beneath the abdomen to correct the lumbar lordosis. The L4 transverse process is visualized on anteroposterior fluoroscopy. After local anesthetic infiltration, a 3-inch, 22-gauge (spinal) needle is advanced until it touches the transverse process. For psoas muscle injection, the tip of the needle touches the superior aspect of the middle or the lateral third of the transverse process and is advanced 1 cm beyond the transverse process. One to 2 mL of contrast agent is injected and the muscle striation pattern is noted (Fig. 64.4). A lateral view is obtained and 6 to 8 mL of local anesthetic (0.5% bupivacaine) and steroid (40 mg methylprednisolone or triamcinolone) is injected. To inject the adjoining quadratus lumborum muscle, the needle touches the lateral tip of the transverse process and is advanced 1 cm. The same procedure as for the psoas muscle is then performed.

ULTRASOUND-GUIDED TECHNIQUE

Single-shot procedures, as well as catheter placement, can be accomplished safely with US guidance. Two US-guided techniques are described as follows.

Lateral Approach

The lateral approach is a technique modified from the one proposed by Kirchmair and colleagues. 50 This technique is recommended in patients with a body mass index lower than 35 since the US view is impaired by a thick abdominal wall. The patient is placed in the lateral decubitus position with a mild anterior tilt. A low-frequency (2 to 6 MHz) curved probe is recommended. The transducer is initially placed lateral to the spine in a cross-sectional view, just above the iliac crest, to identify the transverse process and spinous process. The scan is moved laterally around the waist, while keeping the transverse process in view, to identify the following structures as the probe is kept perpendicular to the skin over the posterior axillary line: skin, fat, lateral part of the erector spinae muscle, quadratus lumborum, part of the external and internal oblique muscles, and the transverse process of L4. At this level it is unlikely that the kidney will be seen unless the patient takes a very deep breath. The transducer is then moved laterally to obtain a full lateral view of the spine and paravertebral structures. The hyperechoic lateral portion of the vertebral body is seen as a thick line curving deeply in the anterior part; lateral to it is the cross-sectional cut of the psoas muscle between the lateral portion of the vertebral body and anterior to the transverse process (Fig. 64.5). Gentle, slow scanning of the psoas muscle while looking at the medial-posterior area will show the nerve root entering the muscle along with a segmental artery. In-plane needle access is recommended, with the entry point in the skin located about 4 cm medial to the medial/posterior end of the transducer. A 12- to 15-cm-long, 20-gauge needle is used for single-shot injections, whereas a long epidural needle is required for insertion of a catheter into the muscle. The needle is advanced toward the junction between the posterior and middle third of the muscle (in the anteroposterior plane) (see Fig. 64.5). If a catheter is placed, it should be advanced 2 to 3 cm beyond the tip of the needle under direct vision, with the bevel of the needle facing cephalad along the fibers of the muscle. The same volumes and drugs as for the fluoroscopy-guided approach are recommended.
Posterior Approach

The patient is prone with a pillow under the abdomen to obtain a flat, more superficial spine position. In this approach the same curved transducer probe is initially positioned longitudinally over the spinous process at the level of L3-4. The spinous processes are identified and the transducer is moved laterally to show the laminae, masses of the facet joints, and finally the transverse processes of L2-4, which look like a trident on the US monitor. Careful observation while the patient pushes the ipsilateral knee against the table will show the fibers of the psoas muscle in between the transverse processes. The needle is aimed so that it crosses in between the transverse processes of L3 and L4 about 1.5 cm deeper than the distance measured from the probe to the posterior surface of the transverse process. When injecting in this location, no liquid should be seen superficial to the transverse processes. The catheter, if required, can be advanced as for the lateral US-guided approach.

The patient should be monitored for signs of intravascular injection (the aorta or vena cava when the needle is too anterior), unilateral lower extremity weakness from lumbar plexus blockade, or bilateral lower extremity weakness as a result of epidural or subarachnoid injection (the needle is too medial or larger volumes are injected).

RESULTS OF TREATMENTS

Very limited information is available on the outcome of treatment of iliopsoas syndrome. One controlled study reported the superiority of botulinum toxin injection (150 units in a 3-mL volume) over steroid and local anesthetic. Another controlled study using a side-to-side comparison in the same individuals was unable to demonstrate the superiority of botulinum toxin injection over local anesthetic or saline injection (see Table 64.1). Stretching in combination with dry needling was reported to be very effective in a case series. Standard physical therapy interventions such as stretching, strengthening, and improving neuromuscular control with the assistance of appropriate physical modalities (such as heat and therapeutic US) are also effective in the treatment of iliopsoas syndrome and associated musculotendinous disorders.

SCALENE MUSCLE INJECTIONS FOR NEUROGENIC THORACIC OUTLET SYNDROME

The incidence of thoracic outlet syndrome (TOS) varies from 3 to 80 cases per 1000 people, and it exists in three different forms: neurogenic, venous, and arterial. The most common type, neurogenic, accounts for 95% of all cases and results from compression of the brachial plexus between the anterior and middle scalene muscles and the first rib. Isolated or repeated trauma from whiplash-induced injuries to repetitive motion stress as a result of work or sports activities is a factor in up to two thirds of neurogenic TOS cases. Other causes include muscle anomalies (presence of the scalene minimus muscle, sickle-shaped middle scalene) and bone abnormalities (cervical rib, elongated transverse process). A small percentage of TOS cases are acquired through tumor metastases, osteomyelitis, or other uncommon sources.

Patients often have unilateral paresthesias, usually in the ulnar nerve distribution, or weakness of the upper extremity and variable other symptoms such as headache and cold intolerance. The diagnosis is difficult to make because of a lack of specific diagnostic criteria, relative insensitivity of imaging modalities and other diagnostic testing, and a long list of differential diagnoses.

Scalene muscle injections are indicated for neurogenic TOS as diagnostic, therapeutic, or prognostic blocks before surgery. Local anesthetic injections into the anterior scalene muscle alone or into both the anterior and middle scalene muscles can relieve TOS. The injection relaxes the muscle or muscles elevating the first rib and mimics the effects of first rib resection or scalenectomy. Relief with this technique correlates well with successful physical therapy and surgical treatment. Successful treatment of TOS with scalene muscle injection has been shown to be independent of any brachial plexus blockade.

RELEVANT ANATOMY

The scalene musculature consists of three muscles located on the lateral aspect of the neck; they have variable origin and insertion sites along the neck, as well as frequently fused fascicles between the individual muscles. A fourth muscle is occasionally present, the scalene minimus. The anterior scalene arises from the anterior tubercles of the transverse processes of the C3-6 vertebral bodies and inserts onto the subclavian artery. The middle scalene stems from the posterior tubercles of C2-7 and inserts onto the first rib posterolateral to the anterior scalene and posterior to the subclavian artery. The anterior and middle scalene muscles contain the brachial plexus between them. The posterior scalene originates from the posterior tubercles of C4-6 and inserts posterolateral to both the anterior and middle scalenes on the posterior border of the second rib. All the scalene muscles have multiple variations in their points of origin and insertion.

The scalene muscles are cervical spine flexors. Cervical spine flexion results when the scalene muscles contract bilaterally, and lateral spine flexion results when the muscles contract unilaterally. Additionally, the scalenes serve as
accessory muscles of respiration when the cervical spine is stabilized, with the anterior and middle scalenes helping to elevate the first rib and the posterior scalene elevating the second rib during deep inspiration. This group of muscles also rotates the spine ipsilaterally and reaches maximal stretch with contralateral rotation.56,59

The scalene muscles are included in the posterior triangle of the neck, which is bordered by the trapezius posteriorly, the sternocleidomastoid anteriorly, and the clavicle inferiorly. Its apex is formed by the junction of the sternocleidomastoid and trapezius at the level of the occipital bone. Also within these demarcations are the brachial plexus (from roots to divisions), cervical sympathetic ganglia, spinal accessory nerve, phrenic nerve, subclavian artery, transverse cervical artery, and lymph nodes.

IMAGING

Imaging modalities, including MRI, usually fail to reveal any abnormalities causing TOS. However, there are reasons to obtain imaging before performing any procedure in the posterior triangle of the neck. Such reasons include confirmation of muscle anomalies (presence of the scalene minimus muscle) and bone abnormalities (cervical rib, elongated transverse process), evaluation of the surrounding soft tissue for evidence of other injuries (e.g., rotator cuff tear), and identification of the presence of tumor, osteomyelitis, or other uncommon causes.

TECHNIQUE

Contraindications to and concerns with scalene muscle injections are the same as those noted for trigger point and piriformis injections. The injections can be done blindly, which is not recommended, with fluoroscopy to visualize the spread of contrast material within the muscle, under CT guidance, or with US. The US-guided technique is preferred for safety reasons since the thyroid, esophagus, carotid, jugular vein, and brachial plexus are visualized, and hence this technique will be the one described.

ULTRASOUND-GUIDED TECHNIQUE

The patient is supine and the area is prepared in sterile fashion. US is used to visualize the anterior and middle scalene muscles through one of two approaches. The probe is placed at the level of the cricoid cartilage/C6 vertebra and moved laterally from the trachea, carotid artery, and internal jugular vein (compressible) to identify the two scalene muscles with the brachial plexus (hypoechoic nerve roots) between them. Alternatively, the US probe can be placed in the inferior (just above the clavicle) and lateral (lateral to the sternocleidomastoid) aspect of the neck. After identification of the subclavian artery and brachial plexus, the plexus is traced cephalad to the level of C7, in between the anterior and middle scalene muscles. After skin infiltration, a 1.5-cm, 21- or 22-gauge needle is advanced out of plane into the belly of the muscle away from the brachial plexus. The out-of-plane approach is preferable to avoid injection of local anesthetic into the brachial plexus (Fig. 64.6). Alternatively, an in-plane approach from the medial side for the anterior scalene muscle and from the lateral side for the middle scalene muscle can be performed. Two milliliters of 0.25% bupivacaine is injected per muscle. Although some authors inject both the anterior and middle scalene muscles, others inject only the anterior scalene muscle.56

Relief of symptoms can occur within 15 to 30 minutes and may last for days or weeks. The brachial plexus may be blocked, with resultant numbness of the upper extremity, since it is not uncommon for the roots of the brachial plexus to pass through the middle scalene muscle. The injected local anesthetic may spill through the fascia of the scalene muscles. If this happens, the patient should be discharged with an arm sling. Note that relief is not dependent on blockade of the brachial plexus. Either series of injections can be performed 2 to 3 weeks apart if the relief is prolonged. Even though the usual duration of relief is days to a week, it may last up to 4 weeks when a series of injections are performed.53 If relief lasts only for hours or a few days, either injection of botulinum toxin or resection of the anterior or middle scalene (or both) can be performed. Published doses of botulinum toxin are 12 to 15 units of botulinum toxin A per muscle (see Table 64.1).37-39 Regarding the results of surgery, a retrospective 2-year functional outcome study showed good and fair results in 49% and 35% of patients, respectively.60

SUMMARY

- Myofascial injections include trigger point injections and injections of the piriformis, iliopsoas, and scalene muscles.
- Trigger point is the hallmark of myofascial pain syndromes; injections of local anesthetics in conjunction with physical therapy and appropriate medication or medications may result in long-term benefit.
- Piriformis syndrome may mimic L5-S1 radiculitis, although the pain starts in the buttock. There are signs and symptoms that help aid in diagnosis of the syndrome. Injections of local anesthetic and steroid may ameliorate the pain. If relief from a series of local anesthetic/steroid injections is transient, botulinum toxin can be injected.
• Signs and symptoms of iliopsoas muscle pain are usually nonspecific. Diagnostic/prognostic local anesthetic injections may be performed, followed by botulinum toxin injection.

• The diagnosis of neurogenic thoracic outlet syndrome can be made from the patient’s symptoms, physical examination, electromyographic findings, and imaging (also to rule out other pathology). Local anesthetic injections into the anterior and middle scalene muscles are preferably performed under ultrasound guidance. Either a series of local anesthetic injections or botulinum toxin injection may be performed; first rib resection and scalenectomy may result in long-term benefit.

• The use of ultrasound has revolutionized injections into the piriformis, iliopsoas, and scalene muscles. Its use with trigger point injections is increasing.

• The injections should be part of a multidisciplinary treatment program that includes physical therapy.

Lumbar Discogenic Pain and Diskography

Michael M. Bottros | Steven P. Cohen

OVERVIEW OF LOW BACK PAIN

Back pain has plagued humanity since time immemorial. In most cases, the development of low back pain (LBP) is self-limited and does not require operative intervention. Fifty percent of cases of LBP resolve without medical attention within 1 week; 90% resolve within 4 months.1 However, the remaining cases exact an enormous burden on society in terms of personal suffering and economic impact. In recent years, the prevalence of disability from back pain has exploded in industrialized societies. In the United States, it was estimated that the direct health care expenditure for back pain was $90.7 billion in 1998.2 A recent systematic review of the global prevalence of LBP revealed that the mean “overall prevalence,” which was defined as all prevalence regardless of the prevalence period, was as high as 31.0%.3 The statistics are even more unsettling when viewed from a personal and economic perspective. In patients with LBP who have not worked in 6 months, the lifetime return-to-work rate is 50%. In those who have been off work for 1 year, only 25% will return to work. For patients whose injury has left them unable to work for 2 years, the return-to-work rate is less than 5%.4,5 This dramatic surge in the incidence and cost of chronic LBP has led to a concurrent rise in the use of diagnostic modalities and therapeutic interventions aimed at ameliorating this growing problem. Among the various types of LBP, internal disk disruption (IDD) is widely acknowledged to be the most common source of axial symptoms.

Diskography was first described in 1948 as a diagnostic tool for herniated nucleus pulposus (HNP).7 Since that time, simpler, safer, and more accurate imaging modalities have largely supplanted diskography as an investigative technique for nerve root compression. Yet in some circles provocative lumbar diskography continues to be a popular, albeit controversial, means of diagnosing axial LBP secondary to IDD. This is because unlike magnetic resonance imaging (MRI) or computed tomography (CT), diskography is not just an imaging modality but a provocative test purported to correlate symptoms with pathology. Although some studies have shown a high degree of correlation between the results of diskography and histologic findings8,9 and between diskography and surgical outcomes,10,11 others have failed to demonstrate such a relationship.12,13

PROVOCATIVE TESTS IN CONTEXT

Much of the criticism surrounding diskography stems from generalized disapproval about the diagnostic value of provocative procedures for other spinal disorders. In a study by Marks, no consistent segmental or sclerotomal referral patterns were found during 385 provocative lumbar facet blocks in 138 patients with chronic spinal pain.14 Bough and coworkers assessed the histologic findings of 127 facet joints surgically removed based on the results of preoperative provocative lumbar facet arthrography.15 The authors found the specificity of degenerative facet joint changes to be 75% but the sensitivity to be only 59%. They concluded that reproduction of symptoms during facet arthrography was of little value as a presurgical screening procedure. Schwarzer and associates conducted a prospective study of 90 patients (203 joints) to determine the relationship between pain provocation and the analgesic response to lumbar zygapophyseal joint blocks.16 Using a single analgesic block as the diagnostic criterion, reproduction of similar or exact pain was found to predict subsequent response to analgesic facet blocks. However, when the more stringent criterion of concordant analgesic response to confirmatory blocks with lidocaine and bupivacaine was used, no significant association was found.

In 1994, Fortin and colleagues conducted two studies designed to evaluate sacroiliac (SI) joint pain referral maps generated by the distention of joints in asymptomatic volunteers. In the first study, the authors designed a pain referral map by distending the SI joint capsule in 10 asymptomatic subjects by injecting radiopaque contrast material and lidocaine.17 Similar to a set of previous studies done on the cervical facet joints,18,19 the authors found that the pain generated during the initial joint injection corresponded with the hypoesthesia experienced after lidocaine was administered. In the second study, independent observers chose 16 patients with chronic LBP whose pain diagrams most closely resembled the pain referral maps generated in the first study and injected their joints with bupivacaine.20 Ten of the 16 patients obtained 50% or greater pain relief after the instillation of bupivacaine. Of note, the pain referral maps generated in the first Fortin study were significantly different from the SI joint referral zones described by other authors based solely on analgesic blocks.21 Finally, Schwarzer and associates conducted an SI joint prevalence study in 43 patients with LBP principally below L5-S1.22 Using the analgesic response to local anesthetic blocks as the sole criterion for diagnosis, 90% of patients were considered to have SI joint pain. Using pain relief combined with a ventral capsular tear on postarthrography CT imaging, 21% of the patients met the diagnostic criteria for SI joint pain. Using the three criteria of concordant pain provocation, abnormal findings on imaging, and analgesic response to
injection of local anesthetic, just 16% were considered to have SI joint pain. Among the 27 patients with similar or exact pain reproduction during provocative testing, only 41% experienced “gratifying” pain relief following local anesthetic injection, thus suggesting that pain provocation may be associated with a significant false-positive rate. The lack of strong validity for provocative facet and SI joint injections as diagnostic tools is consistent with the findings of Slipman and coworkers, who demonstrated distinct differences between dynatomal and dermatomal maps during provocative cervical nerve root blocks. In summary, there seems to be little evidence to support the use of provocative injections to diagnose other sources of LBP.

LUMBAR INTERVERTEBRAL DISK ANATOMY

The intervertebral disk complex is composed of the nucleus pulposus (NP), the annulus fibrosus (AF), and the vertebral end plates. Lying above and below the disk are the vertebral bodies or the sacrum below L3-S1. The disk is attached to the adjacent vertebral bodies via the vertebral end plates centrally and to the ligamentous attachments of the AF peripherally. Together, these components allow the principal movements exhibited by the lumbar spine, which include flexion, extension, axial rotation, and lateral flexion. Horizontal translation does not generally occur as an isolated movement but is involved in axial rotation. Posteriorly, the intervertebral disk is supported by the other two components of the three-part structure, the paired zygapophyseal joints. Working in concert, these structures function to support and stabilize the spine and prevent injury by limiting motion to specific planes of movement.

The NP consists primarily of water (70% to 90%) in a matrix composed of proteoglycan, a substance with high water-binding capacity, and type II collagen. The dry weight of the intervertebral disk consists of approximately 65% proteoglycan, with the remainder of the nucleus being composed largely of type II collagen. The high water content of the disk creates a broad, relatively noncompressible weight-bearing surface that serves to cushion the spine from the stress of the truncal load.

The AF is composed of primarily type I collagen arranged in highly organized, concentric lamellae. These lamellae form 10 to 20 sheets surrounding the NP and are thicker toward the center of the disk. The AF is thick and strong anteriorly and laterally but tends to be weaker posteriorly. This anatomic incongruity accounts for the disproportionate percentage of disk herniations occurring posteriorly. Posteriorly, the AF is concave in the lumbar spine. Like the NP, the AF has a high water content, in the range of 60% to 70% by weight. The annulus helps stabilize the vertebral bodies and limit excess motion.

The vertebral end plate is composed of hyaline cartilage close to the vertebral body and fibrocartilage near the NP. The fibrocartilage surrounds the NP and is formed as an extension of the annular fibers. The end plates completely envelop the NP centrally but taper off peripherally, where the outermost AF lamellae directly attach to the vertebral bodies. The composition of the end plates resembles that of the annulus at its attachments to the vertebral bodies and that of the NP centrally.

A healthy adult disk is basically avascular, with its nutrition supplied through the vertebral end plates and the AF via passive diffusion. Whereas the periphery of the annulus is completely permeable, the bone-disk interface is only partially permeable to substrates. The annulus contains blood vessels just in its most superficial lamellae. The nucleus itself contains no direct blood supply. The oxygen and nutrients that diffuse through the end plates come from branches of the lumbar arteries supplying the vertebral bodies.

The anabolic functions of a healthy disk are maintained by chondrocytes and fibroblasts, whereas its catabolic functions depend on the matrix metalloproteinase (MMP) enzymes collagenase (which degrades collagen) and stromelysin (which degrades proteoglycans). The metabolism of cells in the nucleus is exquisitely sensitive to changes in pH, and it is maximally active in the range of 6.9 to 7.2. Even in the presence of high oxygen concentrations, disk metabolism is mainly anaerobic. Any number of factors can lead to a breakdown in the delicate metabolic function of the disk, including changes in pH, inflammatory mediators, and nutritional deficiencies.

Functionally, innervation of the lumbar intervertebral disks stems from two extensive nerve plexuses that accompany the posterior and anterior longitudinal ligaments. These are known as the posterior and anterior plexuses. The anterior plexus consists of contributions from the anterior branches of the gray rami communicantes, small medioventral branches of the sympathetic trunk, and perivascular nerve plexuses. The posterior plexus is a diffuse network of interconnecting fibers receiving somatic and autonomic input from multiple spinal levels. Its visible components are derived mainly from the sinuvertebral nerves, which are formed from somatic roots arising from the ventral rami, and from autonomic contributions from the gray rami communicantes (which receive input from the sympathetic trunk), but the majority of its nerve fibers are actually microscopic. The posterior and anterior plexuses are connected via a less prominent conglomeration of nerves known as the lateral plexus, which is formed by branches of the gray rami communicantes. Together, these plexuses provide transmission of sensory information from the entire circumference of the intervertebral disk.

In newborns, innervation of the lumbar intervertebral disk is dense, most likely because of the extensive blood supply. This rich vascularization disappears around 4 years of age and is accompanied by a concomitant diminution in nerve density. However, in later years when degenerative processes set in, there is a recrudescence of blood vessels and nerve endings. Nerve fibers are typically sparse in the lumbar intervertebral disks, with only the outer third being innervated, but in patients with degenerative disk disease (DDD), the innervation becomes both denser and deeper and frequently penetrates into the inner AF and occasionally into the NP.

There is some evidence supporting the role that lumbar sympathetic afferent nerves play in the perception of LBP, including provocation of LBP by stimulation of the sympathetic trunk and relief of LBP following lumbar sympathetic block. The contribution of these sympathetic afferents appears to be transmitted mainly via the L2 nerve root, as evidenced by the work of Foerster, who demonstrated that L2 is the dermatome corresponding to LBP, and by the work of Nakamura and colleagues, who...
showed that LBP disappears or significantly decreases after selective blockade of the L2 nerve root. The observation that the lumbar intervertebral disks and their adjacent ligaments are innervated by branches of the sympathetic nervous system does not necessarily mean that sensory input from these structures returns to the spinal cord via the sympathetic trunk. Rather, it has been suggested that somatic afferent fibers from the disks and surrounding pain-generating structures course with the rami communicantes and return to the central nervous system via ventral rami. Several different types of nonvascular nerve endings have been described, including simple, cluster, and partially and fully encapsulated. Although the exact role of each type of nerve ending is unknown, it is speculated that under nonpathologic conditions, they function primarily as mechanoreceptors (Fig. 65.1).

**PATHOGENESIS OF DISCOGENIC LOW BACK PAIN**

**NERVE INGROWTH**

Whether the lumbar intervertebral disks receive sensory innervation continues to be the subject of controversy. In the early and mid-20th century, anatomic studies failed to demonstrate nerve endings within the lumbar intervertebral disks, and it was therefore believed that the disks could not be a principal source of pain generation. Subsequent studies have since disproved this concept. In normal human disks, sensory nerves extend into the outer third of the annulus. In degenerated and herniated disks, the innervation is deeper and more extensive, with some nerve fibers penetrating into the NP.

It is now generally acknowledged that intervertebral disks do receive sensory innervation and indeed can be a significant cause of LBP.

In 1997, two groups described ingrowth of nociceptive nerve endings into degenerate intervertebral disks. Nerve fibers were identified by using a combination of histologic nerve stains. These nerves have the morphology of nociceptive nerves and express GAP43, a marker of nerve growth, and substance P, a nociceptive (and vasoregulatory) neurotransmitter. The mechanisms leading to this nerve ingrowth have been grouped into three categories.

The first of these categories is angiogenesis. During angiogenesis, endothelial cells of vessels growing into the intervertebral disk synthesize the neurogenic stimulator nerve growth factor, one of a family of neurotrophins. Importantly, nerves that are structurally nociceptive in nature are seen only in intervertebral disks that are classified clinically as “pain-level disks.” Hence, when these disks are stimulated (e.g., by diskography or direct probing), the patient’s symptoms of back pain or sciatica, or both, are reproduced. Intervertebral disks that show similar degrees of degeneration but do not provoke concordant pain with stimulation do not exhibit nerve ingrowth. The second mechanism proposed to lead to nerve ingrowth is altered intervertebral disk matrix biology. Johnson and colleagues showed that aggrecan from normal intervertebral disks inhibits neurite growth but that aggrecan from degenerate intervertebral disks has less of an inhibitory effect. This suggests that with degeneration, nerve ingrowth may occur as a consequence of changed aggrecan biology. Finally, the third possible reason for ingrowth is altered cell function. Even though aggrecan normally inhibits neurite outgrowth, this could be reversed by cells derived from degenerated intervertebral disks.

**GENETIC PREDISPOSITION**

Over the last 25 years, several genetic associations have been implicated in the predisposition to intervertebral disk degeneration, but few have been replicated consistently. Only collagen IX and vitamin D receptor polymorphisms have been reliably associated with degeneration in reasonably sized populations. Other possible genes currently being investigated include those for collagen I, interleukin-6 (IL-6), aggrecan, MMP-3, thrombospondin, cyclooxygenase, tissue inhibitor of metalloproteinases 1 (TIMP-1), cartilage intermediate layer protein, and IL-1. Further studies are needed to examine the functional interaction of these genes within the framework of the molecular pathology associated with the degeneration of intervertebral disks.

**MECHANICAL CHANGES**

In a normal disk, mechanical interplay between the AF and NP distributes weight bearing uniformly across the entire disk surface. When a disk becomes physically stressed, such as by flexion of the spine, the nucleus acts as a noncompressible mass, with its gelatinous contents bulging in the axial, sagittal, and coronal planes. A competent annulus resists this outward bulging, thereby resulting in equal distribution of force. In these circumstances the annulus is not unduly stressed since its broad surface area translates into the nucleus bearing the greatest share of the load.

![Figure 65.1](image-url)
Over time, age-related changes or an acute injury can lead to a breakdown in normal load bearing. Histologic studies conducted on cadaver lumbar spine specimens have revealed that as early as the second decade of life, a reduction in blood flow leads to diminished nutritional supply to the end plate. This in turn results in tissue breakdown within the disk that commences in the NP and shortly thereafter in the vertebral end plates. This progressive, macroscopic degeneration, in conjunction with either low-level repetitive stress or an acute traumatic event, can lead to two possible sources of injury: microfracture of the vertebral end plate or an annular tear from torsional overload. When this occurs, the ability of the NP to evenly dissipate a compressive load becomes compromised. Unlike normal disks, a compressive load in degenerated disks is not uniformly distributed. Instead, the preponderance of the weight-bearing burden is borne by the richly innervated AF. Although this can be maintained for short periods, if the end-plate fracture does not heal, repetitive stress on the annulus can eventually lead to tearing of the fibers. These tears further decrease the load-bearing capacity of the disk since torn lamellae can no longer function as a support apparatus. This initiates a vicious circle that causes even more stress on the remaining lamellae and eventually leads to further tearing of the annular fibers, which can ultimately result in the complete loss of annular integrity. The net result of this sequence of events is that the disk is now predisposed to nuclear herniation. The loss of disk height that inevitably ensues may then deteriorate into continued narrowing of the disk, accompanied by the pathologic changes commonly seen in severe DDD, such as Modic changes, sclerosis of the end plates, and bridging osteophytes (Table 65.1). In severe cases, this is manifested as autofusion and ankylosis of adjacent segments.

**CHEMICAL CHANGES**

Several changes can occur in degenerated disks whose end result is a decrease in the threshold for nociception. First, a break in an end plate can lead to the introduction of inflammatory cytokines into the nucleus, which results in reduced oxygen diffusion, a rise in lactate levels, and a decrease in pH. This conglomeration of factors can result in a slowdown in metabolic and reparative processes and thus lead to increased degradative metalloproteinase activity and diminished chondrocyte activity, which can accelerate disk degradation. In certain contexts, proinflammatory cytokines can be a direct source of pain, but in the context of a functional annulus, no pain should be experienced since the inflammatory mediators cannot reach the nociceptors present in the outer part of the disk. However, when an annular tear develops, granulation tissue forms and nerve endings are able to extend through the annulus, with penetration sometimes as far centrally as the NP. Thus, in the presence of a compromised AF, chemical mediators are able to reach sensitized nerve endings, the by-product of which is LBP.

Sensitization and irritation of nerve endings in the end plate may also result in pain. This model of chemical nociception is supported by a number of studies showing disk immunoreactivity to a variety of substances in diseased and herniated intervertebral disks, including vasoactive intestinal polypeptide, substance P, and calcitonin gene–related peptide, as well as elevated levels of nitric oxide, prostaglandin E₂, IL-2, IL-6, IL-8, phospholipase A₂, leukotriene B₄, thromboxane B₂, and tumor necrosis factor-α.

Taken in concert, these factors provide a biochemical and mechanical rationale for performing diskography. The generation of pain at low intradiscal pressure is best explained by a preponderance of inflammatory mediators around the sensitized disk; in medical terminology, this is referred to as “chemically sensitized” disks. When disk degeneration is less severe or the disruption less acute, the disk may react to stimulation only at higher pressure, at which point the nerve fibers of the degraded annulus are stretched to the point of pain induction. This scenario describes a “mechanically sensitized” disk. Perhaps an easier way to conceptualize these models is that a chemically sensitized disk is analogous to the phenomenon of allodynia whereas a mechanically sensitive disk is akin to hyperalgesia. In the later stages of disk disease, the annulus may become functionally incompetent, in which

case injection of contrast material may fail to generate inter-
mediate to high pressure. This can result in an uninterpretable
or even false-negative pain response if manometry is not
used. On CT, severely degenerated disks are likely to show
a diffuse pattern of spread of contrast material with extensive
leakage into the epidural space, but it is possible to miss
small leaks on plain fluoroscopy. Normal disks resist pain
provocation because they lack both the chemical hypersensi-
tivity and the apparatus for mechanical overloading that are
present in diseased disks. In clinical practice, these examples
represent an ideal diagnostic paradigm that fails to account
for the multitude of genetic, social, cultural, and psychological
factors that affect pain perception. To optimize diagnosis
and treatment outcomes, these factors must be considered
when performing any pain-provoking procedure.

LUMBAR DISK PAIN REFERRAL PATTERNS

The premise on which diskography is based is that controlled
pressurization of a painful disk will reproduce a patient’s
symptoms. The limitations of this paradigm have been dis-
cussed previously. In addition to the flaws inherent in any
provocative test, inaccuracies may also result from oversedation
with anxiolytics or opioids (or both), excessive adminis-
tration of local anesthetic, anxiety, procedure-related pain,
the ephemeral nature of disk pressurization, and an inability
to distinguish concordant from noncordant pain in the
brief moments when disk pressure exceeds the nociceptive
threshold. Nevertheless, several investigators have attempted
to categorize the pain patterns with positive diskograms. In a
prospective study conducted in 187 patients with LBP sched-
uled for diagnostic CT-diskography, Ohnmeiss and cowork-
ers found that L3-4 diskograms were likely to be positive if
patients described their pain as involving the lumbar region
with radiation into the anterior but not the posterior aspect
of the thigh and often into the anterior aspect of the leg. 81
For L4-5 disks, the most common pain referral pattern was
lumbar pain involving more equivalent proportions of the
anterior and posterior thigh pain. In L5-S1 discogenic pain,
the pain description generally encompassed the lumbar and
posterior thigh regions, with fewer patients reporting ante-
rior thigh or leg pain. Pain in the absence of disk pathology
tended to be limited to the low back region and buttocks
(Fig. 65.2).

In the late 1980s, Vanharanta and colleagues performed
a series of studies to evaluate the effects of various disk
abnormalities on pain referral patterns. In the first of
these studies, evaluation of CT-diskograms in 91 patients
showed a positive relationship between the occurrence of
pain and the presence of an annular rupture. 82 The sec-
ond study found that narrow disks were more likely to be
associated with “exact pain reproduction” than were disks
of normal height. 83 In the same study it was also suggested
that the degree of pain concordance is influenced by the
spinal level. Specifically, severely degenerated L3-4 disks
were less likely to result in concordant pain than were
comparable disks at the L4-5 and L5-S1 spinal levels. The
third paper, a prospective, multicenter study evaluating the
results of 300 surgical candidates with a variety of clinical
diagnoses, found no significant relationship between con-
cordant pain provocation in four diagnostic groups: disk
herniation (82%), DDD (81%), lumbar syndrome (56%),

---

ral pattern for L5-S1 discogenic back pain. (Adapted from Ohnmeiss
DD, Vanharanta H, Ekholm J. Relation between pain location and disk
1999;15:210-217.)
and radiculopathy (59%). Disks that were deteriorated tended to be painful regardless of a patient’s diagnostic classification. In the fourth study, based partly on the same patient population, the authors found that the percentage of degenerated disks that elicited either “no pain” or “noncordant pain” was higher in elderly patients. A later retrospective study found that outer annular ruptures were the only predictors of concordant pain in a reanalysis of 833 diskograms done in 306 patients with LBP.

Maezawa and Muro came to a different conclusion from Vanharanta and colleagues. In a retrospective analysis of 1477 diskograms performed in 523 patients with axial or radicular LBP, the authors found that elicitation of pain was only weakly associated with IDD whereas the presence of a herniated disk was strongly associated with pain provocation. Saifuddin and coworkers performed a retrospective review of 260 lumbar diskogram reports with the aim of correlating morphologic disk abnormalities with pain referral patterns. The authors demonstrated a highly significant association between annular tears and concordant back and radiating pain of any type. An association between isolated posterior tears and radiating pain was also found, but no relationship between anterior annular tears and any pain radiation was noted. No differences in pain referral patterns were identified when full-thickness and partial-thickness posterior tears were compared. There was an increased incidence of leg pain versus groin, hip, or buttock pain during L4-5 and L5-S1 disk provocation, but this trend did not reach statistical significance. Finally, a retrospective study by Slipsman and colleagues did not find any correlation between the side of a patient’s concordantly painful annular tear on CT-diskography and the side with the pain complaints.

To summarize, the presence of degenerative changes of any type is more likely to be associated with pain than are nondegenerated disks or disks with only minimal degradation. Pain provocation may also be more likely to occur in the presence of annular tears and nuclear herniations, with more evidence supporting the former assertion.

FALSE-POSITIVE PAIN PROVOCATION

In the past 30 years the use of diskography to detect disk pathology has largely been supplanted by more advanced radiologic studies such as MRI and CT. The evidence that these newer modalities are not only safer but also more accurate than plain diskography in detecting herniated nuclear material is indisputable. In a prospective study by Jackson and associates in which myelography, CT-myelography, plain diskography, and CT-diskography were compared with surgical findings in 231 disks, the authors found CT-diskography to be the most accurate test (87%) and plain diskography to be the least accurate (58%). CT-diskography ranked highest in sensitivity for HNP at 92%, as compared with 78% for CT-myelography, 72% for CT, 70% for myelography, and 81% for plain diskography. For specificity, CT-diskography was also the most accurate (81%), followed by CT (76%) and CT-myelography (76%), myelography (70%), and plain diskography (51%).

Since diskography is more invasive and unequivocally less sensitive in detecting most disk pathology than newer imaging techniques are, the primary justification for its continued use lies in its ability to correlate pathology with symptoms. This rationale seems reasonable given that close to two thirds of asymptomatic adults have abnormal findings on MRI of their lumbar spine, with the prevalence of these findings increasing with age. LBP is an epidemic of unprecedented proportion in industrial societies, and the estimated lifetime prevalence ranges from 60% to higher than 80%. Without a corroborative test to validate these abnormal MRI findings, it is likely that many of these patients would be conferred with incorrect diagnoses and subsequently undergo unnecessary surgical procedures. There is little doubt that unnecessary stabilization operations are performed far too frequently in the United States, but there is disagreement about whether diskography prevents or facilitates these unnecessary surgeries. Proponents of diskography believe that correlating pathology with symptoms prevents unnecessary surgical intervention, whereas opponents question both the significance of diskographic pathology and the validity of provoked symptoms. These criticisms are bolstered by the relative lack of specificity of diskography, the inherent difficulty in validating provoked symptomatology, the large number of studies showing false-positive pain provocation in patients without low back symptoms, and disparities with regard to histologic findings on surgical specimens.

In phase 1 of a two-part experiment, Yasuma and coworkers studied 181 lower thoracic and lumbar disks from 30 adult cadavers diskographically and histologically. Their findings revealed 32 true-positive, 15 false-positive, 122 true-negative, and 12 false-negative diskograms. Diskograms were designated false-positive when the injected contrast material was noted to extend beyond the peripheral vertebral margin but histologic sectioning of the disk was negative for protrusion. False negatives were defined as a negative diskogram despite histologically confirmed disk protrusion. In the 32 true-positive disks, both the diskograms and histologic sections showed 10 anterior protrusions, 17 posterior protrusions, and 5 posterior herniations. Among the 15 false-positive diskograms, 9 were misdiagnosed as a protrusion and 6 as a herniation. In part 2 of this study, the authors conducted a retrospective review of 77 diskography patients subsequently found to have a herniated disk during surgical exploration. The diskograms were falsely interpreted as negative in 32% of the 59 patients with a protruding disk and in 56% of the 18 patients with a prolapse. In a previous study the authors found that false-positive diskograms were more likely to occur when fissures or cysts were present in a degenerated annulus but did not establish continuity with the nuclear cavity.

The first study to question the validity of diskography was published in 1968 by Holt, who found false-positive results in 37% of 30 asymptomatic prisoners. More than 20 years later, Walsh and colleagues performed CT-diskography on 10 asymptomatic male volunteers and 7 “control” patients with chronic LBP. Sixty-five percent of the 20 disks injected in the patients with back pain showed radiologic abnormalities, with all 7 patients having at least 1 degenerated disk. In the patients without back pain, CT-diskograms were interpreted as abnormal in 17% of the 35 disks injected and in half of the 10 subjects. However none of these 5 patients experienced concordant pain associated with pain-related behavior during the injections. Thus, the false-positive rate in this study was 0%.
In 1996, Block and coworkers conducted a landmark prospective study in 90 patients with low back and leg pain who underwent CT-diskography at the three lowest lumbar levels. The Minnesota Multiphasic Personality Inventory was administered to each subject before diskography and scored independently. In the 72 patients with at least one nondisrupted disk, 34 reported discordant pain provocation at a normal level, with the remaining 38 patients reporting a “concordant negative response.” In the 34 patients who reported pain during pressurization of normal disks, the mean hypochondriasis, hysteria, and depression scores were significantly higher than in patients in whom stimulation of normal disks did not elicit pain.

In 1999 and 2000, Carragee and coauthors published a series of studies attempting to identify patients at high risk for false-positive diskograms. In the first study, eight patients with no history of back problems or structural spinal abnormalities who had recently undergone iliac crest bone grafting for reasons unrelated to lumbar spine, hip, or pelvic pathology were studied by provocative diskography of their three most caudal disks. Four of the eight study subjects experienced severe LBP similar to the postoperative pain at their bone graft site during injection of at least one disk. All symptomatic disks had an abnormal morphologic appearance.

In the second study, the authors performed lumbar diskography on 10 patients with neck and upper extremity pain but no lower back symptoms, 6 patients with somatization disorder, and 10 control patients devoid of pain symptoms. The three most caudal lumbar disks were injected in all patients, with five patients having the L2-3 disk studied as well. Eighty-three percent of patients in the somatization group, 40% of the chronic cervical pain patients, and 10% of the control patients experienced moderate or severe pain during injection of contrast material into at least one disk. Pain was provoked in 11% of disks with intermediate-grade disruption and in 37% of disks with annular tears. In contrast, injection did not result in pain in any of the 31 radiographically normal disks. In the last study, three-level diskography was performed on 47 patients who had undergone single-level diskectomy for sciatica. Twenty subjects with no recurrent symptoms were designated the “study” group, and 27 patients with persistent back or leg symptoms (or both) formed the “control” group. In the asymptomatic participants, positive injections occurred in 8 of 20 (40%) operative disks. In the “control” patients with symptoms, positive injections occurred in 17 of the 27 operative disks (63%), with the pain being concordant in 15. No significant differences were found in the diskography results between symptomatic and asymptomatic participants with normal psychometric scores. In contrast, patients with abnormal prediskography psychological test scores were more likely to rate their pain as unbearable during injection of both operative and nonoperative disks than were patients in both groups with no psychopathology. All positive disks were radiographically abnormal.

There are several flaws in the studies assessing “false-positive” diskograms in asymptomatic subjects, with the main one being inherent in the study design: in subjects without preexisting LBP, one cannot provoke true concordant pain, which has become a hallmark of modern-day diskography. The second major shortcoming is that although the Carragee studies used manometry to limit intradiscal pressure, pressure readings were not a determining factor in the designation of a positive disk. The guiding principle behind diskography is to identify disks that provoke pain during stimulation, but application of excessive pressure to any bodily structure that contains nerves, including components of the spine besides disks, will provok pain in normal subjects.

In an effort to determine the effect that objective pressure readings have on the incidence of positive disk injections in asymptomatic volunteers, Derby and colleagues performed 43 diskograms on 13 subjects with either no history or infrequent episodes of LBP. In the patients with occasional back pain, 35% of the 20 injected disks were painful versus 52% in volunteers with no history of LBP. Most disks required that high pressure be reached before pain was elicited, and even then, the pain was mild. There was no relationship between painful disk injections and abnormalities on MRI or diskography. Controlling for the intensity of response and the pressures at which pain was elicited, the authors concluded that the incidence of false-positive diskograms was less than 10%. Some potential causes of false-positive diskograms include inadvertent annular injection (Fig. 65.3), contrast-induced irritation of nervous tissue, end-plate deflection resulting from suboptimal needle placement, and stimulation of pressure receptors when excessively high pressure is generated.

Wolfer and coauthors published a systematic review in which data from five previous studies were reanalyzed by using guidelines from the International Association for the Study of Pain (IASP) and the International Spine Intervention Society (ISIS) for a positive lumbar diskogram (Table 65.2). The authors found an overall false-positive rate of 9.3% per patient and 6.0% per disk. False-positive rates dropped to 3.0% per patient and 2.1% per disk in patients without back pain or confounding factors. Chronic pain patients were found to have false-positive rates of 5.6% per patient and 3.9% per disk. Finally, the highest false-positive rates per patient and disk occurred in postdiskectomy patients (15% and 9.1%, respectively) and those with somatization disorder (50% and 22.2%, respectively).

One flaw in these criteria is that they do not consider a patient’s baseline pain rating, which can lead to flagrant inconsistencies. For example, a person with significant back pain disability who rates his baseline pain as 3/10 and in whom disk stimulation provokes 5/10 pain would be considered to have a negative diskogram by ISIS guidelines because the maximum pain score did not exceed the minimum cutoff threshold for designating a disk as positive. Yet a person with less functional impairment and 9/10 baseline pain in whom disk stimulation provokes 7/10 pain could theoretically be classified as having a positive diskogram.

Despite these limitations, given the high propensity for false-positive findings in patients with previous back surgery, psychopathology, or somatization symptoms, positive diskograms should be viewed with caution in these individuals. To optimize specificity, we suggest using two adjacent control disks, a recommendation previously endorsed by Endres and Bogduk in an attempt to improve accuracy in patients at high risk for false-positive diskography. Although it may seem intuitive that this would enhance specificity or improve outcomes, these issues have yet to be addressed.
The subject of “false-negative” diskograms has garnered far less attention but can result in inaccurate diagnoses, unnecessary interventions, and withholding of beneficial treatment from otherwise good candidates. There are several reasons that a person with discogenic pain may fail to experience pain with disk stimulation, including failure to detect an inadequate rise in intradiscal pressure because of the lack of pressure monitoring, injecting too slowly, excessive sedation, overzealous use of local anesthetic, and extensive extravasation of contrast material in severely degenerated disks. False-negative diskograms may be more likely to occur in elderly patients. In a review by Cohen and associates, the authors estimated that between 15% and 25% of degenerated disks fail to elicit concordant pain provocation during stimulation. The proportion of these occurrences that represent false-negative responses versus accurate reflection of a non–pain generator is a question that remains to be answered. The results of clinical studies evaluating false-positive lumbar diskography are presented in Table 65.3.

**PREVALENCE OF DISCOGENIC LOW BACK PAIN**

Axial back pain is one of the most common, yet challenging, problems faced by pain physicians. Numerous structures besides degenerated disks can cause axial LBP, with two of the more common ones being the lumbar facet joints and muscles. The SI and facet joints are implicated as the primary cause of chronic axial pain in 15% to 30% and 10% to 15% of cases, respectively. In a porcine study by Indahl and coworkers, the authors determined that there is significant overlap between the neuromuscular connections of the intervertebral disks, zygapophyseal joints, and paraspinal muscles such that the relative contributions of each of these

Figure 65.3  Anteroposterior (A) and lateral (B) fluoroscopic annulograms at L5-S1. A, Anteroposterior diskogram showing annular injection at L5-S1. B, Lateral diskogram showing annular injection at L5-S1.
paraspinous structures to LBP may be difficult to estimate. One may thus conclude that in many patients with chronic LBP, the cause of the pain is multifactorial.

The prevalence of discogenic LBP varies widely in the medical literature. In one of the most cited studies, Schwarzer and colleagues found the incidence of discogenic pain to be 39% in a prospective cross-sectional study using either zygapophyseal joint blocks or diskography in 92 consecutive patients with chronic LBP. The authors based their diagnoses on exact pain reproduction during provocative disk stimulation, coupled with abnormal findings on CT-diskography and the presence of an adjacent, negative control disk. Collins and associates conducted a prospective study comparing the use of MRI and diskography in the evaluation of 29 patients with unremitting axial LBP without focal neurologic deficits. The authors found exact reproduction of the symptoms to be present in 13 disks in 12 patients, for a prevalence rate of 41%. In all 13 symptomatic disks, both MRI and diskography showed degenerative changes. In another study comparing the results of MRI and diskography, Horton and Daftari performed 63 diskograms in 25 patients with nonradicular LBP. Diskography yielded moderate to severe pain at 26 levels, with 19 patients reporting similar or exact pain reproduction, for a prevalence rate of 76%. Only 1 of the 26 disks was morphologically normal. Long and colleagues conducted a very large epidemiologic study in 2374 patients with LBP seen by spine surgeons at seven academic medical centers. Final diagnoses were rendered after imaging studies were reviewed and treatment prescribed, with tests and therapies being performed at the discretion of the surgeon. Nonherniated degenerated disk was the final diagnosis in 6.1% of patients. Finally, in a retrospective analysis of clinical data from 127 patients with axial LBP who failed facet interventions, Cohen and coauthors reported a prevalence of 65%. Based on the conflicting evidence that does exist, discogenic LBP appears to be the major source of pain in more than a third of patients with chronic axial LBP. Whereas younger and middle-aged people with axial LBP are more likely to have disks as the principal source of their symptoms, the facet joints become more important as pain generators in the elderly.

### CORRELATION WITH RADIOLOGIC STUDIES

There is compelling evidence that diskography, even without CT scanning, may overestimate the prevalence of clinically significant IDD, but it is equally clear that diskography may fail to detect the disk pathology seen with other radiologic studies. In a study by Gibson and associates in which MRI and diskography were compared in making the diagnosis of DDD, agreement between the two techniques was found in 44 of the 50 disks studied. In the six disks in which a discrepancy occurred, evidence of IDD was missed on five diskograms and one MRI study. In the five cases in which diskography failed to detect disk pathology, two were due to incorrect placement of the diskography needle in the annulus. Although disk stimulation symptoms were recorded in the study, the results of diskography were based only on radiographic findings.
Yoshida and coworkers sought to investigate the relationship between plain diskography and T2-weighted and gadolinium-enhanced T1-weighted MRI in 23 patients with chronic LBP. A posterior annular tear was detected in 16 of the 17 positive disks with T2-weighted MRI and in 10 of 14 positive disks with gadolinium-enhanced T1-weighted MRI. The T2-weighted study also detected 11 annular tears in 39 negative disks versus 8 annular tears in 32 negative disks with T1-weighted gadolinium-enhanced MRI. The sensitivity, specificity, positive predictive value, and negative predictive value of the T2-weighted study in detecting symptomatic disks were 94%, 71%, 59%, and 97%, respectively, which compared favorably with the T1-weighted images. The authors concluded that the high sensitivity and negative predictive value of T2-weighted MRI make it a useful screening tool to avoid unnecessary diskography in patients with chronic LBP.

Simmons and coauthors compared CT-diskography with MRI in 164 patients with chronic LBP, with or without radicular symptoms. Correlation between the two techniques was seen in 55% of cases. In the 371 disks in which MRI and diskography were concordant, 172 were normal and 199 were abnormal. In the disks classified as abnormal based on MRI, 37% were asymptomatic during injection. In 13% (n = 60) of the disks, findings on MRI were abnormal but diskograms were normal. In 7% of the disks (n = 34), MRI showed normal and diskography showed abnormal findings. In 21 of these 34 disks, injection of contrast material into the disk elicited exact pain reproduction.

In a comparative study evaluating MRI and diskography in patients with axial LBP, Collins and colleagues found that imaging characteristics for the two diagnostic procedures correlated in 65 of 73 disks (89%). In the other eight cases, four disk levels showed evidence of early degeneration on diskography but appeared normal on MRI, whereas four disks showed decreased signal intensity on T2-weighted MRI but were diskographically normal. In the 12 patients with concordant pain on diskography, spinal fusion was performed. At their 9-month follow-up, 9 of the 12 patients reported clinical improvement.

Aprill and Bogduk performed CT-diskography on 41 patients with chronic LBP who demonstrated a high-intensity zone (HIZ) on T2-weighted MRI. In all patients, CT-diskography revealed either a grade 3 or 4 annular disruption in the affected disk. The sensitivity and specificity of an HIZ for detecting similar pain reproduction during disk provocation were 63% and 97%, respectively. For detection of exact pain reproduction, the sensitivity was 82% and the specificity 89%. In the identification of a grade 4 annular disruption, the sensitivity of an HIZ was only 54%, but the specificity was 89% and the positive predictive value 90%.

Other studies have shown a much stronger correlation between MRI and diskography, Linson and Crowe found the two investigative modalities to be in agreement on 91 of 97 disks studied in 50 patients. In the six disks in which a discrepancy was present, five were read as normal by MRI but abnormal by diskography. In an earlier study by Schneiderman and coworkers, MRI and diskography positively correlated in 100 of 101 levels.

However, not all studies have demonstrated a high degree of correlation. Zucherman and associates reported positive diskography in the face of normal MRI findings in a case series involving 18 patients. Horton and Daltari conducted an observational study involving 25 consecutive patients and 63 disks studied by diskography and MRI. Abnormal diskographic morphology was noted in 42 of 59 cases, but only 23 disks were associated with significant pain. In dark disks, disk stimulation provoked pain in 7 of 11, but 0 of 5 “white” bulging disks were positive. Because of these discrepancies, the authors concluded that both MRI and diskography should be used for surgical planning. Finally, in a retrospective study of 55 consecutive patients who underwent both provocative diskography and MRI, Sandhu and colleagues found poor correlation between the vertebral end plate signal changes observed on MRI and the results of provocation diskography.

Overall, diskography appears to be comparable or slightly more sensitive for the detection of IDD than MRI or CT does, especially with regard to radial annular fissures. Approximately 25% of moderately degenerative disks identified on MRI will fail to have concordant pain on diskography. The main problem with correlative studies is that when an incongruity exists, it is impossible to determine whether the discrepancy is due to a lack of sensitivity (false negatives) or specificity (false positives) in one of the diagnostic procedures (Table 65.4).

**EFFECT ON OUTCOMES AFTER SPINAL FUSION**

The value of spine surgery in treating DDD and axial LBP is a subject that has engendered passionate controversy in the medical and lay literature. Even though the operative results of spinal arthrodesis vary greatly, depending on the success criteria and follow-up period, it is widely acknowledged to be less beneficial than surgery for radicular pain, with success rates ranging from less than 50% to higher than 80%. Moreover, these reported outcomes must be considered in light of the fact that no fusion studies have ever been conducted under strictly controlled conditions. A recent Cochrane database review concluded that there was no scientific evidence supporting any form of surgical decompression or fusion for the treatment of DDD. Among the four randomized studies comparing lumbar fusion with conservative care, only one demonstrated significant benefit at 2-year follow-up. This study has been criticized because the patients allocated to nonsurgical treatment had essentially already failed most of these treatments and the improvements in pain (33%) and function (25%) were modest. The presence of concomitant pain sources in most patients with discogenic pain and the mixed clinical outcomes even when arthrodesis is technically successful are factors that must be considered when evaluating clinical studies examining the correlation between the results of diskography and surgical outcomes.

Several investigators have attempted to correlate the results of diskography with surgical findings and outcomes. Colhoun and colleagues evaluated the surgical outcomes of 162 patients who underwent preoperative diskography for axial LBP. In the 137 patients with concordant pain on diskography, 89% had a favorable outcome at a mean follow-up period of 3.6 years. In the 25 patients whose disks showed morphologic abnormalities but elicited no provocation of symptoms, only 52% reported significant benefit. Diskography in this study was not accompanied by manometry, and the surgical treatments evaluated were mostly spinal fusions.

“Diskography” refers to diskograms performed without CT scanning.
APCD, automated pressure-controlled diskography; CT, computed tomography; DDD, degenerative disk disease; HIZ, high-intensity zone on MRI; HNP, herniated nucleus pulposus; LBP, low back pain; MRI, magnetic resonance imaging.
Esses and coworkers conducted a prospective study examining the role of external spinal fixation in predicting the success of spinal fusion in patients with chronic LBP. Thirty-two of the 35 subjects underwent provocative diskography before placement of a fixator. Neither diskographic findings nor reproduction of the patients’ pain predicted the results of external fixation or fusion. Even in patients with normal-appearing disks or without pain reproduction during disk injection, most improved with both procedures.

Derby and coauthors published a retrospective analysis investigating the predictive value of categorizing positive diskography findings on surgical outcomes in 96 surgical candidates with chronic LBP. Patients with anterolisthesis, local protrusion, or disk extrusion were excluded; those with previous surgery were not excluded. In patients with chemically sensitized disks (i.e., concordant pain at ≤ 15 psi above opening pressure, n = 36), success rates were higher (89%) for interbody/combined fusion. In patients who underwent posterior intertransverse fusion, only 20% had a favorable outcome.

Madan and associates conducted a retrospective analysis aimed at determining the predictive value of provocative diskography on surgical outcomes in 73 patients with chronic LBP. The first 41 patients in this series underwent circumferential arthrodesis without preoperative diskography, with the last 32 patients undergoing surgery only if their pain was reproduced during disk provocation. In the diskography group, 75.6% of the patients had satisfactory outcomes at a minimum 2-year follow-up versus 81.2% in the group that did not undergo preoperative diskography. Manometry readings were not considered a criterion in the interpretation of diskography results, and treatment outcomes were based on a modified Oswestry scoring system.

Carragee and colleagues conducted a prospective observational study of 32 patients with nonradiicular LBP to investigate whether provocative diskography with strict criteria can be used as a reference standard to identify a single painful disk. Generic surgical limitations were controlled for by comparing clinical outcomes in those with a single positive diskogram and in a matched cohort of 34 patients with unstable single-level lumbar spondylolisthesis. The proportion of patients who met the “minimal acceptable positive outcome” (pain score of ≤2, minimal disability, no opioids, and return to work) was 91% in the spondylolisthesis group versus 43% in the presumed discogenic pain group. Although the authors concluded that diskography was not accurate in identifying isolated painful disk lesions, a more likely interpretation is that fusion done for IDD benefits only a small percentage of patients. Another major limitation of this study is that the authors compared two different conditions.

Willems and coauthors published a prospective observational study that aimed to determine whether the presence of “adjacent segment disease,” as identified by provocative diskography, had an impact on the clinical outcome of lumbar fusion in patients with chronic LBP. In 197 patients with an equivocal indication for lumbar fusion, the decision to either perform lumbar fusion or manage the patient conservatively was decided by a trial of temporary external fixation. During the diagnostic workup, all patients underwent provocative diskography that included disks adjacent to the intended fusion levels. In the 82 patients who underwent lumbar fusion, there was no difference in outcome between those with degenerative disks adjacent to the fusion and those with normal adjacent disks.

Finally, Ohtori and colleagues studied 42 patients with axial LBP in a randomized trial comparing the predictive value of provocative diskography with that of analgesic diskography, a controlled infusion of local anesthetic into the disk for the purpose of identifying symptomatic disks. Despite being underpowered, the 15 patients who underwent fusion based on anesthetic diskography had superior outcomes to the 15 who underwent fusion based on provocative diskography.

In summary, the lack of strong evidence for the use of fusion to treat DDD and the methodologic flaws in the existing studies make the interpretation of data exceedingly difficult. For the existing data, the results are conflicting regarding whether preoperative diskography improves fusion outcomes in patients with discogenic LBP. The results of studies evaluating diskography as a predictive tool for surgery are presented in Table 65.5.

**CORRELATION WITH INTRADISCAL ELECTROTHERMAL THERAPY AND DISK REPLACEMENT SURGICAL OUTCOMES**

The advent of new treatments for discogenic LBP such as intradiscal electrothermal therapy (IDET) and total disk replacement surgery has generated significant interest in the medical community. As a minimally invasive treatment for discogenic pain, the reported outcomes with IDET vary widely and range from minimal benefits to an almost 80% success rate. Of the two published placebo-controlled studies, one reported modest improvement in both pain and disability scores, whereas the other failed to show a statistically significant difference from sham IDET. Overall, the majority of studies report improvement rates in the 50% range in carefully chosen candidates. Since all published studies have used preprocedure diskography as a screening test for IDET candidates, it is not possible to determine the effect that diskography has on outcomes.

There have been numerous attempts dating back to the 1950s to design implants aimed at functional reconstruction of a spinal segment. The concept of disk arthroplasty was first put into clinical use in 1966 by Fernstrom, who described using a stainless steel ball as a vertebral spacer to restore lost disk height and preserve motion. Disk replacement surgery has been used in Europe as a treatment of DDD since the 1980s but has been approved in the United States only since 2004 for single-level DDD. The reported success rates in these studies vary from around 50% to greater than 80% improvement at medium-term follow-up (Table 65.6).

The studies evaluating disk replacement surgery are almost equally divided between those that have routinely used preoperative diskography as a screening test and those that have not. Unfortunately, methodologic flaws in these uncontrolled studies, wide variability in outcome criteria, and the absence of any direct comparisons between patients who underwent preoperative diskography and those who did not preclude any meaningful conclusions from being drawn. Taken in this limited context, the use of diskography as a screening tool before disk replacement surgery does not seem to improve outcomes over choosing patients based solely on MRI and clinical findings.

ANALGESIC DISKOGRAPHY

In the past 10 years there has been kindled interest in the role of analgesic diskography as a more robust means of detecting which disks may be contributing to a patient’s LBP. The rationale behind analgesic diskography is that using pain relief provided by the intradiscal administration of local anesthetic as the reference standard for a positive test rather than pain provocation could reduce the false-positive rate. This is consistent with the diagnostic tests used to identify painful facet and SI joints.

DePalma and coauthors published a retrospective analysis examining whether painful annular fissures during provocative diskography were the source of LBP. After injecting 0.8 mL of 4% lidocaine into the disks of a cohort of 28 patients, 50% or greater pain relief occurred in 80% of positive disks based on provocative diskography.

There has been some debate regarding which painful disks are more prone to a positive response with analgesic diskography. In 2007, Bartynski and Rothfus evaluated intradiscal lidocaine administration after provocative lumbar diskography by comparing disks that retained contrast material (n = 82) with those in which contrast material was extravasated (n = 100). In disks with a nonfunctional annulus that extravasated contrast material, 74% demonstrated complete or nearly complete pain reduction versus only 20% of disks with a functional annulus. Possible explanations for this finding include greater distribution throughout the annulus via fissures in the disks that demonstrated extravasation and “false-positive” pain relief in the leaky disks secondary to inadvertent epidural spread of contrast material.

Alamin and colleagues compared clinical outcomes after analgesic and provocative diskography in a prospective clinical trial of 41 patients with LBP. After a positive provocation diskogram, a catheter was placed in the proposed painful disk or disks and local anesthetic was administered. A positive analgesic result was defined as 50% or greater pain reduction following painful movements. Seventeen percent of patients with two-level findings on provocation diskography had only one positive level with analgesic diskography, and 27% with pain during disk stimulation had a negative analgesic test. Fifty-one percent had corroborating results between provocative and analgesic tests. In 49% of patients the results of analgesic diskography changed the plan of treatment that would have been developed with the results of provocation. Those with a changed treatment plan had improved Oswestry Disability Index and visual analog scale scores over a 6- to 24-month follow-up.

Alamin and colleagues later performed a follow-up cohort study investigating the difference between provocative diskography and functional analgesic diskography in 52 patients with LBP. Forty-six percent of the patients experienced discordant results between the two tests, with 26% having positive provocation diskography and a negative analgesic test, 16% of individuals having single-level findings on analgesic testing versus two or more positive levels with provocation testing, and 4% of individuals having new positive findings on analgesic testing after negative provocation diskography.

As discussed earlier, Ohtori and coauthors published a randomized study comparing fusion outcomes in 42 patients who underwent either provocative or analgesic diskography. At the 3-year follow-up in the 30 patients who proceeded to surgery on the basis of positive diskography, those who underwent analgesic diskography had lower pain scores and less disability. Not all studies have shown superior outcomes with analgesic diskography. Derby and associates investigated 70 consecutive patients with LBP who underwent either provocative (n = 23) diskography or provocation in conjunction with analgesic (n = 47) diskography. The authors found that adding local anesthetic to provocative diskography did not affect the number of positive results (73.9% in the provocation-only group vs. 70% in the combination group). The average subjective pain relief 15 minutes after the procedures also did not differ significantly between the two groups.

The main problems with analgesic diskography revolve around inconsistencies in its use and the potential for accelerated disk degeneration as a result of the larger needles required for insertion of the catheter or catheters. Because of the lack of vascularity within the disk, the duration of analgesia following intradiscal injection of local anesthetic may be prolonged and variable. In a randomized controlled study, Simmons and coauthors reported that only 9% of patients experienced significant pain relief 10 to 14 days after injection. However, Kotilainen and colleagues reported that two thirds of patients obtained pain relief 2 weeks following intradiscal bupivacaine administration.

In individuals with suspected multilevel disease who do obtain prolonged benefit after the first disk injection, evaluation of subsequent disks at the same visit would not be possible. Although the conceptual appeal and early reports of analgesic diskography are encouraging, further studies are needed to determine the true clinical utility of the test.

DISKOGRAPHY VERSUS BONY VIBRATION TEST

The main argument for diskography is that it is the only test available that correlates symptoms with pathology. In an attempt to find a less invasive replacement for diskography, Yrjämä and Vanharanta devised the bony vibration test (BVT) whereby a blunt, vibrating object such as the shaft of an electric toothbrush is compressed against the skin overlying successive spinous processes to provoke pain. In the pilot study conducted in 57 patients with LBP, the authors found the sensitivity and specificity of BVT to be 0.71 and 0.63, respectively, in comparison to provocative diskography. When patients with failed back surgery syndrome and painful disk herniations were excluded (n = 40), the sensitivity increased to 0.96 and the specificity to 0.72. The difference in accuracy resulted from the finding that the prolapsed lumbar disks that provoked pain during diskography were almost always painless during vibration testing. In two follow-up studies comparing BVT findings with MRI and CT-diskography, the authors found similarly high sensitivity and specificity when patients with previously operated backs and complete annular tears were excluded.

In an attempt to combine vibration provocation with noninvasive imaging capability, Yrjämä and colleagues added ultrasonic disk imaging to vibratory stimulation in the evaluation of 38 patients with chronic LBP. In the 26 patients in whom pain was provoked during diskography, BVT was painful in 17; in the 12 with negative diskography, BVT was painless in 7. However, in the 14 patients in whom annular
fissures were present, the combination of ultrasound and vibration testing yielded only one “false-positive” and one “false-negative” result in comparison to diskography. To date, the findings of Yrjämä and colleagues have yet to be replicated by other authors, and no studies correlating vibration provocation with surgical outcomes are available.

COST-EFFECTIVENESS

Several third-party payers have recently opted to decline reimbursement for diskography despite evidence that this test is one of the most cost-effective screening tools available. Anterior or anterior-posterior lumbar fusion with rehabilitation costs an average of $61,000, and diskography costs an average of $3400; the rate of positive diskography is 42%. Assuming that all patients with negative diskography do not undergo spinal fusion whereas those with a positive diskogram do proceed to fusion, the use of diskography with its existing flaws has the potential to save approximately $32,000 per patient. This is, of course, overly simplistic because many patients will require ongoing nonsurgical treatment. Nonetheless, this simple calculation emphasizes the need for an effective screening test to eliminate unwarranted surgical intervention in those with discogenic pain.

Cost-effectiveness is an artificial construct in that variations in one parameter can dramatically affect the conclusions that one can draw. For example, should the cost of diskography increase or spinal fusion decrease or either short-term (e.g., diskitis) or long-term (e.g., disk herniation) complications develop after disk stimulation, the cost savings per patient will decrease accordingly. Experienced spine surgeons are also less likely to refer “poor surgical candidates” for screening than inexperienced surgeons are, so the higher positive diskography rate will result in less cost savings per patient.

STANDARDIZATION OF DISKOGRAPHY

Several important variables should be assessed during diskographic examination, including the volume of contrast agent injected, the degree and pattern of pain provocation, morphologic changes in the disk, and the pressure at which pain is elicited. One criticism of diskography is that except for the volume injected and radiologic findings, all other parameters depend on the pain response of the patient. Pain is always subjective, and what one person considers painful may be innocuous to another. In an attempt to standardize diskography, several investigators have sought to objectify the criteria for positive diskography. In their prospective studies in asymptomatic patients, both Walsh and coworkers and Carragee and colleagues used a 0 to 5 pain-related behavior scale that was subsequently correlated with pain intensity and disk morphology. In the Walsh study, disparities between reported pain and pain-related behavior occurred in 6 of 51 disks, with all cases involving patients reporting significant pain (≥3/5) in the absence of corresponding pain behavior (≤2/5 actions). In the three combined Carragee studies, the agreement between pain behavior and numerical pain score was higher than 90%. In both investigations, the authors videotaped the pain response for further review.

Stojanovic and associates performed a prospective analysis of diskography-associated changes in heart rate in 26 patients with 75 diskograms. The authors found that positive diskograms were associated with greater changes in heart rate than were diskograms that elicited no pain or noncordant pain, with all positive disks exhibiting pathologic radiographic changes. When greater than a 3-beat/min increase from baseline was used as the cutoff value, the sensitivity of the heart rate response was 85% and its specificity 100%. The rationale for the use of heart rate changes and pain behavior to validate the reported pain response is based on numerous studies showing both variables to be valid indicators of pain perception.

The problem with the use of secondary variables to corroborate interpretation of diskography is that even though they may be useful in identifying the small subset of patients in whom secondary gain issues and extensive psychological overlay contribute to self-reported pain scores, their effects on treatment outcomes remain unknown.

Although numerous investigators have used manometry during disk stimulation, the use of discrete cutoff values as a reference standard for what constitutes a positive test has been surprisingly scarce. In 1999, Derby and colleagues introduced a three-tiered system whereby concordant pain of 6/10 or greater in severity at less than 15 psi above opening pressure was designated to be a “chemically sensitized disk,” concordant pain of 6/10 or greater in intensity at between 15 and 50 psi above opening pressure was considered a “mechanically sensitive disk,” and concordant pain between 51 and 90 psi was termed indeterminate or normal (Table 65.7). In a retrospective analysis, intermediate-term (mean of 16 months) outcomes were assessed in 96 patients who were treated either conservatively or by spinal fusion. No differences in outcomes were found between patients who underwent interbody/combined fusions and those who received intertransverse fusions across the entire sample. However, subgroup analysis found that patients with chemically sensitized disks who underwent interbody/combined fusions experienced better outcomes than did those who underwent intertransverse fusions. One serious flaw in this diagnostic scheme is that it does not control for baseline differences in pain between patients. Thus, a diskogram that provokes 5/10 in a patient with incapacitating 4/10 baseline pain would be considered negative, whereas a diskogram that provokes 6/10 pain in a patient with 10/10 baseline pain would be positive. A second problem is that significant numerical differences may exist between manometric systems, so a scale developed for one system may not be valid when used in a different system. Factors that may affect the accuracy of diskography are listed in Table 65.8.

PERFORMING DISKOGRAPHY

PATIENT PREPARATION

A detailed history and physical examination should always be performed before the procedure. It is the responsibility of the diskographer to review all pertinent information, including preprocedural laboratory tests, electromyograms, plain films, and MRI scans. It may be helpful to record a description of the pain symptoms or create a pain diagram for reference during the procedure. Although the diskographer reports the final diagnostic conclusions, it is the patient who ultimately communicates the provoked symptoms and their degree of concordance with the typical pain. Patients who have a difficult time describing their typical pain syndrome may have an equally difficult time describing the provoked symptoms. Indications for diskography
have previously been outlined in numerous guidelines and reviews\(^ {107,127,205,212-221} \) and include the following:

1. Evaluation of patients with unremitting spinal pain, with or without extremity pain, of greater than 3 months’ duration that has been unresponsive to appropriate conservative therapy.
2. Patients with severe, persistent, severe symptoms in whom other diagnostic tests have failed to reveal clear confirmation of a suspected disk or disks as the source of the pain.
3. Evaluation of persistent pain in a postsurgical patient whose symptoms may be arising from intervertebral disk degeneration, recurrent herniation, or pseudoarthrosis of a spinal fusion.
4. To determine the number of levels to be fused in spinal surgery or the primary symptomatic disk level.
5. To determine whether levels adjacent to a planned spinal arthrodesis are either normal or painful.
6. To diagnose lateral disk herniations.
7. If the patient prima facie satisfies the criteria for intradiscal treatment. In these cases, CT-diskography may be undertaken to assess disk morphology and determine the optimal placement (if any) of the device (e.g., IDET electrode).
8. For assessment of candidates for minimally invasive surgical decompression to confirm contained disk herniations or to investigate the distribution of dye before chemonucleolysis or other percutaneous decompression procedures.

</table>

At our institutions, before the start of the procedure we review the MRI studies to identify levels with decreased signal intensity on T2-weighted images, increased signal consistent with an HIZ, decreased disk height, or other evidence of degeneration with the idea that we will probably inject all abnormal levels. This notion is supported by studies showing that even though MRI is sensitive in identifying disk pathology, it is less accurate in detecting the pattern of disk morphology.118,123

Previous ISIS guidelines recommended that two control levels be obtained for optimal interpretation of disk stimulation.107 However, given the inherent risks associated with diskography, most authors have not adhered to these stringent guidelines.127,205,222 At our institutions we consider one adjacent, unequivocal negative disk adequate for control purposes. For the most commonly symptomatic L5-S1 disk, only one adjacent control disk is possible.

Preparation of the patient for disk stimulation begins with the initial visit before diskography. It is during this time that the patient is briefed on what to expect during the procedure. Patients must realize that diskography is performed for diagnostic information rather than therapeutic benefit. Some patients may be surprised to learn that the short-term goal of diskography is pain provocation rather than analgesia. They should be familiar with use of the pain scale that will be used during the procedure and be prepared to note whether the pain induced by diskography is concordant with or dissimilar to their typical pain.

Absolute contraindications to the procedure include patient refusal, inability to adequately report their response to the procedure, untreated localized infection, untreated coagulopathy, and pregnancy. Relative contraindications include allergy to the contrast medium, local anesthetic, or antibiotics; systemic infection; and anatomic derangements that preclude safe, successful conduct of the procedure.

**PROCEDURAL PREPARATION**

The operative suite should be equipped with oxygen, emergency medications, and all appropriate monitors. It is our practice that all individuals in the procedure room wear caps and masks and that the operators wear sterile gowns and gloves, as is routinely practiced with open surgical procedures. Whereas ISIS recommends draping the entire patient, as well as the image intensifier and remote console,223 other diskographers create only a small sterile field.

Diskographers vary in their use of sedation. Many different methods of sedation have been described, from none at all to benzodiazepines alone and in various combinations with opioids.127,224 If used, sedation should be aimed toward relieving anxiety and promoting tolerance to the procedure without compromising the patient’s ability to assess symptoms. Excessive use of sedation increases the risk for false-positive results, neurologic injury, and other complications.

Because of the possibility of inadvertent intrathecal administration, only nonionic contrast material should be injected. Nonionic dye also minimizes the risk for allergic reactions, which may be delayed until the contrast material is systemically absorbed from the disk. In patients with known previous contrast reactions, premedication is necessary. Some diskographers use no contrast or contrast only to confirm placement of the needle in the NP and inject saline to elevate intradiscal pressure. Another option is to use gadolinium as the contrast agent.225

**NEEDLE PLACEMENT**

Diskography is an invasive procedure that should be performed only by experienced clinicians. ISIS recommends that anyone performing this procedure should have extensive experience with less technically challenging interventional procedures such as facet blocks. There are numerous different ways to perform this procedure,127,205,222,223,226-228 but this section describes only one (Figs. 65.4 and 65.5).
Image guidance for needle placement is ideally achieved with C-arm or biplanar fluoroscopy. Interspinous and interlaminar approaches have been advocated following fusion with a paraspinal bone graft but are otherwise rarely used because of the necessity for penetration of the dura. Patients can be placed in the left lateral decubitus or prone position. In the prone position, the side of approach is usually determined by the preference of the diskographer unless unilateral pathology or anatomic obstacle is suspected. Though recommended by some authors, we have shown that an approach from the side ipsilateral to a patient’s symptomatology does not affect the rate of false-positive diskograms.

Assuming prone positioning, craniocaudal angulation is adjusted so that the imaging beam parallels the disk space at selected levels. This can be done by lining up the image so that the x-ray beam passes parallel to the subchondral border of the inferior vertebral end plate of the disk. The C-arm is then rotated laterally until the superior articulating process of the lower vertebra is positioned just posterior to the geometric center of the disk. After superficial injection of local anesthetic, an 18-gauge introducer needle is advanced lateral to the superior articular process, preferentially at the midpoint of the superior-inferior margin of the disk (see Fig. 65.4). At this point the fluoroscope is changed from an oblique to a lateral view. A 22- or 25-gauge (150 mm) diskography needle is advanced through the introducer needle into the annulus. The annular fibers provide a firmer feel than do the nucleus and surrounding soft tissue. The needle is then advanced through the annulus until it is situated halfway between the anterior and posterior borders of the disk. The tip of the needle should remain close to the midpoint of the superior-inferior margins of the disk because injection into the end plates can result in a false-positive response. When the needle is satisfactorily positioned on lateral imaging, the fluoroscope is rotated to an anteroposterior view, where the final needle position in the middle third of the disk should be confirmed. If the needle has not passed far enough on the anteroposterior view, the skin entry point was too medial; if the needle has passed clear to the opposite side of the disk, the entry point may have been too lateral. In a normal disk or mildly degenerated one, central needle placement is necessary to avoid injection into the richly innervated AF, which may result in a false-positive diskogram.

At L5-S1, the iliac crests often prohibit use of a needle trajectory aimed directly at the center of the disk. Entry into this level is subject to higher failure rates, which may be substantially reduced by using a curved needle technique. Identification of the target at this level begins with a sharp, caudal angulation of the beam that passes parallel to the subchondral plate of the inferior end plate of the disk. At this point the C-arm is rotated laterally until either the superior articulating process of the S1 vertebra is positioned just posterior to the geometric center of the disk or the iliac crests begin to encroach on the target point. Usually, a small triangular window can be appreciated that is bordered laterally by the iliac crest, medially by the superior articular process, and superiorly by the subchondral border of the superior end plate. Once the entry point is identified, an introducer is advanced toward the lateral margin of the superior articulating process of S1 and walked off just beyond its edge. The C-arm is then positioned in the lateral view. Especially at L5-S1, it is important to adjust the angulation of the camera so that the superior and inferior end plates appear sharp and are discernable. A diskography needle is then bent slightly about 1 cm from its tip and advanced through the introducer until it meets the outer edge of the annulus. A bend may facilitate steering the needle around bony obstacles and, with proper rotation, may promote more central placement. As the needle is advanced toward the edge of the disk, it is not uncommon to have the patient experience paresthesias. If this occurs, either the needle is withdrawn and an approach is made at a different angle or the position of the introducer is moved superiorly or inferiorly. As for the upper disks, the final needle position for L5-S1 should ideally be in the middle third of the disk, but it is not unusual at this level for it to end up in a more peripheral location.

**DISK STIMULATION AND INTERPRETATION**

After all needles have been positioned properly, the patient is prepared for the injection. If patients are still experiencing persistent effects of sedation, it is prudent to wait until they are more awake and answering directed questions. Patients should be questioned again regarding their pain level while care is taken to ensure that they can distinguish residual procedural pain from their typical pain. They should be able to respond appropriately to questions pertaining to the quality, intensity, location, and concordance of the provoked pain, which will provide critical diagnostic information.

Responses may be more reliable if the patient is not informed that an injection is occurring. The patient should also be blinded to the level of injection. The sequence of disk injection depends on the diskographer’s expectation for provocation of pain at each level. Once severe pain is produced, the patient may be less able to tolerate or judge subsequent injections. Therefore, the level considered likely to cause the most intense pain should be injected last.

One modification that is occasionally used is for the diskographer to be blinded to the MRI findings. Although this may remove physician bias from the equation, it can interfere with proper disk selection and the optimal sequencing of injection. After injecting all levels, it is sometimes necessary to confirm the initial reactions by injecting levels a second time.

Verbal and nonverbal reactions, including facial expressions, should be closely monitored and recorded on a diskogram worksheet (Box 65.1). Besides pain response, other data that should be recorded include the total volume of contrast agent, injection end point (reason why the injection was stopped), and nucleogram appearance. Normal disks take less than 1 mL of contrast agent before firm resistance is reached (high-pressure end point). Degenerated disks generally accept larger volumes of contrast and demonstrate moderate or low resistance to injection (low-pressure end point). When the disk communicates with the epidural space because of complete annular disruption, higher (or unlimited) volumes can be injected with little to no resistance (volume end point). When severe symptoms are provoked, the injection should be stopped even if minimal contrast agent has been injected (pain end point).

Injection pressure can be measured with specialized commercially available devices, which is recommended by ISIS. Proponents of manometry state that a pressure-recording
device allows objective designation of painful disks as either chemically or mechanically sensitive. Others have not endorsed the use of these devices and claim that an experienced diskographer can determine relative pressure with only a syringe. To date, no studies have evaluated the effect that manometry has on surgical outcomes or diskographic results. However, it is our opinion that the proper use of manometry can both enhance the accuracy of diskography and reduce the likelihood of inadvertent disk injury. Any bodily structure containing mechanoreceptors, whether diseased or normal, can be a source of pain when subjected to excessive pressure. This effect can be even more pronounced when the pressure is elevated too rapidly, thereby resulting in false-positive diskograms. Conversely, if pressure cannot be generated in a severely degenerated disk because of annular incompetence, a diskogram may be mistakenly interpreted as negative. An additional benefit of pressure measurement is that it alerts the diskographer to the presence of control disks. If none is obtained, the procedure is nondiagnostic.

**Data Collection for Diskography**

- Technical success of the procedure (are the needles positioned properly?)
- The pressure observed when contrast agent is first visible in the disk (opening pressure)
- The pressure at which pain is first noted
- The amount of contrast agent injected (maximum volume)
- The maximum pressure noted (peak pressure)
- Injection end point (reason why the injection was stopped):
  - High-pressure end point (firm)
  - Low-pressure end point
  - Volume end point
- Pain end point
- The pattern of contrast distribution (e.g., diffuse, fissuring, posterior or anterior, right or left, extravasation into the epidural space)
- The pain response. Where does it hurt? Is it identical, similar, or different in location and character from your typical pain? On a 0 to 10 rating scale, how do you rate the intensity? This pain score must be taken in the context of the preinjection pain score
- The presence of control disks. If none is obtained, the procedure is nondiagnostic

opening pressure, the disk is considered mechanically sensitive, and the diskogram may or may not be positive. If pain is noted at greater than 50 psi above opening pressure, “the response cannot be considered clinically significant.”

Pain at higher pressures may be due to mechanical irritation, end-plate deflection, or stimulation of mechanoreceptors (see Table 65.7). Although numerous diskographic classification systems have been advocated, including some devoid of pressure measurements, no single set of criteria is universally accepted as standard (Table 65.9).

Some authors have advocated videotaping to document patient reactions during disk injections. Videotaped findings are later correlated with fluoroscopy or compared with simultaneous changes in physiologic parameters such as heart rate and blood pressure. If relevant, the videotape can be made available to the referring surgeon.

**IMAGE INTERPRETATION**

For morphologic interpretation of fluoroscopic images, even though plain diskography is clearly inferior to CT-diskography, useful information may nevertheless be garnered from the overall appearance of spread of contrast material. A small central “cotton ball” appearance usually indicates a normal painless disk. Normal disks may also have a central bilobular appearance, like a “hamburger in a bun.” A thin line of contrast that extends to the posterior edge of the disk is consistent with an annular tear, and it is not unusual for patients to complain of pain when the contrast agent moves posteriorly. Small lines of anterior extravasation are sometimes seen but are less likely to elicit pain. More diffuse posterior spread of contrast can indicate a large annular tear. Spread of contrast into the epidural space is consistent with a complete tear of the annulus and loss of integrity of the outer annular wall. Diffuse spread in all directions, with or without spread into the epidural space, is indicative of a severely degenerated disk (Figs. 65.6 to 65.8).

Fluoroscopy can show morphologic differences between normal and degenerated disks but poorly characterizes the locations of annular tears and their relationship to nerve roots. Disk architecture is much better assessed by CT because of its cross-sectional acquisition of thin slices parallel to the disk spaces. Thus, many annular tears seen on CT images are invisible with fluoroscopy. For this reason, we perform procedures requiring a functional annulus, such as percutaneous disk decompression, only after CT-diskography. Contiguous helical CT images enable longitudinal reformations in the identical coronal and sagittal planes obtained with MRI. Coronal and sagittal CT reformations demonstrate the distribution of contrast in relation to both the internal and external annulus, as well as focal contour abnormalities relative to the central spinal canal, lateral recesses, neural foramina, and nerve roots (Figs. 65.9 to 65.11).

The most commonly used terminology of disk disease was adapted for MRI. This terminology is difficult to apply to CT-diskography because it addresses only contour abnormalities, such as disk bulges, extrusions, and sequestrations. Internal disk abnormalities that cannot be detected on MRI become obvious on CT because they are filled with contrast material. On CT-diskographic images, morphologic analysis of disk architecture, including the NP and AF, can be applied to disks with normal MRI contours, as well as to

Interpretation: >70 points is positive, 40-60 points is indeterminate, and <40 points is negative.

1. For each disk studied (see columns), enter the appropriate score for each of the variables indicated (rows).
2. For disks with concordant pain:
   - Enter 30 if the concordant pain is produced.
   - Enter 5 if the pain produced is greater than 5/10.
   - Enter another 5 if the pain produced is also greater than 7/10.
   - Enter 10 if the pressure at which pain occurred is anything less than 50 psi.
   - Enter another 10 if the pressure is also less than 15 psi.
3. For disks at control levels (i.e., not concordant pain):
   - Enter +30 if the disk was painless.
   - Enter −10 if pain occurred at a pressure less than 50 psi.
   - Enter another −10 if pain occurred at a pressure also less than 15 psi.
4. For the concordant disks, add up the scores in each row and record the sum of each row in the column labeled Sum of Rows.
5. Add up the totals of the sums column below the double line while taking care to heed negative numbers.
6. Interpret the results.

**Figure 65.6** Anteroposterior view of a diskogram showing early degenerative changes in the L3-4 and L4-5 intervertebral disks.

**Figure 65.7** Lateral view of normal L3-4 and L4-5 diskograms. The L5-S1 diskogram reveals a partial tear in the anterior annulus that was clinically insignificant.
herniated disks. The Dallas diskogram scale was originally developed to describe and grade annular tears and has subsequently undergone several modifications\(^{127,224}\) (Fig. 65.12). The modified Dallas classification for disk morphology takes into account annular tears, as well as extra-annular contrast leakage and diffuse degenerative changes. In this modified scheme, disk morphology is graded from 0 to 7\(^{127}\) (Fig. 65.13; Box 65.2).

The final interpretation of lumbar diskography should take into consideration not only disk stimulation data and morphology but also less tangible factors such as a patient’s psychological profile, expectations, behavior, and physiologic parameters during pain provocation, as well as potential confounding factors such as secondary gain and return-to-work issues. In a well-chosen diskography candidate, pain is
infrequently reproduced in a disk that is morphologically, manometrically, and volumetrically normal. In the rare instances when this does occur, the diskographer must consider the patient’s clinical picture, including historical and physical examination findings, the presence of spinal and psychological pathology, additional radiologic and diagnostic tests, and the technical success of the diskogram, before deciding on a treatment course.

**POSTPROCEDURAL CARE**

At the conclusion of disk stimulation, disks may be injected with local anesthetic. In a small case series by Kotilainen and colleagues, the authors found that 83% and 67% of patients who received 0.5% bupivacaine intradiscally obtained good pain relief 1 day and 2 weeks after the procedure, respectively. In clinical practice, the amount injected into the disk is largely determined by the disk itself since trying to force fluid into a fully pressurized disk may do more harm than good. Typically, in a degenerative disk with an annular tear, 0.5 mL of local anesthetic should safely help reduce postprocedural pain. It may also be helpful to reanesthetize the track of the needle, but care must be taken to avoid unintentionally anesthetizing a nerve root. Although one retrospective study concluded that intradiscal steroids confer adequate pain relief, two placebo-controlled trials failed to demonstrate any benefit.

</thead>
<tbody>
<tr>
<td>Type 1:</td>
<td>The diskogram is normal manometrically, volumetrically, and radiologically and produces no pain. CT-diskography shows contrast material to be centrally located in both the axial and sagittal projections.</td>
</tr>
<tr>
<td>Type 2:</td>
<td>Identical to type 1 except that it is positive for pain reproduction.</td>
</tr>
</tbody>
</table>
| Type 3: | The annular tears lead to a radial fissure. This group can be further subdivided into the following:  
  Type 3a: The radial fissure is posterior.  
  Type 3b: The fissure radiates posterolaterally.  
  Type 3c: The fissure extends laterally to a line drawn from the center of the disk tangential to the lateral border of the superior articulating process. |
| Type 4: | When the radial fissure reaches the periphery of the annulus fibrosus, nuclear material protrudes and causes the outer annulus to bulge. |
| Type 5: | When the outer annular fibers rupture, nuclear material may extrude beneath the posterior longitudinal ligament and directly contact either the dura or a nerve root. |
| Type 6: | When the extruded fragment is no longer in continuity with the interspace, it is said to be sequestrated. Manometrically, volumetrically, and radiologically, these diskograms are always abnormal. Concordant pain may be reproduced only if enough pressure is generated against the free fragment to cause stimulation of pain-sensitive structures. |
| Type 7: | The end stage of the degenerative process is internal disk disruption, in which multiple annular tears occur. The diskograms are abnormal manometrically and volumetrically, and familiar pain may or may not be reproduced. Radiologically, the contrast material usually fills the entire interspace in a chaotic fashion. CT-diskography shows extravasation of contrast material throughout multiple annular tears. |

COMPlications

Diskitis

Diskitis is the most feared complication of diskography because infection can be extremely difficult to treat as a result of the poor blood supply that intervertebral disks receive. Procedure-related pain is commonplace following diskography, yet any patient who experiences a new neurologic finding or complains of increased pain 1 week after the procedure warrants re-evaluation. At minimum the postdiskography workup should include a focused history, physical examination, and laboratory screening tests. The erythrocyte sedimentation rate (ESR) and C-reactive protein are the most sensitive indicators of diskitis, but elevation does not usually occur until 3 weeks after the procedure.\(^{231,232}\) If the ESR is higher than 50, a bone scan or MRI is needed to rule out diskitis. The most common etiologic agent in postprocedure diskitis is *Staphylococcus aureus*.\(^{232}\)

In a retrospective study conducted in 432 patients, Fraser and colleagues found that the incidence of diskitis was reduced from 2.7% to 0.7% when a through-and-through double-needle technique was used.\(^{233}\) However, a confounding factor when interpreting these results is that no stylet was used during the single-needle technique. A review by Guyer and Ohnmeiss found an overall incidence of diskitis of less than 0.15% by patient and less than 0.08% by disk, with most of the studies included not administering prophylactic antibiotics.\(^{234}\) Osti and associates advocated mixing 1 mg/mL of cefazolin with the injected contrast agent as a safe and effective means of preventing diskitis following a two-part study.\(^{235}\) In the first phase of the study, intradiscal cefazolin was found to be equivalent to parenteral antibiotics administered 30 minutes before the procedure in preventing diskitis in sheep inoculated with intradiscal *Staphylococcus epidermidis*. In the second phase of the study, radiographic or clinical evidence of diskitis developed in 0% of 127 patients following diskography conducted by mixing 1 mg/mL of cefazolin with the contrast material. A recent in vitro study by Klessig and colleagues supports the prophylactic use of intradiscal antibiotics in lieu of systemic therapy for patients undergoing provocative diskography.\(^{236}\)

The administration of prophylactic antibiotics is by no means universal. Willems and colleagues performed a literature review of postdiskography diskitis cases with and without the use of prophylactic antibiotics.\(^{237}\) Inclusion criteria were use of the double-needle technique and stringent reporting of complications and dropouts. Including their own report on 200 patients who underwent 453 diskograms, 11 studies were analyzed, only 1 of which administered prophylactic antibiotics. Among the 4981 patients included in the analysis who did not receive prophylactic antimicrobial therapy, the incidence of diskitis was 0.25% (0.09% of 12,770 diskograms). The authors concluded that there was not enough evidence to support prophylactic antibiotics as a means of preventing diskitis.

A more recent systematic review by Sharma and coworkers concluded that although preclinical animal models support the use of prophylactic antibiotics before iatrogenic disk inoculation, neither intravenous nor intradiscal antibiotics have been conclusively shown to reduce the incidence of infection following diskography.\(^{238}\) Another review conducted by Kapoor and associates for cervical diskography similarly found that the overall evidence for the use of prophylactic antibiotics to prevent diskitis was not definitive.\(^{239}\)

In view of the inherent difficulties in treating diskitis and the fact that no serious complications have ever been reported from the use of low-dose intradiscal antibiotics, the authors believe that the prophylactic use of intradiscal cefazolin or clindamycin is justified in patients (e.g., diabetics, human immunodeficiency virus infection, steroid use) or circumstances that may increase the risk for infection (Box 65.3). Collectively, we have performed more than 8000 diskograms with intradiscal antibiotics and had only a single case of diskitis in a patient with diabetes. If diskitis should occur, the mainstay of treatment is antibiotics and pain control; surgical intervention is not usually necessary. Potential complications of diskitis include epidural abscess, intervertebral fusion, and paralysis.\(^{240}\)

Box 65.3  Antibiotic Prophylaxis Guidelines

**Intravenous**

- Cefazolin, 1 g in 50 mL normal saline 30 to 60 minutes before the procedure or
- Clindamycin (for patients with cephalosporin or penicillin allergy), 900 mg in 50 mL normal saline 30 to 60 minutes before the procedure or
- Ciprofloxacin (for patients with cephalosporin or penicillin allergy), 400 mg in 50 mL normal saline 30 to 60 minutes before the procedure

**Intradiscal**

- Cefazolin, 1 mg (10 mg/mL) either before the start of contrast injection or mixed with the contrast agent or
- Clindamycin, 0.6 mg (6 mg/mL) either before the start of contrast injection or mixed with the contrast agent

**Diskography and the Progression of Disk Degeneration**

A key question surrounding diskography is whether artificial elevation of intervertebral disk pressure can worsen existing LBP or injure the intervertebral disk.

In an experimental biochemical model tested in 113 cadavers, Lencean determined that the amount of pressure required to rupture the annulus was inversely proportional to the degree of degeneration and ranged from 108 to 188 psi.\(^{241}\) However, vigilance should be exercised at all times during disk stimulation because there are many reports of diskography-induced lumbar disk herniation occurring at lower pressures.\(^{242}\)

Careage and associates attempted to answer this question by conducting a controlled, prospective study to examine whether provocative lumbar diskography is associated with long-term low back symptoms in 26 subjects without low back complaints.\(^{243}\) In the 10 patients who were pain free after unrelated neck surgery, none reported persistent LBP 1 year following diskography. In 10 patients with chronic neck or arm pain after cervical spine surgery, 2 reported persistent pain 1 year after diskography. In the six patients with somatization disorder, two thirds (four of six) reported ongoing pain after diskography. In two control groups composed of somatization patients who did not undergo diskography and LBP patients with positive
diskograms but no other nondiscogenic spine abnormalities, no significant change in low back symptomatology was noted during the 1-year follow-up. After a 4-year follow-up study, the authors concluded that painful disk injections and annular disruptions are poor and weak predictors of future low back problems in patients without preexisting low back complaints, respectively.244 Conversely, the authors found psychological distress and preexisting pain complaints not involving the low back region to be stronger predictors of the subsequent development of LBP.

In three studies evaluating the clinical and anatomic sequelae of diskography, Johnson,245 Flanagan and Chung,246 and Saifuddin and coworkers247 all found no evidence that diskography causes damage to intervertebral disks based on repeated diskograms, clinical and radiographic findings, and MRI findings, respectively. Although the study by Saifuddin and colleagues used the reference standard (i.e., MRI) for detecting disk pathology, only a small number of patients (n = 7) were involved, and repeated imaging was done at a mean follow-up period of just 72 days, which may not be sufficient to detect long-term sequelae.

In an effort to better elucidate this issue, Carragee and associates248 performed a prospective, matched-control cohort study to evaluate disk degeneration over a 7- to 10-year period in patients who underwent diskography. The rationale behind this endeavor was that annular puncture has been used for many years as an animal model of disk degeneration,249,250 but little is known about its long-term effects in humans. Seventy-five patients without serious LBP underwent a protocol MRI and L3-4, L4-5, and L5-S1 diskography as part of previous studies designed to identify “false-positive” responders. A matched group enrolled at the same time underwent the same protocol MRI examination. Seven to 10 years after the baseline assessment, subjects underwent a repeated MRI examination. In all measured parameters, disks that had undergone diskographic evaluation demonstrated greater progression of the degenerative findings (35% vs. 14%) and more new disk herniations (35% vs. 15%) than did control (noninjected) disks. Moreover, new disk herniations were disproportionately found on the side of annular puncture. Quantitative measures of disk height and disk signal also showed significantly greater progression in the diskography group. This was the first study of its kind showing that diskography using a small-gauge needle (25 and 22 gauge) with limited pressurization could result in accelerated disk degeneration.

**OTHER COMPLICATIONS**

In a study analyzing 146 lumbar diskograms in 52 patients, Tallroth and colleagues found that 2% of patients experienced nausea, 4% convulsions, and 6% severe back pain during the procedures.251 Ten percent of patients reported severe headache and 81% worsening LBP 1 day after the procedure. The headaches were attributed to neuraxial leakage of contrast material. In a retrospective study assessing complications in 4400 cervical diskograms performed in 1357 patients, Zeidman and coauthors reported a complication rate of 0.6%, or 0.16% of disk injections.292 Adverse events included seven cases of diskitis and one abscess. Prophylactic antibiotics were administered only to patients deemed to be at high risk for infection. Pilet and colleagues reported a patient with worsening pain following diskography in whom herniation through the vertebral end plate (Schmorl’s node) was found to have developed.255 Other possible complications of diskography include meningitis, spinal headache, subdural or epidural abscess, intrathecal and retroperitoneal hemorrhage, arachnoiditis, nerve root injury, paravertebral muscle pain and contusions, postprocedural pain exacerbation, vasovagal reactions, allergic reactions, and damage to the disk, including but not limited to herniation.285,274-279

**CONCLUSION**

Considering the long history of diskography in diagnosing disk pathology and the advent of more advanced imaging techniques, wherein lies the future of disk stimulation? Diskography has already come under scrutiny by third-party payers, with many refusing to reimburse for the procedure. Nonetheless, diskography appears to be a cost-effective screening test in view of the high cost of spinal fusion. Because of the high lifetime prevalence of LBP, which approaches 80% by some estimates, and the fact that various stages of disk degeneration can be detected in a majority of people—even without low back symptoms—it is clear that some sort of test is needed to determine whether a causative relationship exists between the two phenomena. Even though diskography, with or without CT, remains the only imaging tool that ostensibly allows a clinician to relate pathology with symptoms, the value of this test remains unclear.

When assessing diskographic pathology, proponents of diskography argue that it is necessary to correlate provoked pain with anatomic abnormalities. In regard to symptomatic disk herniations, the enhanced accuracy and safety of MRI have rendered plain diskography obsolete for this purpose. For IDD, CT-diskography is a more sensitive diagnostic tool than plain MRI, although T2-weighted MRI may detect some pathology missed with plain diskography. Based on cadaveric studies, diskography seems to be more accurate in identifying radial than transverse or concentric tears in the AF. Disk stimulation studies have consistently found that degenerated disks of all types are more likely than normal disks to provoke pain and that annular disruption seems to be a prominent source of pain generation. However, the significance of these findings is limited by the high prevalence of abnormal features, the fact that in clinical contexts diskography is almost exclusively performed on disks already noted to be abnormal on CT or MRI, and the observation that a substantial percentage of patients with LBP may be at increased risk for “false-positive” diskograms.

As a diagnostic procedure that carries substantial risk, including possible acceleration of disk degeneration in some patients, the critical question that will determine whether diskography remains a viable preoperative screening tool or becomes merely another footnote in history is whether it improves patient outcomes, and presently, evidence for this is lacking. In studies directly comparing fusion outcomes between patients who underwent routine preoperative diskography screening and those who did not, the results are conflicting. For intradiscal procedures targeting discogenic pain, the controversy surrounding its efficacy and the fact that all published studies have consistently used
One point on which there does seem to be consensus is that potential for false-negative results has yet to be determined. Increased risk for iatrogenic disk injury, increased cost, and whether the purported increased specificity outweighs the risk of false-positive pain provocation, symptoms may be prone to false-positive pain provocation. Although anesthetic diskography was developed as a tool to screen patients for an inexperienced surgeon in whom the positive diskography rate may be much higher. This recommendation is also contingent on the results of randomized studies were to be conducted on the benefits of diskography, they would be unlikely to definitively resolve this controversy.

There clearly exists a wide discrepancy in the use of lumbar diskography to treat discogenic LBP. Routine use of diskography as a screening tool before minimally invasive surgical procedures is inconsistent, and the procedure is used sporadically before spinal arthrodesis and disk replacement surgery. After weighing the risks and benefits of diskography, the authors believe that the procedure should be strongly considered before any invasive surgical procedure used to treat discogenic LBP except when the evidence implicating a particular disk or disks as the pain generator is strong or definitive. Consequently, diskography may be more beneficial when screening patients for an inexperienced surgeon than it is for selecting patients for an experienced surgeon, in whom the positive diskography rate may be much higher. Inherent in this recommendation is that the procedure be conducted according to evidence-based standards, which remain the subject of ongoing debate. These standards might include the routine use of manometry, obtaining two adjacent control disks in patients at high risk for “false-positive” pain provocation, performing psychological screening similar to that used routinely before spinal cord stimulation, and requiring at least one objective measure to confirm a positive diskogram, such as a significant increase in heart rate or elicitation of certain facial expressions. This recommendation is also contingent on the results of disk stimulation being considered in the context of other diagnostic screening tests and with the understanding that patients with preexisting psychopathology and somatization symptoms may be prone to false-positive pain provocation. Although anesthetic diskography was developed as a tool to reduce the high false-positive rates in selected individuals, whether the purported increased specificity outweighs the increased risk for iatrogenic disk injury, increased cost, and potential for false-negative results has yet to be determined.

One point on which there does seem to be consensus is that clinical studies are needed to better elucidate the role that diskography will assume in the diagnosis of disk pathology in the future and to determine what effect, if any, it has on the surgical treatment of discogenic LBP.

Intradiscal Procedures for the Treatment of Discogenic Lower Back and Leg Pain

Leonardo Kapural

SUMMARY

Although establishing the diagnosis of lumbar disk herniation with associated leg pain is usually intuitive, diagnosis and treatment of lumbar discogenic pain remain difficult. It may account for one third of patients with lower back pain. The mechanism of this pain is still unclear, clinical presentation can vary, and imaging may be misleading. Provocative diskography remains the only diagnostic test that can correlate changes observed on imaging tests and the patient’s pain, despite questioned validity of provocative diskography as an appropriate diagnostic test.

Percutaneous treatments for discogenic lower back pain emerged in the early 2000s, and these therapeutic approaches seem to be more efficacious and less invasive alternatives to currently available surgical options. They are cost-effective, when compared to surgical approaches, and may cause fewer side effects. However, the true therapeutic value of these therapies has yet to be established. Proper patient selection may significantly improve successes of those minimally invasive treatments, so that fewer patients elect to undergo open spinal surgery.

Percutaneous disk decompression procedures when used as minimally invasive approaches to treat back and leg pain caused by contained disk herniation clinically had generally favorable clinical outcomes and complication rates were low. However, studies with higher level of evidence are lacking.

INTRODUCTION

Frequently cited causes of lower back pain include myofascial, discogenic, facetogenic origins, conditions originating from the sacroiliac joint, compression fractures, and lumbar stenosis.\(^1\)\(^,\)\(^2\) Low back pain is one of the most common causes of lost work time and is becoming a major economic burden.\(^1\) Discogenic pain remains one of the main causes of lower back pain.\(^3\)

This chapter highlights some interesting, novel, and minimally invasive therapeutic interventions, and those procedures should be used as a part of comprehensive, multidisciplinary treatment in order to produce the best results in a patient’s functional capacity and improvements in pain scores.

Intervertebral disk as a pain generator is difficult to evaluate using conventional and conservative methods. Patients frequently describe unrelenting low back discomfort and groin or occasionally leg pain that worsens with axial loading that improves with recumbency. Patients complain of increased pain in their lower back with Valsalva maneuver, prolonged sitting, or driving a car. The signs and symptoms provide a clue to the causative factors so that further steps can be taken to determine an accurate diagnosis.\(^14\) Imaging (e.g., magnetic resonance imaging [MRI]) correlates poorly with clinical findings, leaving open the question of pain causality.\(^14\) One approach to substantiate clinical findings and correlate the patient’s pain to the imaging study is to conduct a provocative or analgesic diagnostic diskography. Currently, this approach is the only diagnostic method to correlate anatomic abnormalities with clinically observed lower back pain. Despite wide clinical use, the diagnostic value of this test has been repeatedly questioned, mainly because of potentially high false-positive rates.\(^2\)\(^7\)

After a provisional diagnosis of discogenic pain has been established, an effective treatment is desired. Several commonly used minimally invasive intradiscal therapies involve careful denervation of the annulus fibrosus (Fig. 66.1). So-called annuloplasty procedures have been clinically used, despite a lack of objective histologic findings of nociceptive fiber denervation or any changes in collagen fiber structure expected after intradiscal heat is used.\(^8\)\(^12\) The minimally invasive approach, low cost, and relative simplicity of these procedures, as well as a short recovery time, are major advantages of annuloplasty procedures when compared to surgical approaches such as lumbar fusion or disk replacement. Intradiscal electrothermal therapy (IDET; Smith and Nephews, London, United Kingdom), DiscTRODE (Valleylab, Boulder, Colorado), and Intradiscal Biacuplasty (Baylis Medical, Inc., Montreal, Canada) (see Fig. 66.1) have been historically used to treat discogenic pain.

The process of intervertebral disk degeneration includes induced dehydration of the intervertebral disk and a loss of nuclear material. Delamination and fissuring of the lamellar layers are physical changes, and the production of certain cytokines and other mediators is one of the biochemical and cellular changes occurring within the disk. Inside the intervertebral disk, the production of inflammatory cytokines including tumor necrosis factor-\(\alpha\) (TNF-\(\alpha\)), nitric oxide, and matrix metalloproteinases (MMPs) can be greatly altered.\(^13\)\(^14\) Nociceptors, normally limited to the outer third of the annulus, could be the substrate for discogenic pain when they are expanded over the larger annular area and penetrate further into the degenerated disk along the vasculature and fissures.\(^15\)\(^18\) Those C- and A\(\delta\) fibers are
likely responsible for transmitting pain responses, and their elimination may, in theory, disrupt transmission of the pain signal.

Minimally invasive thermal procedures deliver heat inside the disk annulus via a resistive heating coil in, for example, IDET, bipolar biaxoplasty (Kimberly Clark, Atlanta, Georgia), or unipolar, flexible (DiscTRODE; Valleylab, Boulder, Colorado) radiofrequency (RF) electrode to denervate nociceptive fibers and coagulate collagenous tissues.

During the application of RF, similar to any other tissue, alternating flow of electrical current causes ions in the tissue to alternate fast movements. This molecular vibration results in frictional heating and ablation. Ionic heating produces thermal injury of the cells when tissue temperature reaches > 42° C. The extent of cellular damage depends on multiple factors including the temperature, position, thickness of electrodes, and duration of heating. An increase in tissue temperature is a function of current density, which is greatest at the proximity of the electrode and decreases with increasing distance from the electrode. However, by increasing the power output, current density around the electrode is increased and lesion size is limited by the given current density.

Cooling the RF electrode internally can increase lesion size and is currently used during intradiscal biaxoplasty procedures. Cooled RF probes have cooling sink lumens that extend to the tip of the electrode. The cooling fluid (water) circulates from the tip of the electrode to a synchronized water pump. As coolant removes heat from the tissue adjacent to the electrode, larger lesion volumes are produced by increasing power deposition and the duration of the current interval. An even larger lesion volume can be produced by using two internally cooled RF electrodes in a bipolar arrangement at significantly lower temperatures.

**INTRADISCAL ELECTROTHERMAL THERAPY (IDET)**

IDET technology, although limited in its use clinically, is still considered a valuable intradiscal procedure and will be briefly discussed (see Fig. 66.1 C). It provides focal heat via an elongated resistive coil of very small diameter to the limited area of the posterior annulus. Possible mechanisms of pain relief were already discussed. The limited use results from the high temperatures attained just around the electrode itself and quick dissipation of the heat at 2- to 4-mm radius away from the coil. Positioning of the resistive coil within the posterior annulus of the disk can be prolonged, and multiple attempts may be required, or it may be necessary to pass another coil from the opposite side of the posterolateral disk to achieve optimal electrode placement within the interface between the annulus and the nucleus (see Fig. 66.1 C). This may further damage the intervertebral disk, and sometimes placing the tip of the coil within the posterior annular fissure may extend too close to the neural canal. Indications for IDET include persistent discogenic low back pain despite prolonged and comprehensive conservative treatments including physical therapy and a directed home exercise program, similar to other annuloplasty procedures. Provocative or analgesic diskography should replicate or eliminate concordant pain at low disk pressurization (< 50 PSI). The clinical outcome studies on intradiscal electrothermal therapy (IDET) are listed with other annuloplasty studies in Table 66.1. Multilevel disk degeneration seen on magnetic resonance imaging (MRI) appears to be an important negative predictor for the success of annuloplasty, especially when compared to a group of patients with one or two degenerated disks as shown on the MRI. There are few patients with a single disk disease compared to those with multilevel degeneration present on the MRI. Two other groups of patients who have much lower chance of successful functional capacity improvement after annuloplasty are overweight patients and patients receiving workers’ compensation benefits.

Another approach to annuloplasty utilizes a flexible radiofrequency electrode and is called DiscTRODE or percutaneous intradiscal radiofrequency thermocoagulation (PIRFT). Two studies, utilizing proper patient selection, showed minimal or no benefit from PIRFT. Karstein and coworkers reported minimal or no improvements in functional capacity, as did Kapural and associates. It appears that the design of the PIRFT electrode provided minimal heat dissipation, which, in turn, could not adequately denervate the posterior annulus.

INTRADISCAL BIOACUPLASTY (IDB)

Intradiscal biacuplasty (IDB) is the latest, and seems to be the most promising, of the minimally invasive posterior annulus heating techniques (see Fig. 66.1B). This technology employs bipolar cooled RF electrodes named transdiscal electrodes (Kimberly Clark, Atlanta, Georgia). Initial data are encouraging.48-52 Internally cooling the electrodes provides more substantial and even heating over the wider area of the posterior annulus (Fig. 66.2).26-28

The procedure itself is fluoroscopy guided with the patient lying in the prone position. Electrodes are percutaneously inserted bilaterally in the posterior annulus of the intervertebral disk (see Fig. 66.1A and Fig. 66.2). The generator delivers RF energy led by a temperature thermocouple near the tip of the electrode. The temperature increases gradually to 50°C, with an overall heat time of 15 minutes. During this time, the patient should be awake and conversant to decrease the probability of neurologic injury.

Initially, clinical biacuplasty data from two case series of 14 and 15 patients were completed. Both studies demonstrated significant pain relief following the disk biacuplasty procedure at 3, 6, and 12 months.50-52 The Turkish case series suggested > 50% improvement in pain scores at 6 months with good patient satisfaction. The U.S. pilot study involving 15 patients described reduction in the median visual analog scale (VAS) pain score from 7 to 3 cm at 6 and 12 months’ follow-up, respectively; an improvement in the Oswestry index from 23.3 to 16.5 points; and a significant increase in the SF-36 bodily pain scores.50,52

The authors completed a sham, prospective randomized study on IDB (Table 66.2).52 The aim of the study was to compare the efficacy of intradiscal biacuplasty with placebo using 1:1 randomization. Sixty-four patients were enrolled using the same selection criteria as in the pilot study (see the previous discussion and Table 66.2). Patients in the IDB group exhibited statistically significant improvements in physical function, decreased pain, and disability at 6 months’ follow-up as compared to patients who received the sham treatment (see Table 66.2).

Those who had one-level degenerative disk disease (DDD) had better outcomes than those with two disks involved; therefore, IDB is not as successful as alleviating pain for many patients with multilevel DDD and should be recommended only to properly selected patients.52

Intradiscal biacuplasty may offer several advantages over the earlier techniques. There is negligible disruption to the native tissue architecture, and thus the biomechanics of the spine are likely unchanged and the relative ease of electrode placement abolishes the need to thread a long heating catheter (e.g., IDET).

COMPLICATIONS OF ANNULOPLASTY PROCEDURES

The incidence of various complications related to annuloplasty could be as high as 10%.53,54 but serious complications are rare. If the radiofrequency electrode or resistive coil is positioned in close proximity to the neural elements, the high temperatures that are delivered may cause nerve

injury manifested as radicular pain, or transient palsy. Transient radiculopathy and even motor deficit with footdrop were previously reported following the IDET procedure. 54

Catheter breakage, 54 vertebral osteonecrosis, 55 and cauda equina syndrome were also reported after the IDET procedure. The classic risk factors such as the duration of back pain, obesity, smoking, history of leg pain, and diabetes may not be associated with the higher incidence of complications. 53, 57 Discitis is a rare complication of any intradiscal procedure. 57, 62 The appropriate timing of the intravenous antibiotic seems to be effective in preventing discitis after provocative diskography and any minimally invasive intradiscal procedure. 57, 62 The incidence of disk herniation following annuloplasty could be as high as 0.3%, which was assumed to be due to a thermally mediated loss of tensile strength of the collagen fibers. 63 There were reports on disk herniation after the IDET procedure. 53, 54, 57

**DISK HERNIATION AND PAIN RELIEF FROM PERCUTANEOUS DISK DECOMPRESSION**

A herniated disk can cause radicular pain that manifests over an appropriate dermatomal area. Abnormal weight-bearing loads with internal disk disruption (IDD) could cause changes in shape or disruption of the annular fibers. Contained disk herniation or even extrusion of the disk may compress the nerve root. 64

Inflammatory mediators present in the intravertebral disk—such as phospholipase A2, prostaglandin E2, interleukin-1β, interleukin-6, interleukin-1α, interleukin-1β, interleukin-6, tumor necrosis factor-α, and nitric oxide (NO)—may be additional pain culprits. 65 Nuclear material, in addition to or without mechanical pressure, may produce painful chemical radiculitis.

Contained disk herniation may exert pressure on a nerve root, and possibly the dorsal root ganglion, providing a basis for intradiscal percutaneous disk decompression. Removal of a small amount of the nuclear material from the affected disk or applying heat through radiofrequency within the nucleus can cause a decrease of intradiscal pressure and, possibly, retraction of the herniation away from the nerve. A significant drop in intradiscal pressure may not be produced if the elasticity of the disk is not preserved and the disk contains a high-grade (Dallas 5) fissure. This may be less likely if disk extrusion is present (Fig. 66.3).

The appropriate candidate for percutaneous, minimally invasive intradiscal disk decompression is the patient who experiences radicular pain that correlates with the imaging findings, has contained disk herniation, and experiences predominantly leg pain. Patients with spinal stenosis, extruded disk herniation, progressive neurologic motor deficits, and cauda equina syndrome are not candidates for this minimally invasive approach.

**THE DEKOMPRESSOR DEVICE**

During percutaneous decompression of the disk in patients with contained disk herniation, the Dekompessor device extracts variable amounts of nuclear disk material via an auger that ends inside the nucleus and collects extracted material into the specially designed chamber. Depending on the volume extracted, a decrease in intradiscal pressure follows. The annular wall must be intact (without completed annular disruption) in order for the herniated portion to retract. Provocative diskography is needed before this procedure to detect complete annular disruption. 66, 68

The technique of needle placement of the Dekompessor is similar to nucleoplasty, or standard diskography. First, the introducer is placed in the nucleus of the disk, and the probe is advanced via an introducer contrast that is injected to delineate the size of the treated disk nucleus. A collection chamber is attached to the probe, which can be removed to be inspected together with the probe for the amount of collected nuclear tissue. Assessment of the tissue volume removed should include measurement of the tissue volume in the collection chamber and that along the probe. The Dekompessor probe is removed when a sufficient amount of material has been taken out from the disk.

Although it has been used clinically for the treatment of contained, symptomatic disk herniation since the early 2000s, the Dekompessor device still has not been tested in a controlled, randomized study. There are a few observational studies that provided positive outcomes. Lierz and coworkers (Table 66.3) 66 studied 64 patients and reported an average decrease in pain scores from 7.5 to 2.1 at 12 months. Similar data were provided by Amoretti and associates, 67 who reported that 50 patients had a > 70% decrease in pain in 72% of cases, and Alo and colleagues, 68 who reported an 80% success rate (see Table 66.3).

**COBLATION: NUCLEOPLASTY**

Nucleoplasty (ArthroCare Corporation, Austin, Texas) uses coblation technology to ablate and coagulate nucleus pulposus to decompress the disk and minimize contained disk herniation. 69 Therapeutic decompression is more likely in a nondegenerated intervertebral disk. 70, 74 Similar to the Dekompessor, the disk is accessed by an introducer using fluoroscopy. Once the introducer is in place, the SpineWand coblation electrode is then placed through the introducer. Channels are created across the nucleus during forward

PLDD, percutaneous laser disk decompression; Dekompressor (visual analog scale [VAS]).
movement of the cannula and then withdrawn to the starting position five to six times all within the nucleus.69

Again, this relatively simple procedure is intended only for radicular pain without large disk protrusions or disk extrusions. The best candidate for nucleoplasty is someone who has a contained disk protrusion of < 6 mm with preserved annular integrity.69-75 To date, no randomized, prospective studies have been conducted to prove the efficacy of nucleoplasty. Multiple observational and prospective studies have shown an improvement in functional capacity in treated subjects (see Table 66.3).70-74

OTHER INTRADISCAL METHODS FOR TREATMENT OF CONTAINED DISK HERNIATION

Two other commonly used percutaneous disk decompression methods have been applied sparingly in recent years. One is the Nucleotide (Clarus Medical, Minneapolis, Minnesota), which uses an automated shaver with continuous irrigation to remove nuclear disk material. Although it can remove large amounts of disk material, it also employs a bulky probe, which can potentially produce significant annular damage. The same concerns are shared by most practitioners who had an experience with the percutaneous laser disk decompression (PLDD) device (see Table 66.3).75-77

COMPLICATIONS OF PERCUTANEOUS DECOMPRESSIVE PROCEDURES

A higher prevalence of leg pain and increased weakness in patients who received nucleoplasty, compared to a conservative group, has been documented. The most common postoperative complaint was soreness at the site of the needle insertion.78 Discitis is a serious complication described after PLDD (see Table 66.3).76 Another complication with the Dekompressor was probe breakage within the disk nucleus.79

KEY POINTS—cont’d

- Biacuplasty produces positive therapeutic effects in properly selected patients.
- Future areas of clinical research in discogenic pain may include cytokine inhibitors, ablative agents, and growth factors.
- It is less clear if any of the percutaneous disk decompression procedures will show long-term pain relief when tested in a randomized, sham-controlled study format.

34. Eichen SI, Fiedler GA, Larson KL. Effectiveness of intradiscal electrothermal therapy in increasing function and reducing chronic low back pain in selected patients. WMJ. 2002;101:31-34.

One in two women and one in five men older than 50 years will experience an osteoporotic fracture, which can result in substantial pain, morbidity, and health care utilization. A new osteoporotic vertebral fracture occurs every 22 seconds; 1.4 million occur worldwide every year. The majority are asymptomatic or result in tolerable symptoms, with only a third of patients with a new fracture seeking medical attention. In the vast majority, the acute back pain symptoms subside over a period of 6 to 8 weeks as the fracture heals.

Vertebroplasty and kyphoplasty are minimally invasive, image-guided procedures that involve the injection of cement into a fractured vertebral body (Figs. 67.1 and 67.2). The majority of these vertebral augmentation procedures are performed in a small subset of patients with symptomatic osteoporotic compression fractures that fail conservative medical therapy. Failure of medical therapy is variably defined but can be considered if the pain persists at a level that severely compromises mobility or activities of daily living despite analgesic therapy or if unacceptable side effects such as confusion, sedation, or constipation occur as a result of the doses of medication required to reduce the pain to tolerable levels. Notably, the first report of augmentation (published in 1987) was for neoplastic disease. As survival rates in cancer patients continue to improve, symptomatic neoplastic vertebral fractures and neoplastic vertebral tumors have increased in prevalence. A selected subgroup of these patients, in particular, those with symptomatic fractures from multiple myeloma and metastasis that fail to respond to conservative therapy, also benefit from vertebral augmentation. The primary goal of augmentation is pain relief and enhanced functional status with the secondary goal of vertebral body stabilization in cases of fracture. Key points, indications for, and contraindications to vertebral augmentation are summarized at the end of the chapter.

**CONSERVATIVE MEDICAL THERAPY FOR VERTEBRAL COMPRESSION FRACTURES**

The goals of conservative therapy are pain reduction (with analgesics, bed rest, or both), improvement in functional status (with orthotic devices and physical therapy), and prevention of future fractures (with vitamin D and calcium supplementation and bisphosphonate therapy).

Although conservative management of those with mild pain and no limitation of function is appropriate, conservative treatment of those with more severe pain or limitation of function is not benign. In this cohort, conservative therapy often involves a period of bed rest, which may lead to undesirable side effects such as loss of bone mass and muscle strength, decubitus ulceration, and venous thromboembolic disease, all of which can prolong the recovery period and result in loss of independence. Bone loss occurs at a rate of approximately 2% per week, muscle strength is reduced by 10% to 15%, and infectious complications can lead to sepsis and osteomyelitis. Moreover, the presence of fracture or malignancy combined with bed rest elevates the risk for venous thromboembolic disease in this cohort. Overall, the complications of prolonged bed rest, combined with opioid analgesic use and its associated side effects, can result in a vicious cycle of physical deconditioning, poor nutrition, and subsequent increased risk for vertebral insufficiency.

**TECHNICAL ASPECTS OF VERTEBRAL AUGMENTATION**

Evaluation of patients for vertebral augmentation should identify those likely to benefit from vertebral augmentation, as well as screen for contraindications. The decision to proceed with treatment must be based on a good history, physical examination, appropriate laboratory evaluation, and imaging, as summarized in Boxes 67.1 and 67.2.

**SEDATION**

Analgesia is typically necessary for vertebroplasty and kyphoplasty. In the majority of cases, it is achieved with a combination of local analgesics (e.g., lidocaine with bicarbonate or bupivacaine) and moderate sedation (intravenous midazolam and fentanyl). In some cases, general anesthesia is needed to provide adequate comfort and safety, particularly in patients at high risk for airway or respiratory complications with prone positioning or those with significant preprocedure narcotic analgesic requirements. However, having the patient awake is desirable because it allows feedback (e.g., increasing pain, neurologic dysfunction) that can alert the operator to potential complications. In all cases, continuous monitoring is performed with a minimum of electrocardiography, blood pressure measurements, and pulse oximetry. Sedation and monitoring are performed by anesthesiologists, nurse anesthetists, or certified nursing
Figure 67.2 Kyphoplasty. Once access to the vertebral body is achieved (A), the inner stylet is removed and a balloon tamp is inflated within the vertebral body (B) to create a cavity within the bone (C) into which cement is delivered (D).
**Box 67.1 Indications for and Contraindications to Vertebral Augmentation**

**Indications**
1. Treatment of symptomatic osteoporotic vertebral body fractures that are refractory to conservative medical therapy
2. Treatment of symptomatic vertebral bodies weakened or fractured because of neoplasia that are refractory to medical therapy

**Absolute Contraindications**
1. Active systemic infection, in particular, spinal infection
2. Uncontrollable bleeding diathesis
3. Insufficient cardiopulmonary health to safely tolerate sedation or general anesthesia
4. Myelopathy resulting from fracture retropulsion or epidural tumor extension
5. Known allergy to bone cement

**Relative Contraindications (Should Be Treated Only by Experienced Practitioners)**
1. Marked loss of vertebral body height (greater than 75% loss of height), which makes the procedure more difficult since there may be little space for placement of a cannula.
2. Vertebroplasty above T5, which is challenging because of the small size of the vertebral bodies and pedicles. The shoulders often limit fluoroscopic imaging at these levels.
3. Severe osteopenia resulting in poor visualization of osseous structures on fluoroscopy, which increases the risk for improper needle placement and cement leakage. This can be overcome with guidance by computed tomography.
4. Disruption of the posterior cortex, which increases the risk for posterior cement leakage and therefore the risk for spinal cord or nerve root compression. This is frequently seen with burst fractures and neoplasm. The integrity of the posterior cortex is best evaluated with computed tomography.
5. Substantial canal narrowing (without neurologic dysfunction), which increases the risk that even a small amount of cement leakage will produce neurologic compromise.
6. Retropulsion of fracture fragments, which increases the risk for further canal compromise with vertebral augmentation, particularly if the posterior vertebral body wall is unstable.
7. Epidural extension of tumor, which in the setting of pathologic fractures results in significantly higher rates of spinal canal leakage than osteoporotic fractures do.

In patients with substantial preexisting respiratory or cardiac disease, anesthesiologist can be asked to evaluate the patient and determine whether monitored anesthesia care is warranted. The patient should not eat or drink for at least 4 to 6 hours before the procedure.

**PATIENT POSITIONING**

Prone or oblique prone is the ideal patient position for thoracic and lumbar procedures. In practical terms, we allow patients an amount of freedom to place themselves in the prone oblique position should it promote greater comfort throughout the procedure. This can introduce 10 to 15 degrees of obliquity, depending on the patient’s position. In addition to the clear advantage of easy access, this position with proper cushion support under the upper part of the chest and lower part of the abdomen maximizes extension of the fractured segments, thereby promoting reduction of kyphosis. The patient’s arms should be placed sufficiently toward the head to keep them out of the path of the fluoroscope. Analgesia should be considered before placement on the table because this part of the procedure may be quite painful. Particular care must be taken when transferring patients who are aged or have osteoporosis or myelomatous infiltration since this may result in new rib or vertebral fractures.

**ANTIBIOTIC PROPHYLAXIS AND SKIN PREPARATION**

The risk for infection is minimized by following standard operating room guidelines for sterile preparation of the skin, draping, operator scrubbing, and use of sterile gowns, masks, and gloves. Few data support or oppose antibiotic administration, but there are reports of spine infections after these procedures, and the presence of polymethyl methacrylate (PMMA) makes these infections difficult to treat successfully. We routinely use antibiotic prophylaxis. Prophylaxis for these procedures comes in one of two forms. An intravenous antibiotic such as cefazolin (1 g) or clindamycin (600 mg with penicillin allergy) may be administered before skin incision. Alternatively, the PMMA may be mixed with an antibiotic, such as tobramycin (1.2 g), as the cement is being prepared; this practice has diminished in favor of intravenous antibiotics.

**NEEDLE PLACEMENT**

The most important aspect of needle placement is to keep the needle trajectory lateral to the medial cortex and superior to the inferior cortex of the pedicle. This prevents entry of the needle into the spinal canal or neural foramen. The needle may be placed via a transpedicular or parapedicular approach. In the transpedicular approach, the needle is directed from the posterior surface of the pedicle, through the length of the pedicle, and into the vertebral body. The long intraosseous path protects the postganglionic nerve roots and other soft tissues. However, the pedicle configuration can limit one’s ability to achieve a final needle tip position near the midline. In the parapedicular approach, the needle is directed along the lateral surface of the pedicle, with the pedicle being penetrated along its path or the vertebral body at its junction with the pedicle. This approach may permit more medial tip placement, which can be useful during treatment of levels with anatomically small pedicles, in particular, in the thoracic spine.

For either of these approaches there are multiple potential image guidance strategies, including anteroposterior (AP) and end-on (“down the barrel”) views, with the latter technique involving ipsilateral oblique rotation of the image intensifier to place the fluoroscopy beam and needle track parallel to each other. The following description assumes the use of two perpendicular image intensifiers simultaneously (biplanar fluoroscopy):

1. Rotate the image intensifier to a true AP position by aligning the spinous process midway between the pedicles (Fig. 67.3).
2. Change the craniocaudal angulation by bringing the pedicles to the midportion of the vertebral body. Use
the lateral fluoroscopic view to aid in determination of the correct craniocaudal adjustment required.

a. For the end-on view, rotate image intensifier approximately 20 degrees ipsilateral to the target pedicle so that the medial cortex of the pedicle is at the middle third of the vertebral body. The vertebra adopts the “Scotty dog” configuration. Place the needle so that it is "end on" to the image intensifier and appears as a dot.

3. Plan the trocar trajectory. For the AP and partial ipsilateral oblique views, the trocar entry site should be at the 3-o’clock position of the right pedicle or the 9-o’clock position of the left pedicle for the transpedicular approach. In the end-on view, it is centered within the circle formed by the cortex of the pedicle. For parapedicular approaches an entry site just lateral to the 3- or 9-o’clock position of the pedicular cortex is best.

4. Anesthetize the skin and periosteum by subcutaneous injection of lidocaine or bupivacaine via a 22-gauge needle along the planned trajectory. Use this smaller-gauge needle to assess and adjust the planned trajectory.

5. Make a small vertical skin incision (allows easier cranio-caudal needle angulation), and insert the 11- or 13-gauge diamond-tipped needle stylet (sheathed in a cannula).

6. Advance the needle to the bone surface while making small corrections in cranio-caudal angulation on the true lateral view (care is needed to angle the image intensifier so that a true lateral view is obtained). For the parapedicular approach, the position at which bone is encountered (i.e., at the junction of the pedicle and vertebral body) is more anterior on the lateral view.

7. Once in the bone, advance the needle either with a drilling motion and controlled forward pressure or by carefully tapping the needle handle with an orthopedic mallet.

8. Maintain a true AP view of the image intensifier for advancement of the needle unless using the end-on view, in which case the needle is kept as a dot during initial placement through the pedicle. The needle must remain lateral to the medial cortex of the pedicle until it has traversed the entire pedicle on the lateral view.

9. Once the needle has traversed the pedicle, one can replace the diamond-tipped needle with a straight bevel-tipped needle or curved needle for better maneuverability (Fig. 67.4). Advance the needle further via the lateral view to the anterior third to quarter of the vertebral body.

### ADDITIONAL STEPS FOR KYPHOPLASTY

For vertebroplasty, the PMMA is delivered through the cannula after placement of the needle as just described. Kyphoplasty involves the additional steps of balloon tamp insertion and inflation to create a cavity within the bone (Fig. 67.5). For kyphoplasty, pull the cannula back to the posterior aspect of the vertebral body to allow the insertion of the balloon tamp. After the needle stylet is removed, insert the balloon tamp through the cannula and slowly inflate with iohinated contrast medium. The balloon is attached to a locking syringe with a digital manometer.
Monitor the inflation with both the pressure transducer and intermittent fluoroscopy. Continue inflation until one of two conditions is met: the system reaches significant pressure or maximum balloon volume or further inflation results in patient discomfort. Balloon placement can be either unipedicular or bipedicular. Deflate and then remove the balloon.

CEMENT PLACEMENT

The consistency of the cement, when ready for injection, is similar to that of toothpaste. Wong and Mathis recommend a drip test, in which the cement should ball up at the end of the needle and not drip downward, which will result in a cement consistency that is slightly more viscous than toothpaste.\textsuperscript{12} Working time varies from 10 to 20 minutes, depending on temperature and the specific PMMA formulation being used. A variety of delivery systems are available for the cement. These systems vary from a few 1-mL syringes with a spatula and a mixing bowl to self-contained delivery devices. A screw-syringe injector with long, flexible delivery tubing has the advantage of minimizing exposure of the operator to radiation.\textsuperscript{13}

VERTEBROPLASTY

- After removing the needle stylet, fill the cannula with saline to prevent pressurized injection of air and air embolism. Connect the delivery system to the cannula and inject the cement slowly.
CHAPTER 67 — MINIMALLY INVASIVE PROCEDURES FOR VERTEBRAL COMPRESSION FRACTURES

Figure 67.4 Photographs of typical vertebroplasty needles. A, Typical coaxial vertebroplasty needle—the inner stylet locks into the outer cannula. Note the large handles to facilitate insertion and removal from the bone. Manufacturers may use different colored or marked handles to indicate the type of needle tip (magnified in B). A needle with a beveled tip can be used to facilitate directing the needle along the desired trajectory.

Figure 67.5 Additional steps for kyphoplasty. A, Lateral fluoroscopic image. The unipedicu lar needle has been placed into the anterior third of the T10 vertebral body. B, The needle is withdrawn to the posterior third of the vertebral body and the inner stylet removed. C, The balloon tamp is introduced into the needle track and inflated to create a cavity within the bone. D, Cement opacifies both the cavity and extends into adjacent trabecular bone.

Figure 67.6 Balloon kyphoplasty. The balloon is attached to a digital manometer, which allows assessment of balloon pressure. Note the long flexible tubing, which permits the operator's hands to remain out of the primary radiation beam during fluoroscopic assessment of balloon inflation.
Monitor carefully with fluoroscopic imaging to ensure that the cement remains within the vertebra. Posterior or posterolateral leakage could result in irritation of or damage to the spinal cord or nerve roots and should be avoided. New pain with a different character should prompt an immediate pause in the procedure and additional views.

End points for cement injection include passage of cement beyond the marrow space or cement reaching the posterior quarter of the vertebral body on the lateral projection. In the case of cement leakage, one may wait 1 to 2 minutes to allow the cement to harden and then reinject to see whether the cement is redirected within the vertebral body. Ideally, the cement will extend across the midline to the opposite pedicle by the end of the injection. The optimal volume of cement remains a matter of controversy.

The final portion of cement may be delivered by inserting the needle stylet. Alternatively, the cement may be allowed to harden and the needle removed with a gentle rocking motion to ensure that the cement within the cannula separates at the tip of the cannula.

KYPHOPLASTY

The cavity created by the balloon tamp allows injection of cement that is more viscous than that typically used for vertebroplasty. The cavity and more viscous cement theoretically minimize the risk for extravasation of cement. Sufficient time is allowed for the cement to reach a doughy consistency, with loss of the “sheen” of the initial mixed cement.

Many practitioners use manual bone filler devices to inject cement, although one can use injector systems. The delivery system is connected to the cannula and the cement is injected slowly under fluoroscopic guidance. The cavity is filled with cement from anterior to posterior until it matches or slightly exceeds the volume of the inflated balloon tamp.

CONTROVERSIES AND SPECIAL TOPICS

BIPEDICULAR VERSUS UNIPEDICULAR APPROACH

Vertebroplasty and kyphoplasty can be performed with placement of bilateral needles or a single needle. In either case the goal is to place cement across the midline within the vertebral body—we use placement of PMMA to the opposite pedicle as our general landmark. Therefore, use of a single needle with a relatively medial position of the needle tip is sufficient in many cases. If a unilateral approach is attempted during kyphoplasty and balloon expansion does not cross midline, a second system may then be placed on the other side, depending on the distribution of cement fill. In many cases, cement fill will continue across the midline, thereby obviating the need for a second needle. Moreover, hemivertebal fill (cement traverses <10% of the contralateral unfilled vertebra) has been shown to be as efficacious in reducing pain and improving function without an increased risk for fracture.

Importantly, there is no statistically significant difference in the pain relief achieved with unipedicular and bipedicicular vertebroplasty or kyphoplasty. There are advantages to each approach. Advantages of a unipedicular approach include a decrease in procedure time and elimination of the risk associated with placement of a second needle. A unipedicular approach is also associated with lower rates of cement leakage. The major advantage of a bipedicular approach is that access is typically transpedicular with a less aggressive lateral to medial approach that may result in less paravertebral vessel and nerve injury and a potential biomechanical advantage for bilateral delivery of cement.

VOLUME OF CEMENT INJECTED

The optimal volume of cement is a matter of controversy, with some practitioners advocating injection of maximal amounts of cement to completely fill the vertebral body and others advocating lower cement volumes with an emphasis on safety. The theoretical goal of more complete filling is to achieve restoration of biomechanical strength within the vertebral body to prevent refraction without creating excessive stiffness that may be transmitted to the adjacent levels. Based on an in vitro biomechanical study, Mathis and Wong recommended filling 50% to 70% of the residual volume of the vertebral body with cement. However, much smaller amounts of cement (as little as 0.5 mL) appear to result in similar clinical outcomes as do larger-volume injections in terms of the primary goal of pain relief, with no association between the volume of cement injected and the clinical outcomes of pain and medication use. The decreased risk for extravasation of cement with smaller-volume injections and meticulous attention to the end-of-injection criteria outlined earlier favor an approach using a smaller volume of cement.

VERTEBRA PLANA

When the vertebral body loses 70% of its original height, safe needle placement becomes a challenge. According to Stallmeyer and associates, at least 8 mm of residual height is required for cannula placement. Vertebra plana often adopts a bow-tie configuration in which the center is compressed the most. This usually requires a lateral needle position with placement of bilateral needles. Only a small amount of cement is needed to achieve pain relief. If there is a cystic cleft within the fracture (Kummel’s disease), the needle may be placed near the midline within the cleft in the hope of expanding the height of the vertebra during needle placement and cement injection.

FRACTURES WITH AN INTRAOSSEOUS VACUUM PHENOMENON (KUMMEL’S DISEASE)

The intraosseous vacuum phenomenon is thought to be related to osteonecrosis. A fluid-filled cleft seen on magnetic resonance imaging (MRI) is an equivalent finding. Pain in this setting is believed to arise from motion between the unhealed fracture fragments. In some cases this motion can even be seen under fluoroscopy as the height of the vertebral body changes with respiration. Prone positioning during the procedure promotes restoration of height because of the traction placed across the vertebral body. The needle
should be placed into or as close to the cleft as possible so that cement will fill the cleft. Vertebral augmentation yields significant rates of pain relief in the setting of an intraosseous vacuum phenomenon, and in our experience it can provide considerable restoration of height. It is important to keep the patient prone for 15 to 20 minutes after injection of the cement to allow the cement to harden within the cleft before moving the patient off the fluoroscopy table.

**MALIGNANT FRACTURES WITH POSTERIOR WALL OSTEOLYSIS OR EPIDURAL TUMOR EXTENSION**

Although vertebral augmentation may be performed in the setting of posterior wall osteolysis or epidural tumor extension, there should be heightened awareness of the potential neurologic complications related to epidural extension of cement or posterior displacement of tumor. In a study of 51 patients with a vertebral lesion and epidural extension treated by vertebroplasty, 30% had preprocedure symptoms of partial or complete cord compression/cauda equina syndrome.26 These patients were terminally ill and did not undergo surgical decompression because their paraplegia was deemed irreversible (present for more than 1 month or associated with spinal cord atrophy) or their general condition was a contraindication to surgery. Although no further clinical deterioration was observed in this subgroup after vertebroplasty, in 1 of the 36 patients without neurologic symptoms, cauda equina syndrome developed 2 days after vertebroplasty and required surgical decompression.26 Cement leakage (as detected on postprocedure computed tomography (CT)) occurred in 62%, with half of these leaks extending into the epidural space. Importantly, extension of cement beyond the confines of the vertebral body but within the epidural tumor was still classified as a leak.27 Nonetheless, the aforementioned was the only symptomatic cement leak. No systemic complications occurred. Analgesic efficacy, based on 50% or greater improvement in pain as compared with baseline, was impressive—94% (48 of 51 patients) at day 1, 86% (31 patients) at 1 month, 83% (19 patients) at 6 months, and 92% (11 patients) after 1 year (data are from surviving patients).26 Safeguards to prevent complications in this cohort include performing the procedure with the patient awake (new pain may be the first sign of dangerous cement leakage) and more modest cement injection than used for routine cases. Limiting the cement to the anterior two thirds of the vertebral body may be a good rule of thumb, as well as injection of thicker cement, which may in turn reduce the risk for epidural cement leakage.28

**SAFETY OF MULTILEVEL TREATMENT**

A patient scheduled for vertebral augmentation may have multiple fractures that require treatment. Ideally, all the levels would be treated at one time. However, treating an excessive number of levels in a single session raises many concerns, including PMMA toxicity, difficulty for the elderly to lie prone and cooperate for the extended amount of time that this would require, discomfort after the procedure related to placement of multiple needles, and fat emboli being extruded from marrow during the cement injection. There have been two reported deaths in patients who underwent vertebral augmentation at eight or more levels.29 Even though there is no established guideline, a good rule of thumb is to treat a maximum of three levels per session.30,31

**OUTCOMES ASSOCIATED WITH VERTEBRAL AUGMENTATION**

The mechanism by which vertebroplasty and kyphoplasty relieve pain is uncertain.32 Hypotheses include mechanical stabilization of mobile fracture fragments, thermal or chemical neurolysis, or inherent tumorcidal or cytotoxic effects on malignant fractures. A cadaveric study has also demonstrated new bone formation after PMMA injection.33

Two highly publicized placebo-controlled randomized clinical trials on vertebroplasty have been published in the New England Journal of Medicine. Both trials used a sham procedure in the placebo arm that involved injection of local anesthetic down to the periosteum of the pedicle and injection of local anesthetic combined with passage of a 13-gauge needle to rest on the lamina.35 Both studies found that there was no significant reduction in pain or pain-related disability in patients undergoing vertebroplasty versus the sham procedure.

The INvestigational Vertebroplasty Efficacy and Safety Trial (INVEST) included 131 patients, with 68 randomized to vertebroplasty and 63 to the sham procedure.34 Even though at 1 month there was a trend toward a higher rate of clinically meaningful improvement in pain (30% decrease from baseline), no statistical difference in regard to pain scores, back pain–related disability, or quality of life was noted.34 Buchbinder and colleagues studied 78 patients, with 38 randomized to vertebroplasty and 40 to the sham procedure.35 After the procedure, both groups had similar improvements in pain, physical functioning, and quality of life. There were no significant differences between the groups at 1 week, 1 month, 3 months, and 6 months of follow-up.35

These reports are in contrast to previous retrospective case series that had documented impressive rates of pain relief with these procedures.36 The New England Journal of Medicine trials were criticized for potential inclusion of patients with chronic fractures of up to 12 months in duration. The average duration of back pain was 18 weeks in INVEST, with a third of all randomized patients having pain for longer than 6 months. The trial of Buchbinder and coworkers had four patients randomized after 6 months. In the INVEST trial, marrow edema seen on MRI or increased uptake on bone scanning was required only for fractures of an uncertain age (rate of use was not reported). In the trial of Buchbinder and colleagues, MRI demonstrating marrow edema or a fracture line (or both) was required; however, determination of bone marrow edema was not described. Further criticisms include inconsistent use of physical examination, difficulties in recruitment, and absence of a control group without intervention.

Since then, the vertebroplasty versus conservative treatment in acute osteoporotic vertebral compression fractures (VERTOS II) investigators performed a nonblinded trial in which 202 patients with severe back pain for 6 weeks or less, focal tenderness at the fracture level, and MRI demonstration of bone edema were randomized equally into the vertebroplasty or conservative arms. All patients were prescribed analgesics that were individually titrated, bisphosphonates, and calcium and vitamin D.
supplements. Vertebroplasty was performed at a mean of 5.6 weeks after the onset of symptoms. There were statistically significant reductions in mean visual analog scale (VAS) scores in favor of vertebroplasty at 1 month \((P < 0.0001)\), with the benefit persisting at 1 year \((P < 0.0001)\). There were significant reductions in the use of drugs in the vertebroplasty group at 1 day \((P < 0.0001)\), 1 week \((P = 0.001)\), and 1 month \((P = 0.033)\). Moreover, significant pain relief (reduction in VAS score of 3 or more points) was achieved earlier and in more patients after vertebroplasty (29.7 days; 95% confidence interval \([CI\), 11.45 to 47.97]) than after conservative treatment (115.6 days; 95% CI, 85.87 to 145.40). Notably, the same investigators have already planned VERTOS IV—a prospective, multicenter, randomized controlled trial using the same strict inclusion criteria as in VERTOS II that is designed to compare pain relief after vertebroplasty and a sham intervention in patients with acute osteoporotic vertebral compression fractures. The FREE trial was another large trial supporting the efficacy of vertebral augmentation. A total of 300 patients were randomized to undergo kyphoplasty \((n = 149)\) or conservative therapy \((n = 151)\). Fractures were to have a minimum of 15% loss of height and MRI evidence of edema. Although both osteoporotic and malignant fractures were included, 96% of the fractures were related to primary osteoporosis. At randomization, fractures were a mean of 6 weeks old, kyphoplasty was performed at a mean of 7 days after randomization, and patients with fractures older than 3 months were excluded.

The primary outcome measure was the mean 36-Item Short-Form Health Survey (SF-36) physical component summary (PCS) scale, a validated global quality-of-life measure weighted on physical ability. Statistically significant improvements in SF-36 PCS scores in favor of kyphoplasty were noted at 1 month \((P < 0.0001)\) and 12 months \((P = 0.0004)\). There were greater reductions in Roland-Morris Disability Questionnaire (RDQ) scores in favor of kyphoplasty at 1 month \((P < 0.0001)\) and 12 months \((P = 0.0012)\). Patients in the kyphoplasty group also had greater reductions in back pain scores, lower rates of narcotic analgesic use, and fewer days of restricted activity than those managed with conservative therapy. By 12 months, the differences between the conservative therapy arm and kyphoplasty group were diminished, most likely because of fracture healing.

Further randomized controlled trial evidence comes from the Cancer Patient Fracture Evaluation (CAFE) study, which reported a benefit of kyphoplasty over conservative therapy for malignant painful vertebral compression fractures. The CAFE study investigators recruited 134 patients with malignant fractures at 22 sites in Europe, the United States, Canada, and Australia. Approximately 50% of the patients had breast, lung, or prostate cancer metastasis, and 40% had multiple myeloma–related fractures. Patients with osteoblastic tumors, primary bone tumors such as osteosarcoma, or plasmacytoma at the index compression fracture were excluded. Patients were randomly assigned to kyphoplasty \((n = 70)\) or conservative therapy \((n = 64)\). The median estimated symptomatic fracture age was 3.5 months (interquartile range, 1.2 to 6.8); 87 of 129 patients had edema on MRI. The primary end point was back-specific functional status as measured by the RDQ at 1 month. There was a statistically significant reduction in RDQ scores in favor of kyphoplasty at 1 month \((P < 0.0001)\). The mean RDQ score in the kyphoplasty group was reduced from 17.6 at baseline to 9.1 at 1 month, as opposed to a mean change in score from 18.2 to 18.0 in the control group, and the kyphoplasty treatment effect on the RDQ score was −8.4 points at 1 month (95% CI, −7.6 to −9.2; \(P < 0.0001)\). Patients in the kyphoplasty group also had greater reductions in back pain—both groups had baseline mean back pain score of 7.3; the mean score at 7 days was 3.5 versus 7.0 in the conservative arm \((P < 0.0001)\), which remained significant at 1 month \((P < 0.0001)\). In addition, there were significant reductions in analgesic use and days of bed rest and improvement in quality of life (as measured by the SF-36 PCS) and Karnofsky performance status in the kyphoplasty group versus the conservative arm. These improvements in pain, overall functional status, and quality of life continued for the 12 months of the study period.

With regard to longer-term outcomes, there are few data. Two-year outcome data from the FREE trial revealed that although there were no longer statistically significant differences in SF-36 PCS or RDQ scores at 24 months, patients in the kyphoplasty arm maintained a statistically significant reduction in back pain scores relative to conservative therapy at 24 months \((P = 0.009)\). A similar benefit was also reported at 36 months following kyphoplasty in a smaller prospective nonrandomized study of 60 patients.

For height restoration, the results are less dramatic. Studies have shown that the magnitude of partial height restoration after vertebroplasty ranges from 2.5 to 8.4 mm and is overall similar to that reported after kyphoplasty. However, many of these studies did not report the incidence of fracture clefts. Overall, restoration of height appears to be related to dynamic mobility of fracture fragments from the presence of a fracture cleft. Dynamic mobility refers to a change in vertebral body height during changes in position, typically an increase in vertebral body height with supine or prone positioning versus the erect position; this typically occurs with fractures at the thoracolumbar junction (T11-L1), where the relatively fixed thoracic spine joins the more mobile lumbar spine. A study of 65 vertebral compression fractures referred for vertebroplasty revealed dynamic mobility in a third of treated levels. All fractures that were mobile had a fracture cleft, and all fractures that were fixed did not have a fracture cleft. Fractures that were mobile had an average absolute increase in anterior vertebral height of 8.4 mm (range, 2.0 to 17.4 mm) and a decreased kyphosis angle of 7.2 degrees (40%) after vertebroplasty. There was no restoration of height or correction of kyphosis in fixed fractures. In general, restoration of vertebral body height and correction of kyphosis may be desirable to improve postural endurance, reduce abdominal crowding, and improve overall pulmonary capacity. However, it remains unclear whether these results have any clinical significance.

### Complications Associated with Vertebral Augmentation

With adherence to careful technique and optimal visualization, the risk for morbidity or mortality from vertebral augmentation is low (Box 67.3). For treatment of benign osteoporotic fractures, complication rates are approximately 1%. Not surprisingly, they are higher for inexperienced practitioners or those attempting the procedure without
adequate image guidance or cement opacification. In the VERTOS II trial, the only complications referable to vertebroplasty that occurred in the 101 patients treated were a urinary tract infection in 1 patient and asymptomatic cement deposition into a segmental pulmonary artery in another. Similarly, in the FREE trial, complications referable to kyphoplasty in the 149 patients treated were one soft tissue hemATOMA and one urinary tract infection. Of note, almost all kyphoplasty procedures in the FREE trial were performed under general anesthesia, and in neither cohort were rates of urinary catheterization reported. In our experience, both vertebroplasty and kyphoplasty can be performed with local anesthesia and conscious sedation in most cases, and urinary catheterization is not required.

The risks are greater in patients with malignancy-related fractures, with an overall complication rate of 5% to 10% being reported. In the CAFE trial, of the 70 patients treated with vertebroplasty, 5% (3/60) had a local complication, with an overall complication rate of 5% to 10% in most cases, and urinary catheterization is not required. In the CAFE trial, of the 70 patients treated with vertebroplasty, 5% (3/60) had a local complication, with an overall complication rate of 5% to 10% in most cases, and urinary catheterization is not required.

In performing kyphoplasty, a cavity is created and will fill first, which theoretically results in a lower rate of cement leakage. In VERTOS II, 72% of treated vertebral bodies demonstrated cement leaks on postprocedure CT, with the majority being discal or into segmental veins; none extended into the spinal canal. All patients remained asymptomatic. There was one patient (1%) with an asymptomatic cement segmental pulmonary embolus.

be performed. Importantly, up to a third of patients will suffer a repeated fracture within 1 to 3 years, with the greatest risk in those with steroid-induced osteoporosis.\textsuperscript{55,56} Thus, prevention of future fractures is particularly important. Although the vast majority of recurrent fractures occur at new levels, a small percentage of patients suffer recurrent fracture at a previously treated level and may gain pain relief from repeated vertebral augmentation.\textsuperscript{57} This being said, caution should be taken when interpreting marrow edema at a previously treated level because according to one study, normal MRI findings following vertebroplasty include persistent or progressive marrow edema at the treated level in up to a third of patients and for up to 6 months after the procedure.\textsuperscript{58}

Biopsychosocial Prescreening for Spinal Cord and Peripheral Nerve Stimulation Devices

Robert J. Gatchel | Robbie Haggard

Pain is a complex and serious medical condition, affecting more than 75 million Americans. Moreover, Gatchel and Gremillion have reported that the most frequently cited reason patients in the United States seek medical care is due to pain. Besides the human suffering, there are enormous economic costs as well associated with chronic pain, in terms of medical care and lost productivity. According to recent statistics from the National Academy of Sciences, the societal costs of chronic pain and related disability in the United States alone is $560 billion to $635 billion each year. Gaskin and Richard have also reported similar costs and note that these annual costs for pain were greater than the annual costs for heart disease, cancer, and diabetes. Unfortunately, many chronic pain conditions are not being successfully treated. Indeed, the important and influential Institute of Medicine (IOM) report, Relieving Pain in America, has highlighted the urgent need for the development of more cost-effective approaches to pain management because the ever-increasing costs associated with current treatment approaches cannot be sustained. Moreover, ongoing pain has been underdiagnosed and undertreated in nearly all health care settings. Therefore, there is still an urgent need for the development of treatment- and cost-effective methods for managing chronic pain, especially when it becomes intractable.

As Gatchel noted, since the early 2000s there has been an expanding role of spinal cord and peripheral nerve stimulation as a potential treatment option for intractable chronic pain. Stimulated by Melzack and Wall’s gate-control theory of pain, which proposes that the activation of low-threshold afferent nerve fibers decreases the response of dorsal horn neurons to unmyelinated nociceptors (thereby “closing the gate” to pain transmission from the spinal cord), a number of clinical applications of this theory have been developed. For example, Shealy and colleagues were the first to apply this theory when they stimulated the dorsal columns for the treatment of chronic, intractable pain. Since that time, implantable dorsal column stimulation (i.e., spinal cord stimulation [SCS]) was developed to treat a wide variety of pain syndromes. As Cameron and Elliot noted, since the time that the SCS procedure was first prompted by the gate-control theory, its potential efficacy has been linked to a number of other mechanisms, such as the activation of spinal pain inhibitory circuits, as well as regional blood flow to various regions at the cerebral level. Subsequently, several groups started to use implantable peripheral nerve stimulators. Peripheral nerve stimulation (PNS) applies an electrical current to the peripheral nerves to relieve the chronic pain symptoms. PNS techniques are used for treating pain in a nerve region that is not accessible by SCS. Nerve regions that are more easily accessed by PNS include the trigeminal nerve, occipital nerve, and subcutaneous peripheral nerves. Conditions for which PNS might be indicated include trigeminal neuropathic pain, occipital neuralgia, supraorbital neuralgia, and inguinal neuralgia. Headache disorders, including migraines and cluster headaches, might also benefit from cranial forms of PNS currently under investigation.

Thousands of stimulators were implanted in the decade following the first attempts. However, successful results with SCS and PNS have been difficult to define empirically, although some consensus in the literature has identified greater than 50% relief of index pain 12 months following implantation as a potential benchmark. Although success rates vary widely from 40% to 80%, conditions commonly treated by SCS include failed back surgery syndrome, peripheral vascular disease, neuropathic pain, multiple sclerosis (MS), and reflex sympathetic dystrophies. Moreover, the initial short-term expense of these implantable therapies has proven to be potentially offset in the long term by the benefits and resultant reduction in treatment expenses. For example, Kumar, Malik, and Demeria evaluated costs for patients who received SCS and compared them to the costs for treatment by conventional pain therapies (CPT) in a control group. Although the cost for SCS was significantly higher than for CPT in the first 2.5 years, after that time point the cost of treating patients with SCS not only became less than the cost for CPT, but it also remained less expensive during the rest of the 5-year follow-up period. Demonstrated success rates are no greater than 50%, although these initial high costs for implantable therapies make it necessary in the current evidence-based medicine environment to find means of better identifying those 50% of patients who are more likely not to benefit from the procedure.

It should also be noted that various side effects (e.g., neural impairment and scarring) have been observed. There were reports of high complications and failure rates. In an attempt to determine both the positive and negative outcome indicators for surgical procedures, Spengler and Freeman initially performed a retrospective analysis of 30 patients who...
had unsuccessful outcomes from various surgical procedures for low back pain, sciatica, or both. Among their findings, the most commonly reported cause of the poor results was a poor initial candidate-selection process, despite initial indications for the surgical procedures. A more focused investigation identified instances of drug abuse, alcoholism, marital discord, and personality factors that were likely to have played a role in the patients’ postsurgical success or failure. Spengler and colleagues therefore recommended presurgical psychological evaluation in order to reduce the likelihood of unsuccessful procedures. Following closely on the heels of the report by Spengler and colleagues, Long and colleagues performed a retrospective analysis of their own patients, who received surgically implanted dorsal column stimulators between 1970 and 1973. At that time, the only method for identifying candidates for this procedure was a persisting self-report of pain after failing all other treatments. Long and colleagues found that too few patients achieved satisfactory pain relief with SCS and that approximately half of those patients originally selected for the procedure would have been rejected using updated inclusion criteria. Psychosocial factors were the most frequent reasons for failures, including substance use disorders.

Thus, it was soon recognized that not all patients were good candidates for such implantable devices. Indeed, starting with spinal surgery, clinical researchers became more involved in prescreening patients for these invasive interventions. Before discussing an example of more current attempts, a discussion of the biopsychosocial approach to assessment is warranted.

### THE BIOPSYCHOSOCIAL APPROACH TO ASSESSMENT

The biopsychosocial approach is recognized as the most comprehensive and heuristic approach to the evaluation of medical disorders. The biopsychosocial model focuses on the complex interaction among biologic, psychological, and medicolegal variables that patients encounter when coping with a persistent, distressing medical condition. This interaction may perpetuate, and even worsen, the clinical presentation. This complex interaction accounts for the likelihood that a patient’s life will be adversely affected in a variety of ways by his or her medical condition, thus requiring a comprehensive assessment and treatment approach designed to address all aspects of required care (i.e., biologic and psychosocial). This approach is in contrast to the former biomedical reductionist approach, which mistakenly assumed that most medical conditions, such as chronic pain, can be separated into distinct, independent physical and psychosocial components. Each patient experiences a medical condition uniquely. The complexity of a condition can be especially evident when it persists over time as a range of psychological, social, and economic factors emerge. These factors interact with the physical pathology to modulate a patient’s discomfort and disability associated with the condition. Therefore, any successful assessment of patients needs to comprehensively evaluate these various factors.

A review by Gatchel and coworkers highlighted how individuals significantly differ in the frequency of reporting physical symptoms, in their tendency to visit physicians when experiencing identical symptoms, and in their responses to the same treatment. Moreover, the nature of a patient’s response to treatment has little to do with his or her objective physical condition. A comprehensive assessment of a patient proceeds from a global biopsychosocial diagnosis of the disorder in question, to a more detailed evaluation for the most important interactive factors needed for the diagnosis. For example, for a patient reporting low back pain, a comprehensive physical examination would initially be conducted to assess the bio-component of the equation. This examination would consist of the assessment of range of motion, tenderness, gait, posture, sciatic stretch tests, and the neurologic components of myotomal/dermatomal deficits or reflex change. The examination is valuable when it defines objective signs that may lead to further diagnostic or treatment recommendations. It is less valuable when it is nonspecific or demonstrates pain inhibition. Waddell and colleagues were the first to describe behaviors of back pain patients on physical examination that they termed nonorganic or behavioral signs. They suggested that a patient might not have a simple, straightforward physical diagnostic problem. Thus, a comprehensive biopsychosocial assessment of each patient is needed before the development of a treatment plan. The same such comprehensive assessment is needed before prescribing use of implantable devices for chronic pain.

### THE BIOPSYCHOSOCIAL PRESCREENING PROCESS

#### SUMMARY OF CLINICAL RATIONALE AND PROCESS OF PRESCREENING

The process of test selection for prescreening can be difficult for the clinician not experienced with this process. The instruments described herein are a comprehensive battery, based on the work of Block and colleagues. These can be used as a foundational starting point for the clinician who has been asked to screen and evaluate patient candidates for SCS or PNS (Block’s work will be reviewed at greater length in the next section of this chapter). A general survey of pain symptoms is a necessary starting point for any pretreatment evaluation in a pain program. A general intake assessment should include a survey of pain symptoms, along with other self-report items such as demographic information, date of onset and pertinent details of the pain condition, prior treatments or surgeries, employment status, education level, disability payment status, workers’ compensation or personal injury litigation involvement, health care utilization, additional contact numbers, and other comorbid chronic health problems. A brief summary of these assessment tools is provided here:

- First developed in 1976, the visual analog scale (VAS), also referred to as the pain drawing analog (PAD), is a scale designed to rate the patient’s degree of pain on a scale from 0 (no pain) to 10 (worst possible pain). It is made up of a 10-centimeter horizontal line divided at two-point intervals, and patients mark an “X” on the line to represent current levels of pain. The psychometric properties
and utility with chronic pain populations of the VAS/PDA are further described in the literature.37,38

- A further development of the VAS/PDA is the million visual analog scale (MVAS).39 The MVAS consists of 15 self-report items specific to perceived pain and disability. Patients respond on a similar 10-centimeter line, representing a range of possible answers from 0 to 10, in which the total score is the sum of all responses. Various cutoff points have been described based on psychometric testing of the MVAS. Scores of 0 to 39 indicate “mildly disabling” pain, scores of 40 to 84 indicate “moderately disabling pain,” and scores of 85 and above indicate “severely disabling pain.” The MVAS is especially helpful for discrepancies, such as when self-reported pain is higher than expected based on physical findings. This is often suggestive of a potential psychosocial component in the patient’s experience of pain.40

- The Oswestry Disability Questionnaire41 is another self-report scale designed to assess the degree of functional impairment. Consisting of 10 items regarding limitations of activities of daily living due to pain, the Oswestry has demonstrated test-retest reliability of .99 with a 24-hour interval between administrations, as well as acceptable levels validity.42,43 Each item is scored on a 0- to 5-point scale, with a potential range of scores from 0 to 50, with higher scores significant for higher levels of pain-related limitations.

- Adams and colleagues44 developed the Pain Medication Questionnaire to determine the risk of medication misuse among chronic pain patients. Identified behavioral correlates and attitudes suggestive of medication misuse were used to develop the 26 self-report items that make up the PMQ. Higher scores indicate a likely greater incidence of substance abuse potential, emotional distress, impaired coping skills, reduced physical functioning, as well as higher rates of unemployment.44

- The Beck Depression Inventory (BDI-II) is a 21-item self-report inventory designed to assess the intensity of depressive symptomatology.45 Each item is scored from 0 to 3, with a potential range of scores from 0 to 63. A total score of 0 to 9 is considered normal, 10 to 15 is mild depression, 16 to 19 represents mild to moderate depression, 20 to 29 reflects moderate to severe depression, and 30+ indicates severe depression. Being able to identify symptoms of depression is important in chronic pain populations, as is being able to delineate between cognitive and somatic specific symptoms, which is an option allowed by the BDI-2. To obtain more than the subjective self-reported symptoms of depression available with the BDI-2, an experienced clinician will also want to perform a more objective assessment of depression to validate or clarify his or her findings. One such tool that is widely available, but does require some training and experience, is the Hamilton Rating Scale for Depression (HAM-D),46 which is administered by the clinician in a brief interview format and could potentially be incorporated into the overall clinical interview.

In addition to examining the current emotional status of the patient candidate prior to SCS or PNS implantation, long-standing personality traits are important to consider before a patient begins a life-changing process that implantable therapies entail. Although these inventories are lengthy and time consuming, they have been used extensively in chronic pain populations. Third-party payers may limit the type or extent of testing that is performed with presurgical candidates, but the two inventories reviewed here provide valuable insight into the characteristic way these patients relate to the people and situations around them. If time and the situation allow, they should be considered as part of the comprehensive prescreening evaluation. The Millon Behavioral Medicine Diagnostic (MBMD)47 is a 165-item, self-report inventory that examines psychosocial factors that may impact treatment outcomes with medical patients. The MBMD includes 29 clinical scales, three response pattern scales, one validity indicator, and six negative health habits indicators. It is intended for adult clinical and rehabilitation patients (ages 18 to 85) who are undergoing medical care or surgical evaluation, making this a valuable resource for the prescreening process.

A more widely recognized personality assessment, which has been used extensively in chronic pain research, is the Minnesota Multiphasic Personality Inventory-2 (MMPI-2).48 Although the MMPI-2-RF is gaining popularity in clinical settings, most research relating to pain is based on the MMPI-2, so this chapter will focus solely on that particular inventory. The MMPI-2 is a 567-item, self-report measure of personality functioning and psychiatric symptoms. It is the most commonly used personality assessment for patients with chronic pain, who often demonstrate a higher prevalence of emotional distress, specifically depressive symptoms and potential personality disorders, relative to the general population.49 There are 10 empirically derived clinical scales, various supplementary scales, and validity scales provided to assess the test-taking attitudes of the patient. The MMPI-2 has a great deal of utility when used as part of the prescreening process with chronic pain patients. Findings from the MMPI-2 can help in the identification of psychopathology, personality and behavioral characteristics, treatment planning, and prediction of treatment outcomes.49

Current quality of life is also an important factor for patients being considered for an implantable therapy device, as this can interrupt current lifestyle during training and adjustment and can also improve quality of life for many of those receiving this option. The Medical Outcomes Survey 36-Item Short Form Health Survey (SF-36)50 is a 36-item questionnaire that assesses health-related quality of life, both physical and mental, from the patient’s perspective. The SF-36, and variants of this measure, is widely used for assessment and follow-up monitoring of health care treatment outcomes. The SF-36 consists of eight subscales and two standardized summary scales, the Mental Component Scale (MCS) and the Physical Component Scale (PCS). The MCS and PCS provide an overall gauge of the patient’s sense of physical and mental well-being.

The coping skills that patients already rely on are necessary for the clinician performing the prescreening to identify, as these will likely be the set of coping skills employed during the training and postimplant phase of treatment. If there is a notable lack of healthy coping skills, this is something that might be managed prior to, and following, surgery with biobehavioral therapy. The Coping Strategy Questionnaire (CSQ)51 is a 42-item self-report inventory that assesses how often pain patients use six cognitive coping
strategies and two behavioral coping strategies. These strategies include diverting attention or distraction, reinterpreting pain sensations, ignoring pain, praying and hoping, coping self-statements, increasing behavioral activities, and catastrophizing. Additionally, the CSQ measures the subjective ability to control and decrease pain. Patients rate on a 6-point scale activities they engage in when experiencing pain, where 0 = never do that, 3 = sometimes do that, and 6 = always do that.

Although all of the aforementioned assessment tools are useful for performing a comprehensive prescreening evaluation, again it is up to the clinician to obtain the proper training to perform these assessments, along with a thorough clinical interview. These data can then be used to prepare a detailed report of the findings for both the patient and the physician performing the implantation procedure. In addition to performing these tasks, it should also be within the clinician’s repertoire to know how to ask about what treatments the patient has found helpful in the past, what prescriptions and over-the-counter medications the patient is taking, what the patient’s activities of daily living entail now and prior to the pain condition, and what the patient’s realistic expectations are for life postprocedure.

THE PRESCREENING PROCESS DEVELOPED BY BLOCK AND COLLEAGUES

As noted earlier, there have been attempts to prescreen patients who were being considered for surgery.29 Epker and Block53 reviewed the methods for predicting positive outcomes for spine surgery in general and highlighted the positive and negative psychosocial risk factors that appeared to impact recovery from spine surgery. They delineated specific risk factors that had been shown to predict a poor surgical outcome and suggested the evaluation and quantification of these factors before performing spine surgery in order to predict positive outcomes. Three major categories of psychosocial factors were described: (1) personality/emotional, (2) cognitive/behavioral, and (3) environmental/historical. Scale elevations on the MMPI-2 associated with pain sensitivity (scales 1 and 3), depression (scale 2), anger (scale 4), and anxiety (scale 7) were the most noteworthy factors negatively influencing outcomes. Other significant factors included maladaptive coping strategies, workers’ compensation status, litigation related to pain, and drug and alcohol abuse. Epker and Block53 also discussed “quasi-medical” risk factors that could predict poor results: the duration of pain and number of previous surgeries for pain are negatively correlated with positive outcomes, and smoking and obesity can also have a negative effect on recovery from surgery. Finally, they noted that the presence of nonorganic Waddell signs (see Waddell and coworkers35) can help identify candidates who will have poor outcomes.

Subsequently, the most comprehensive screening approach for spine surgery was presented by Block and colleagues.29 They developed a “scorecard” to clarify the spine surgery candidate’s biopsychosocial risk factors, using an array of factors. The scorecard lists and quantifies each of psychosocial risk factors, along with additional medical risk factors. Based on the extant research demonstrating predictive ability, each risk factor is assigned an a priori weight of high risk (2) or medium risk (1), and the risk factors in each group (medical and psychosocial risks) are then totaled to arrive at a surgical prognosis. They based this approach on a study conducted by Block and colleagues.35 In that study, 204 patients were referred for spine surgery and were evaluated no more than 1 month prior to surgery. A semistructured interview and two psychosocial questionnaires, the MMPI-2 and the Coping Strategy Questionnaire (CSQ),55 were used to evaluate the psychosocial and medical risk factors. Based on the results of screening, patients were placed into one of three predictive categories (“good,” “fair,” or “poor”). Analyses of results showed the screening achieved an 82% accuracy rate, with 82.3% of patients in the “good” group experiencing a good outcome and 83.0% of patients in the “poor” prognostic group resulting in poor outcome. Logistic regression analyses were also conducted to determine which variables were the most significant predictors of outcome. These analyses yielded psychosocial test data as the most significant cluster of variables to correctly classify patients, with a correct classification rate of 78.4%. The addition of psychosocial interview data brought the model up to an 83.3% correct classification rate. Finally, the addition of the medical risk factors contributed slightly, bringing the total model to 84.3% correctly classified. This study was the first empirical investigation to show that a large number of psychosocial and medical risk factors can be identified, quantified, and used to accurately predict surgical outcomes.

The original screening scorecard, developed by Block and associates,35 was subsequently replaced with a new prognostic algorithm by the same group.29 This algorithm added several new features that enhanced its predictive utility. The changes involved the following:

- The algorithm placed psychosocial risk factors above all others because they have proven to have the most predictive power.
- A category termed adverse clinical features was also included to account for factors such as inconsistency, compliance issues, and medication seeking (which were often found in the patients’ medical charts and observed during the clinical interview).
- A set of general treatment recommendations was added. The psychologists’ recommendations fell into five categories: (1) proceed with surgery; (2) surgery, but with postoperative psychosocial treatment sessions; (3) preoperative treatment psychosocial sessions prior to surgery; (4) only noninvasive therapy recommended; or (5) no treatment of any kind is recommended.

REVIEW OF CLINICAL STUDIES

In the past, only a few studies have systematically evaluated the predictive value of biopsychosocial risk factors and treatment outcomes for implantable devices.55-57 Moreover, they have varied in their methodologies. Our clinical research group therefore decided to use a more structured, standard approach. Using the presurgical screening algorithm developed by Block and colleagues, we were the first to evaluate its validity and application in categorizing patients’ potential suitability as candidates for a subset of
implantable modalities (specifically, spinal cord stimulators and intrathecal opioid pump systems). \(^{58,59}\) The rationale for using an algorithm developed for spinal surgery for patients being considered for potential implantable devices was noted as follows:

Of course, one might argue that, because neuromodulation is quite different from spine surgical intervention, this algorithm would not be applicable to the former. However, for any type of presurgical screening that involves stress and uncertainty, such as the current one, the global psychological resilience of the patient (including the psychological strengths and weaknesses in dealing/coping with stress) is the key entity that is evaluated. That is to say, the global capacity of the patient to respond adaptively, whatever the specific challenges of any particular surgery, is the key ingredient. With this in mind, it was expected that Block’s algorithm would be clinically applicable to neuromodulation procedures. We attempted to delineate differences found among prognostic groups with regard to psychosocial, functional and medical risk factors. (p. 238)\(^{59}\)

The algorithm used in the investigation by Schocket and colleagues\(^{59}\) included both psychosocial and medical risk factors, as delineated in \textbf{Box 68.1}. On the basis of this algorithm, patients were classified into one of five groups: Green (proceed with surgery); Yellow I (proceed with surgery, but administer postoperative psychosocial intervention); Yellow II (administer preoperative psychosocial intervention before surgery); Red I (only noninvasive intervention is recommended); and Red II (no treatment of any kind is recommended). Although this investigation did not provide the opportunity for long-term follow-up of all patients, data were collected from patients who were able to complete a 6-month follow-up evaluation. The results of this evaluation revealed a trend among the groups in terms of additional medications being taken. As expected, the Green group showed 40% of patients to be taking no new medications at the 6-month follow-up. This percentage decreased as prognosis worsened (Yellow I, 27.3%; Yellow II, 25%; and Red I and II, 0%). Although these were only statistical trends, due to limited power because of a relatively small sample size, the results do suggest a clinically significant change. Obviously, additional clinical research of this type is needed.

\textbf{SUMMARY AND CONCLUSIONS}

In this chapter, we initially highlighted the fact that chronic pain is a very prevalent and costly medical condition in the United States. When it becomes intractable in nature, more invasive methods often must be employed. One category of methods consists of implantable devices, such as SCS and PNS. This category of methods was then reviewed, as well as the pain syndromes they have been used for. It soon became apparent, though, that not all patients experienced positive outcomes after implantation. This prompted the need for more careful prescreening methods to help determine which patients would be good versus bad candidates for such an implantable-device intervention. A comprehensive biopsychosocial evaluation was presented as the best method to use for prescreening purposes. The various instruments that have been could be used in the evaluation were reviewed.

In terms of the evaluation, as recently reviewed by Gatchel,\(^{10}\) many complex biopsychosocial interactions can significantly affect how individuals respond to implantable devices, such as spinal cord and peripheral nerve stimulation. Indeed, again, appropriate biopsychosocial screening before such interventions are essential to maximize the benefits of the devices. As discussed in this chapter, we are beginning to make promising advances in this area by developing standardized prescreening protocols. For example, Block and colleagues\(^{29,35}\) have developed an impressive screening algorithm for patients being considered for spine surgery. As an extension of this screening algorithm, Gatchel and colleagues\(^{58,59}\) were the first to develop a modified prescreening protocol (based on that developed by Block and colleagues) for patients being considered for surgically installed implantable devices, specifically spinal cord stimulators and intrathecal pump devices. The results of this novel approach have been found to be quite promising, but it was pointed out that additional clinical research is still greatly needed to both refine the screening technique and examine long-term outcomes of its efficacy. There is also still a great need for evaluating the short- and long-term cost-effectiveness of these implantable devices, relative to

\textbf{Box 68.1 The Psychosocial and Medical Risk Factors Used by Schocket and Colleagues}

less invasive forms of treatment. The final conclusion is that despite the promising results reviewed in this chapter, there is still a dearth of well-controlled evidence-based clinical research studies addressing this potentially useful approach for relieving unremitting chronic pain using palliative approaches. This research has been called for a great many times, starting with Gatchel in the early 2000s, but to no avail.

Spinal cord and Peripheral Nerve Stimulation

Robert W. Hurley | Allen W. Burton

SPINAL CORD STIMULATION

Spinal cord stimulation (SCS), sometimes called dorsal column stimulation, describes the use of pulsed electrical energy near the spinal cord to control pain. This technique was first applied in the intrathecal space and later in the epidural space as described by Shealy and associates in 1967. In the present day, neurostimulation commonly involves the implantation of leads in the epidural space to transmit this pulsed energy to the spinal cord or the desired nerve roots. This technique has notable analgesic properties for neuropathic pain states, anginal pain, and peripheral ischemic pain. The same technology can be applied in deep brain stimulation, cortical brain stimulation, and peripheral nerve stimulation. These latter techniques are typically in the realm of the neurosurgeon, although more and more pain physicians are using peripheral nerve stimulation techniques. This chapter concentrates on the modality of spinal cord (dorsal column) stimulation.

MECHANISM OF ACTION

Neurostimulation began shortly after Melzack and Wall proposed the gate control theory in 1965. This theory posed that painful peripheral stimuli carried by unmyelinated C fibers and lightly myelinated Aβ fibers terminated at the substantia gelatinosa of the dorsal horn (the gate). Large myelinated Aβ fibers responsible for touch and vibratory sensation also had collateral input to “the gate” in the dorsal horn. It was hypothesized that their input could “close the gate” to the cephalad transmission of painful stimuli. As an application of the gate control theory, in 1967 Shealy implanted the first spinal cord stimulator device for the treatment of chronic pain. This technique was noted to control pain and has undergone numerous technical and clinical refinements in the ensuing years.

Although the gate theory was initially proposed as the mechanism of action, the underlying neurophysiologic mechanisms are not clearly understood. Research has given us insight into effects occurring at the local and supraspinal levels and through dorsal horn interneuron and neurochemical mechanisms. Linderoth and colleagues have noted that the mechanism of analgesia when SCS is applied in neuropathic pain states may be very different from those involved in analgesia as a result of limb ischemia or angina. Experimental evidence points to SCS having a beneficial effect at the dorsal horn by favorably altering the local neurochemistry, thereby suppressing the hyperexcitability of the wide dynamic range (WDR) neurons. Specifically, there is some evidence for increased levels of gamma-aminobutyric acid (GABA) release, serotonin, and perhaps suppression of levels of some excitatory amino acids including glutamate and aspartate. In the case of ischemic pain, analgesia seems to be obtained through restoration of a favorable oxygen supply and demand balance, perhaps through alteration of sympathetic tone. Guan and colleagues made three substantial findings in an in vivo model of SCS and neuropathic pain: (1) stimulation of either the dorsal horn or dorsal nerve roots at intensity and frequency to selectively activate Aβ fibers reduced WDR neurons spontaneous firing in animals with neuropathic injuries; (2) this same stimulation reduced WDR responses to mechanical stimulation of normal and injured animals; and (3) stimulation of the dorsal columns, but not the dorsal root, reduced activity-dependent neuronal excitability (wind-up). Other experimental evidence has suggested that antidromic stimulation from dorsal column stimulation of cutaneous fibers plays a role in the analgesic effect of SCS and possibly the result of antidromic inhibition of orthodromic transmission.

PATIENT SELECTION

Patient selection is the most challenging and important step in the decision to offer neurostimulation. Although it can be viewed as a burden or barrier by both the patient and the physician, the additional time dedicated to the selection of patients who are most likely to positively respond to the therapy in the short and long term is time well invested. The challenge pain physicians face is being able to predict who will respond well with durability. There are relatively few data to guide pain physicians in this realm; most of the studies examining who is a good candidate for SCS therapy are small prospective or retrospective studies. In a study examining 36 patients with complex regional pain syndrome (CRPS) treated with SCS, the authors found that mechanical allodynia of the affected limb was negatively correlated with SCS therapy success, and patient age, duration, or intensity of pain had no relationship to SCS outcome. In patients with CRPS, response to a sympathetic nerve block may positively correlate with SCS therapy outcome. Many patients with chronic pain have some symptoms of depression; psychological screening can be extremely helpful for avoiding failed implants in patients with major psychological disorders. An interesting study by Olson and colleagues revealed a high correlation between many items on a complex psychological testing battery and favorable response to trial stimulation. In a systematic review, it was noted...
that symptoms of depression, somatization, anxiety and poor coping skills were predictors of poor SCS outcome.\cite{15}

It appears that overall mood is an important predictor of outcomes. Paradoxically, the psychological construct of catastrophizing, which has been negatively associated with other pain therapies, was not detrimental to the positive SCS outcome in patients with CRPS.\cite{16} Sex and age of patients as well as laterality of pain have also been examined for predictive value and none have been found to impact the results of the SCS therapy.\cite{17} Relatively few randomized controlled studies have been performed that evaluate long-term predictors of success or failure from SCS therapy for specific pain disease processes.\cite{18,22}

The evaluation of a patient for spinal cord stimulation is a staged process (Box 69.1). Appropriate patients for a trial of neurostimulation must meet the following criteria: (1) the diagnosis is amenable to this therapy (e.g., neuropathic pain syndromes), (2) the patient has failed conservative therapy, and (3) significant psychological issues have been ruled out.\cite{23}

### IMAGING

Magnetic resonance imaging (MRI) or computed tomography (CT) to determine patency and sufficiency of the high lumbar and low to mid thoracic epidural space should be used to evaluate patients progressing forward to the implantation phase of the thoracic SCS. Ruling out moderate to severe stenosis increases the safety of the procedure. This evaluation may also guide the pain physician’s decision to refer the patient to a surgeon for implantation—for instance, if a surgical decompression is needed prior to implantation of the lead system. Cases of mild (nonoperative) spinal stenosis at the target levels could lead the physician to choose a smaller cylindrical lead rather than the paddle-type leads.

### CONSERVATIVE THERAPY

Despite the increase in the number of agents available to treat neuropathic pain, a substantial number of patients still suffer from poorly controlled neuropathic pain. Puig estimates that many as 50% of patients with neuropathic pain have ineffective pain relief even with appropriate pharmacological management.\cite{24} Recommended selection criteria from these authors include (1) confirmed diagnosis of neuropathic pain; (2) chronicity of greater than 6 months; (3) failed trials of polypharmacy including anticonvulsants, antidepressants, and other drugs (such as opioids) because of lack of efficacy or side effects; (4) a lemniscal pathway (spinal connection to painful site) that has been preserved so that stimulation-induced paresthesias can be felt; and (5) the absence of contraindications including nociceptive pain syndromes, psychological disturbance, infection at site, systemic bacterial infections, and a lifestyle that is incompatible with longevity of therapy (patient employed in field requiring excessive repetitive flexion and extension, MRI technician, etc.).

### TRIAL

A careful trial period is essential to avoid a failed implant. Trials of different lengths have been advocated; the risk of a longer trial is mainly infection, whereas the primary risk of too short a trial is a false-positive result. We use a 5- to 8-day trial and encourage patients to be as active as possible in their usual environment, with the exception of limiting bending and twisting movements. In rare circumstances, the author (RWH) uses a permanent trial implantation (discussed later) whereby the percutaneous leads are placed and secured in the same fashion and the entire permanent system is placed with the exception of the implantable pulse generator (IPG); a tunneled lead extension is externalized and connected to the trialing system. Patient selection and physician discretion are exceptionally important in these cases, as there is a natural bias to going forward with the remainder of the implant because of the commitment that has already been made by implantation of the permanent leads. In “perm-trial” cases, the trial period is often much longer than the percutaneous trial, as in this author’s (RWH) experience of up to 3 weeks.

Despite advances in our understanding of diagnoses that respond to neurostimulation, improved psychological screening, and the availability of improved multilead systems, clinical failures of implanted neurostimulator devices remain all too common. Pain physicians must critically evaluate their own outcomes and adhere to the strict selection criterion outlined here. Simpson published a neurosurgeon’s perspective on the use of SCS in treating chronic pain.\cite{25} To paraphrase Simpson,

*The mindset of the public and many physicians favors drugs over physical treatments such as surgery and neurostimulation, and many physicians exhibit a “protective” reluctance to refer for these procedures, but are prepared to persist with polypharmacy despite the real risks of mental impairment, nausea, constipation, weight gain, and addiction. The worst thing a neurostimulator can do is fail to work.*

Many pain specialists are beginning to side with Simpson on this issue, preferring a trial of SCS before committing a patient to chronic opioid therapy. Although this is true, the corollary is also the case and would suggest caution against the overly liberal application of the technology.
In examining one’s own outcomes with SCS therapy, several factors must be considered:

1. Examination of your trial to permanent ratio data. These data will tell you what percentage of the patients you trial go on to have a permanent implantation. All things being equal (with the assumption that all permanent implantations were the correct decision) this ratio will give a hint to your ability to select appropriate patients for this therapy. A ratio below 50% would suggest you are not being selective in your application of the therapy, and a ratio of 95% would suggest you are being too selective and more than likely not offering the therapy to those who could benefit.

2. Examination of your permanent implantation data:
   a. Number of patients who continued to use the SCS in the long term
   b. Number of patients who had the permanent system removed
   c. Number of surgical site infections (within 1 year of implant) and proximate cause
   d. Number of clinically significant migrations
      i. How many were resolved with re-programming
      ii. How many were resolved with re-operation
   e. Number of other adverse events (not already listed)

3. Long-term pain relief success of therapy. This applies to follow-up with your SCS patients at regular intervals to reassess their success or lack thereof. A common interval recommended is every 6 months to every year (at the maximum).

4. Assessment of other quality-of-life indicators:
   a. Improvement in activities of daily living (household chores, fitness activities)
   b. Improvement in psychological factors (mood, pain coping, anxiety)
   c. Improvement in patients’ sleep, personal relationships

5. Assessment of medication intake. What reductions in pain medication have occurred? (Have you, as the physician, addressed this issue and attempted to wean medications?)

**TECHNICAL CONSIDERATIONS**

SCS is a technically challenging interventional/surgical pain medicine technique. It involves the placement of an electrode array (leads) in the epidural space, a trial period, anchoring the lead(s), positioning and implantation of the pulse generator or radiofrequency (RF) receiver, and the tunneling and connection of the wires. This is one of the more complex procedural skills in pain medicine and is an excellent example of why pain medicine is a subspecialty of the practice and should not be performed by a nonphysician or non-pain medicine trained physician.

A spinal cord stimulator system is made up of three parts: (1) electrodes or leads (Fig. 69.1), (2) IPGs or the battery (Fig. 69.2), and (3) the charging and programming systems (see Fig. 69.2). Electrodes are of two types: cylindrical (formerly known as percutaneous) and paddle (formerly known as surgical) (see Fig. 69.1). These electrodes are connected to an IPG or (historically, but no longer available) an RF unit. Currently, three companies—Medtronic, Inc., St. Jude Medical, Inc., and Boston Scientific Corp. (formerly Advanced Bionics, Inc.)—make neurostimulation equipment (Appendix A). Historically the paddle-type lead could only be implanted via a laminotomy or more extensive surgical procedures.
laminectomy. In 2011, one neuromodulation company introduced a system by which a surgical paddle lead (single 8-contact column) could be implanted in a percutaneous fashion using a wide flat introducer that is placed via the Seldinger technique (Fig. 69.3). This has allowed advanced pain physicians who are not spine surgeons to take advantage of these lead systems.22

A spinal cord stimulator trial may be accomplished in two ways: percutaneous or permanent lead trial. In both trial methods, under fluoroscopy and sterile conditions (Table 69.1), a lead is introduced into the epidural space with a standard epidural needle or curved epidural needle. To facilitate threading of the lead cephalad in the dorsal midline region, it is imperative to have the needle at a shallow angle (often less than 45 degrees). It is essential to avoid perpendicular or near perpendicular needle placement into the epidural space (unless using a curved needle) because of the consequent 75- to 90-degree bend then required to introduce the stimulator lead. The lead is directed under fluoroscopic imaging into the posterior or dorsal paravertebral epidural space up to the desired anatomic location—generally the low thoracic cord region (commonly T8 to T10) to obtain paresthetic coverage of the lower extremities or the midcervical level to obtain coverage of the upper extremities (i.e., the lead is moved cephalad and caudad in the epidural space until the pattern of resulting electrical stimulation overlaps the painful region; Fig. 69.4). Trial stimulation is undertaken to attempt to cover the painful area with an electrically induced paresthesia. After the painful area is captured with either one or more leads, the two techniques of trialing differ.

In the percutaneous trial, the needle is withdrawn, the lead is adhered in place (with a suture, surgical skin glue, or surgical adhesive), a chlorhexidine impregnated patch (RWH) and a sterile dressing is applied. The lead passes from the epidural space, through the skin to the external pulse generator throughout the trial period. When the patient returns after a trial of several days, the dressing is removed, and the lead is removed and discarded regardless of the success of the trial. When the patient returns for an implant, a new lead is placed in the final location of the trial lead contacts and connected to an IPG.

In the permanent lead trial, after successful positioning of the trial lead(s), local anesthetic is infiltrated around the needle(s) and an incision is made, cutting down to the supraspinous fascia to anchor the leads securely using nonabsorbable suture. The anchoring device should be placed as closely as possible to the fascia entry site, ideally with the “nose” of the anchor protruding into the fascia to lessen the bending angle of the lead. The anchor is secured using nonabsorbable suture, such as 2.0 silk. At this point, two approaches can be used. The first method requires opening up the midline back incision. In this technique, the proximal end of a temporary extension wire is connected to the permanent lead, and the distal end is tunneled away from the back incision and out through the skin. The second method does not require reopening the midline back incision; instead a pocket for the IPG is created. With this technique, the IPG pocket is created and the permanent lead is tunneled into this pocket; an extension lead is then connected to the permanent lead and the distal end is tunneled away from the IPG pocket. The IPG pocket is then sutured closed. With either technique, this exiting connector is secured to the skin using a suture (or surgical skin glue), antibiotic ointment, and a sterile dressing. If the trial is successful, at the time of implant the back incision (or IPG site incision) is opened and the percutaneous lead extension is cut, pulled out through the
skin site, and discarded. The permanent lead(s) that was used for the trial is attached to a new sterile extension(s) (not needed if at the IPG site) and tunneled (or directly connected) to the IPG.

The permanent lead trial method has the advantages of saving the cost of new electrodes at implant and ensuring that the implanted lead position matches the trial lead position. Advantages of the “percutaneous lead” approach include avoiding the costs of two trips to the operating room (even for an unsuccessful trial, this is necessary to remove the anchored trial lead); avoiding an incision and postoperative pain during the trial, which may confuse trial interpretation by the patient; and avoiding the risk of infection associated with the percutaneous temporary extension. The percutaneous extension must be anchored and meticulously dressed or the risk of infection may be higher than with the straight percutaneous technique. The majority of clinicians favor the percutaneous trial method. Most consider 50% or more pain relief to be indicative of a successful trial, although the ultimate decision also should include other factors such as activity level and medication intake. Some combination of pain relief, increased activity level, and decreased medication intake is indicative of a favorable trial.

A trial with paddle-type electrodes (with the exception of the previously mentioned percutaneous paddle introduction technique) requires the implanted lead approach with the significant addition of a laminotomy to slip the flat plate electrode into the epidural space. Some physicians trial the patient with the percutaneous approach and if successful send the patient to a neurosurgeon for a paddle-type implant.

The IPG is generally implanted in the flank, occasionally in the posterior superior gluteal area or rarely the lower abdominal area or pectoral region. It should be in a location the patient can access with the dominant hand for adjustment of the settings with the patient-held remote control unit. The decision to use a rechargeable implantable IPG is based on several considerations. If the patient’s pain pattern requires the use of many anode or cathode settings with high power requirements during the trial, consider a rechargeable, higher-capacity unit. The IPG battery life largely depends on the power settings used, but the newer IPG units generally last several years at average

| Table 69.1 Sterile Setup for Spinal Cord Stimulator Trial and Permanent Implant |
|---------------------------------|-----------------|-----------------|
| Surgeon                         | Patient         | Instruments     |
| Percutaneous Trial Lead         | Hair coverage, eye protection | Pre-procedure chlorhexidine shower | Sterile covering for fluoroscopic machine |
|                                 | Surgical scrub  | Sterile skin preparation with alcohol-based chlorhexidine scrub | Lead kit from company |
|                                 | Sterile gown, gloves | Towels and full surgical drape | 
| Permanent or Perm Trial Lead    | Hair coverage, eye protection | Pre-procedure chlorhexidine shower | Sterile covering for fluoroscopic machine |
|                                 | Surgical scrub  | Pre-operative antibiotics for coverage of skin flora (cefazolin or clindamycin) | Lead kit from company |
|                                 | Sterile gown and gloves | Sterile towels  | Implantable pulse generator (IPG) from company (if IPG implantation is intended) |
|                                 |                 | Iodine-impregnated adhesive dressing (unless iodine allergic) | |
|                                 |                 | Full surgical drape | |

power settings. All three manufacturers offer rechargeable IPG systems with two significant advantages over the previous IPG devices: (1) the patient may use higher voltage settings without worry of prompt battery depletion, allowing more flexibility in programming, and (2) the promise of a much longer interval until replacement is required, perhaps 10 years or more. The unit is recharged via an external recharge every 7 to 14 days as needed.

**COMPLICATIONS**

Complications associated with spinal cord stimulation range from simple, easily correctable problems—such as lack of appropriate paresthesia coverage—to devastating paralysis, nerve injury, and death. Prior to implantation of the trial lead, an educational session should occur with the patient and family members. This meeting should include a discussion of possible risks and complications. In the postoperative period, the caregiver should be involved in identifying problems and alerting the health care team.

North and colleagues reported their experience in 320 consecutive patients treated with SCS between 1972 and 1990.27 A 5% rate of subcutaneous infection was observed, which is consistent with other published trials. The most frequent complication was lead migration or breakage, and that remains the predominant weakness of neurostimulation. The revision rate for patients with modern multichannel devices was 16%. Failure of the electrode lead was observed in 15% of patients and steadily declined over the course of the study as the lead systems were modernized. When analyzed by implant type (single-channel percutaneous, single-channel laminectomy, and multichannel), the lead migration rate for multichannel devices was approximately 7%. Analysis of hardware reliability for 298 permanent implants showed that technical failures (particularly electrode migration and malposition) and clinical failures had become significantly less common as implants had evolved into programmable, multichannel devices and anchoring technique and equipment have improved.

Occasionally, a short-lived series of SCS complications can occur at sites. In 2008, an outbreak of staphylococcus aureus infections related to intervention procedures including SCS resulted in temporary closure of a private pain practice.28 Other outbreaks of infection have been noted during quality assessments of current practices. One such assessment of the experience at the Johns Hopkins Pain Clinic in 2010 revealed that, during a 6-month period in 2010, five patients with SCS trial lead implantations became infected as compared to one trial lead in the previous 3.5 years.29 The median time to infection diagnosis was 4.5 days. The infections associated with the five trial lead infections in 2010 ranged from superficial cellulitis to radiographically confirmed epidural abscess. Unfortunately, no independent risk factors (implanting pain fellow, SCS company, use of pre-operative antibiotics, lead location, or patient comorbidities) were identified as the causative agent.

In a 5-year experience prior to 2006 at the Cleveland Clinic, Rosenow and colleagues reported a 43% revision or removal rate among 289 patients implanted with SCS systems.30 Thirty-three percent of all leads required revision, with the most common reasons being lead breakage, poor pain coverage, migration, and infection in descending order of frequency. Ten percent of patients had a lead migration requiring revision. Paddle-type leads broke twice as often as percutaneous leads. Twenty-two percent of all patients required more than one revision procedure; 49% requiring at least one lead revision underwent multiple revisions. Anatomically, cervical leads were the most likely to require revision. Their overall infection rate was 3.6%. This experience was somewhat exceptional and the data are no longer current, so they are included only for historical guidance. A more recent retrospective review from the same institution shows the progress made in SCS therapy complication rates.31 In this review, the only documented complication associated with SCS trials was lead migration in 5 of 707 patients (0.7%). There were no permanent neurologic deficits or deaths as a result of SCS permanent implantation. The most common complications were hardware related (38% of all complications) and included lead migration (22.6%), lead connection failure (9.5%), and lead breakage (6%). Revisions or replacements were required in these cases. Related complications included pain at the generator site (12%) and clinical infection (4.5%; 2.5% with positive culture). The rates of infection varied among the different diagnoses with the highest in failed back surgery syndrome (6.3%). Patients with diabetes had an infection rate of 9%, over the 4% rate in nondiabetics. Infections were managed successfully with explantation and antibiotic therapy without permanent sequela.

May and coworkers and Barolat and associates reported lead revision rates caused by lead migration of 4.5% and 13.6% and breakage of 0% and 13.6%, respectively.26,32 Infections occurred in 7% and 2.5% of cases, respectively. No serious complications were observed in either study. These studies are representative of the complication rate of neurostimulation therapy. Kumar and colleagues in Saskatchewan have quantified the costs of SCS complications and published suggestions to improve outcomes.33 Their series included 160 patients treated over 10 years with SCS implantation. They noted 42 patients with 51 complications classified as hardware related (39) or biologic (12) with the range of costs of treatment from $130 (hematoma aspiration) to $22,406 (system reimplantation) (in 2005 Canadian dollars). Their most common hardware failures were lead displacement (11% of patients), followed by fractured electrode (5.6% of patients). Their most common biologic complication was wound infection at 4.4% overall, with subcutaneous hematoma next at 3% overall. These authors presented an analysis of engineering work done at Medtronic, Inc. with regard to lead migration and fracture. This manufacturer recommends the use of a silicon anchor (not hard plastic) with the tip of the anchor pushed through the deep fascia to reduce the pressure point or fatigue point on the lead with repeated bending. Further, the manufacturer recommends a strain relief loop between the anchor and the IPG, with the flank being the preferred site of IPG implant because of less stress on the leads during bending. Another poorly understood phenomenon described by Kumar is late tolerance to stimulation in 16 of 160 patients (10%).

Infections range from simple infections at the surface of the wound to epidural abscess. The patient should be instructed on wound care and recognition of signs and symptoms indicative of infection. Many superficial infections can be treated with oral antibiotics or simple surgical incision
and drainage followed by wound irrigation. For an excellent review on infectious complications of SCS, the reader is referred to Follett and colleagues’ review of 114 cases with recommendations for avoidance. They found that the most common sites of infection were the IPG (54%), the connector tract (17%), and the back incision (8%). Staphylococcus species were the most common pathogen, cultured in 18% of cases, with system explant required in 82% of cases. One death related to infection and one case of epidural abscess leading to paralysis caused by SCS have been reported. Standard practice includes prophylactic preoperative antibiotics (30 minutes pre-incision).

If infection reaches the tissues involving the devices, in most cases the implant should be removed. In such cases, one should have a high index of suspicion for an epidural abscess. Abscess of the epidural space can lead to paralysis and death if not identified quickly and treated aggressively. The likelihood of epidural abscess from a percutaneous SCS trial is exceptionally low, although exceptions do exist.

**PROGRAMMING**

There are four basic parameters in neurostimulation that may be adjusted to create stimulation paresthesias in the painful areas, thereby mitigating the patient’s pain. They are amplitude, pulse width, rate, and electrode selection.

Amplitude is the intensity or strength of the stimulation measured in volts. Typically, voltage may be set from 0 to 10 volts, with lower settings used over peripheral nerves and with paddle-type electrodes. Pulse width is a measure in microseconds (µs) of the duration of a pulse. Pulse width is usually set between 100 and 400 µs. A larger pulse width typically gives the patient broader coverage. Rate is measured in hertz (Hz) or cycles per second, between 20 and 120 Hz. At lower rates the patient feels more of a thumping, whereas at higher Hz the feeling is more of a buzzing. Electrode selection is a complex topic that has been the subject of research by Barolat and colleagues, who provided mapping data of coverage patterns based on lead location in 106 patients. The primary target is the cathode (−), with electrons flowing from the cathode(s) (−) to the anode(s) (+). The newest stimulator systems allow for partial anode and cathode arrangements at different contacts, which have been termed “current steering.” This expands the ability to cover most painful areas with a well-placed lead or leads and makes the number of possible configurations available for programming almost infinite. Thus, a programming strategy is important, and each company has developed computer-assisted programming to narrow down the possible choices. Most patients’ stimulators are programmed with electrode selection changes until the patient obtains anatomic coverage, then the pulse width and rate are adjusted for maximal comfort. The patient is left with full control to (1) turn the stimulator on and off, (2) choose between numerous programs in the device (which have different effects), and (3) adjust the intensity of stimulation up and down for comfort.

The lowest acceptable settings on all parameters are generally used to conserve battery life unless using the newer rechargeable systems. Other programming modes that save battery life include a cycling mode during which the stimulator cycles full on and off at patient-determined intervals (minutes, seconds, or hours). The patient’s programming may change over time, and reprogramming needs are common. The neurostimulator manufacturing companies help clinicians with patient reprogramming. Many busy pain practices designate a nurse practitioner or physician’s assistant to handle patient reprogramming needs.

**OUTCOMES**

The most common use for SCS in the United States is failed back surgery syndrome (FBSS), whereas in Europe, peripheral ischemia is the predominant indication. With respect to clinical outcomes, it makes sense to subdivide the outcomes based on diagnosis (Boxes 69.2 and 69.3). There have been prospective randomized controlled trials (RCTs) examining SCS therapy in FBSS, CRPS, angina, and peripheral vascular disease (PVD) meeting Class II evidence requirements. However, in a review of the available SCS literature, most evidence falls within the Class III (limited) category, as a result
Box 69.3 Spinal Cord Stimulation by Disease

Failed back surgery syndrome. Level A (favorable pain relief, functional capacity, health-related quality of life, and return to work all favorably affected)
Complex regional pain syndrome. Level B (favorable global perceived effect, pain reduction, and a variety of other quality of life/disability measures)
Peripheral ischemia. Level A (favorable limb salvage rates and quality of life measures)
Angina pectoris. Level A (fewer anginal attacks, lower nitrate requirements, improved exercise capacity and equivalent cardiovascular outcomes to revision coronary bypass surgery, and lower complication rate—no meta-analysis done)

SPINAL CORD STIMULATION OUTCOMES: FAILED BACK SURGERY SYNDROME

Cruccu and the European Federation of Neurological Societies (EFNS) reviewed this topic extensively and found significant supportive literature for SCS in the patient with FBSS. Other reviews have similar results and specifically pointed out sufficient evidence for sustained long-term pain relief with medication reduction, improvement in quality of life, increased ability to return to work, increased patient satisfaction, minimal side effects, and cost-effectiveness compared with alternative therapies. Further advantages noted include the trial period for SCS, which limits treatment failures, and the reversibility of the technique.

There has been one prospective randomized study looking specifically at reoperation versus SCS in patients with FBSS as well as others that are under way. North and associates selected 51 patients as candidates for repeat laminectomy. All the patients had undergone previous surgery and were excluded from randomization if they presented with severe spinal canal stenosis, extremely large disk fragments, a major neurologic deficit such as footdrop, or radiographic evidence of gross instability.

In addition, patients were excluded for untreated dependency on narcotic analgesics or benzodiazepines, major psychiatric comorbidity, the presence of any significant or disabling chronic pain problem, or a chief complaint of low back pain exceeding lower extremity pain. Crossover between groups was permitted. The 6-month follow-up report included 27 patients. At this point they became eligible for crossover. Of the 15 patients who had undergone reoperation, 67% (10 patients) crossed over to SCS. Of the 12 who had undergone SCS, 17% (2 patients) opted for crossover to reoperation. For 90% of the patients, long-term (3-year follow-up) evaluation has shown that spinal cord stimulation continues to be more effective than reoperation, with significantly better outcomes for SCS. Overall, 47% of patients in the SCS group achieved 50% or greater pain relief compared with 12% in the reoperation group (p < 0.01). Additionally, patients randomized to reoperation used significantly more opioids than those randomized to spinal cord stimulation. Other measures assessing activities of daily living and work status did not differ significantly.

More recently, Kumar and colleagues published a study examining the real-world comparison of SCS therapy versus conventional medical management (CMM) in patients with FBSS. One hundred FBSS patients with predominant leg pain of neuropathic radicular origin received spinal cord stimulation plus conventional medical management or conventional medical management alone for at least 6 months. In the intention-to-treat analysis at 6 months, 24 SCS patients (48%) and 4 CMM patients (9%) (p < 0.001) achieved the primary outcome of 50% pain reduction. Compared with the CMM group, the SCS group experienced improved leg and back pain relief, quality of life, and functional capacity, as well as greater treatment satisfaction. Between 6 and 12 months, 5 SCS patients crossed to CMM, and 32 CMM patients crossed to SCS. In a 2-year follow-up study of these same patients, Kumar and colleagues noted that the 42 patients continuing SCS (of 52 randomized to SCS) reported significantly improved leg pain relief, quality of life, and functional capacity. At 24 months, 46 of 52 patients randomized to SCS and 41 of 48 randomized to CMM remained in the study, and the primary outcome was achieved by 17 (37%) randomized to SCS versus 1 (2%) to CMM and by 34 of 72 patients who received SCS (including crossovers) as final treatment versus 1 (7%) of 15 for CMM. In subsequent analysis of secondary measures, it was noted that SCS improved health related quality of life measures up to the last time point examined at 24 months following implantation.

In an effort to identify those patients who are likely to benefit from SCS therapy, Turner and colleagues undertook a prospective cohort trial that examined the success of SCS therapy in patients receiving workers’ compensation insurance. They examined patients who received at least a trial of SCS (n = 51) versus those who (1) were evaluated at a multidisciplinary pain clinic and did not receive SCS (n = 39) or (2) received neither SCS nor a pain clinic evaluation (n = 68). Patients then completed measures of pain, function, medication use, and work status at baseline and 6, 12, and 24 months later. The most important finding of this study was that very few (< 10%) patients in any group achieved success at any follow-up on the composite primary outcome (reduced daily opioid use, reduced leg pain, and
Research of high quality regarding SCS and CRPS is limited, but existing data are positive in terms of pain reduction, quality of life, analgesic use, and function. Kemler and colleagues published a prospective randomized comparative trial to compare SCS versus conservative therapy for CRPS. Patients with a 6-month history of CRPS of the upper extremities were randomized to undergo trial SCS (and implant if successful) plus physiotherapy versus physiotherapy alone. In this study, 36 patients were assigned to receive a standardized physical therapy program together with SCS, whereas 18 patients were assigned to receive therapy alone. In 24 of the 36 patients randomized to spinal cord stimulation along with physical therapy, the trial was successful, and permanent implantation was performed. At a 6-month follow-up assessment, the patients in the spinal cord stimulation group had a significantly greater reduction in pain, and a significantly higher percentage rated themselves as “much improved” for the global perceived effect. However, there were no clinically significant improvements in functional status. The authors concluded that in the short term, spinal cord stimulation reduces pain and improves the quality of life for patients with CRPS involving the upper extremities. A subsequent publication including a 2-year follow-up of the same patients showed durability of these positive findings in SCS. The 5-year follow-up data had such significant patient dropout rates to render the positive and negative findings essentially meaningless.

Taylor performed a meta-analysis on the use of SCS to treat CRPS and concluded that level A (the highest level) evidence is available supporting the use of SCS to treat CRPS. Stanton-Hicks recently expanded upon the usefulness on SCS in the treatment of CRPS in the context of an overall treatment strategy, which included analgesics, physiotherapy, psychological therapies, and other interventions in a time-contingent manner because of the progressive debility of untreated or undertreated CRPS, stressing a step up in the aggressiveness of therapy every 12 to 16 weeks in the face of lack of response. This treatment algorithm is from a 2002 consensus panel and review of the literature (Fig. 69.5).

Cook and associates reported in 1976 that SCS effectively relieved pain associated with peripheral ischemia. This result has been repeated and noted to have particular efficacy in conditions associated with vasospasm such as Raynaud’s disease. Many studies have shown impressive efficacy of SCS to treat intractable angina. Reported success rates are consistently high and these indications, already widely used in other countries, are certain to expand within the United States. SCS increases distal extremity skin temperature. The beneficial effects of SCS on the ischemic limb are attributed to an improvement in the microcirculatory status of the limb, as the nutritional health of the skin and nerves is dependent on this microcirculatory blood flow. Microvascular perfusion is measured by multiple methods; the most sensitive is the transcutaneous partial pressure of oxygen (TcPO2) measurement. TcPO2 is increased by sympathetic blockade or SCS therapy. However, the relationship between pain relief and limb survival has not been demonstrated.

Ubbink and Vermeulen performed a meta-analysis on SCS for peripheral ischemia or critical leg ischemia (CLI). The authors used Cochrane Review criteria for inclusion of an article into their analysis. They found nine reports describing six clinical trials, five of which were randomized. The overall sample size was 444 patients and a variety of end points were evaluated, but consistently the primary end point was limb salvage at 12 months. The limb amputation rate was 11% lower in the SCS group versus the conservative treatment group. Overall, SCS-treated patients showed higher quality-of-life indices and less analgesic consumption. Only two of these six trials used TcPO2 measurements, which should lead to optimal outcomes. One of the latter trials suggested a TcPO2 of less than 10 is likely to require amputation regardless of treatment, and a TcPO2 of greater than 30 is likely to improve regardless of treatment. Further, that group advocates an increase in TcPO2 of at least 10 mm Hg during the SCS trial. By using these selection criteria, limb salvage rates approach 83% versus conservative care rates, which run between 20% and 64%. Thus, existing high-level grade A recommendation exists for the use of SCS in CLI. Further RCTs should show higher success rates (versus conservative therapy) based on the refined TcPO2 selection criteria.

A European RCT of SCS in the treatment of non-reconstructable chronic critical leg ischemia (NR-CCLI) did not conclusively show prevention of major amputation of limbs in patients. A subsequent European trial replicated this study but included measures of microvascular perfusion including TcPO2. The researchers again found no global improvement in limb salvage but found in a subgroup of patients with poor baseline (pre-SCS) microcirculation (TcPO2 < 10 mm Hg), 78% of those who responded with increased TcPO2 (delta > 20 mm Hg) with SCS therapy had improved wound healing and limb salvage.

SCS has been used in the treatment of refractory angina pectoris states since first reported by Murphy and Giles in Australia. It is estimated that millions of patients suffer refractory angina in spite of the endoluminal revascularization procedure.
Figure 69.5  Treatment algorithm for complex regional pain syndrome (CRPS). IV, intravenous; MFP, myofascial pain; ROM, range of motion.  
strategies currently used in clinical cardiology. Buchser and coworkers reviewed the topic, and in spite of numerous favorable studies, little support for this technique has been forthcoming in the cardiology realm. The lead or leads are placed at the T1-2 level just to the left of midline with manipulation of the lead until the chest is covered with paresthesia in the usual anginal region. SCS has been shown to have similar efficacy to coronary bypass surgery in treating refractory angina, but with lower morbidity and mortality rates acutely. The mechanism of action of SCS in the angina pectoris patient, as with the CLI patient, is a relief of the ischemia with a favorable shift of the oxygen supply and demand relationships.

Although SCS is thought to be effective in treating refractory angina (at least in Europe), blinded RCTs have been absent from the literature because of the perceived need for SCS-related chest paresthesia that has made placebo-controlled trials exceptionally difficult to perform. Lanza and associates circumvented this problem in an interesting model in which they examined subliminal (non-paresthetic) SCS on anginal pain in a small blinded RCT. In this trial they compared subliminal SCS with paresthetic SCS and with sham SCS. After 1 month, no SCS patients (sham SCS, SCS implanted but not turned on) were randomized to either group (paresthetic SCS or subliminal SCS). After 1 month, changes in angina episodes (p = 0.016), nitroglycerin use (p = 0.015), angina class (p = 0.02), quality-of-life score (p = 0.05), and items 2 (p = 0.008) and 3 (p = 0.009) of the Seattle angina questionnaire differed significantly among groups. The group with paresthetic SCS showed significant improvement in outcomes compared to the group with no SCS, whereas there were no significant differences between the subliminal SCS group and the no SCS group. At 3 months, a significant difference between the paresthetic SCS group and the subliminal SCS group was observed in angina attacks (p = 0.002), but not in other variables. Thus, in this study, paresthetic, but not subliminal, SCS was superior to sham SCS in improving clinical status in refractory angina patients.

**COST-EFFECTIVENESS (IN U.S. DOLLARS)**

The cost-effectiveness of SCS therapy has been a secondary outcome measure in the RCTs examining SCS therapy in CRPS and FBSS patients as well as economic models. North and colleagues examined the cost utility of the 2005 trial in which lumbar spine reoperation was compared to SCS therapy. Three years after the initial trial, 13 of 21 patients (62%) crossed from reoperation to SCS versus 5 of 19 patients (26%) who crossed from SCS (p < 0.025) to reoperation. The mean cost per success was $117,901 for patients who crossed over to SCS. There were no crossovers to reoperation that achieved pain relief despite the mean per-patient expenditure of $260,584. Regardless of the success, the mean per-patient cost was $31,530 for SCS versus $38,160 for reoperation without crossover (intention to treat), and $48,357 for SCS versus $105,928 for reoperation with crossover (treated as intended). SCS was more effective and less expensive in the incremental cost-effectiveness ratios and incremental cost-utility ratios. Therefore, the authors concluded SCS was less expensive and more effective than reoperation in selected failed back-surgery syndrome patients and should be the initial therapy of choice. SCS is most cost-effective when patients forego repeat operation. Should SCS fail, reoperation is unlikely to succeed and should be discouraged. This contrasts with the results from the analysis of the cohort study of workers’ compensation patients with SCS treatment for FBSS. Hollingworth and colleagues found that the mean medical cost per SCS patient over 24 months was $52,991. This was $17,291 higher than in the group treated conservatively in a pain clinic and $28,128 higher than in the group treated by the group members’ primary care physicians. Adjusting for baseline covariates, the mean total of medical and productivity loss costs per patient of the SCS group were $20,074 higher than those of the pain clinic group and $29,358 higher than those of the primary care group. The authors concluded that in the workers’ compensation patient population, SCS was unlikely to be the most cost-effective intervention. In an economic modeling study, Taylor used a decision analytic model to examine the cost-effectiveness of SCS versus conventional medical management and versus reoperation in patients with FBSS. In this study the costs were from the National Health Service of Great Britain and the British pound has been converted into U.S. dollars. The incremental cost-effectiveness of SCS compared with medical management was −$8000 per quality-adjusted life-year, with an 89% probability that SCS is cost-effective at a willingness-to-pay threshold of −$31,300. Compared with reoperation, the incremental cost-effectiveness of SCS was −$10,000 per quality-adjusted life-year, with an 82% probability of cost-effectiveness at the −$31,300 threshold.

In 2002 Kumar and colleagues evaluated the cost-effectiveness of SCS (in the treatment of chronic back pain). They prospectively followed 104 patients with FBSS. Of the 104 patients, 60 were implanted with a spinal cord stimulator using a standard selection criterion. Both groups were monitored over 5 years. The annual cost for the stimulation group was $29,000 versus $38,000 for the control group. The authors found that 15% returned to work in the stimulation group versus 0% in the control group. The higher costs in the nonstimulator group were in the categories of medications, emergency center visits, x-rays, and ongoing physician visits.

Kemler and Furnee performed a similar study but looked at “chronic reflex sympathetic dystrophy (RSD)” using outcomes and costs of care before and after the start of treatment. This essentially is an economic analysis of the outcomes paper. Fifty-four patients with chronic RSD were randomized to receive either SCS together with physical therapy (SCS + PT; n = 36) or physical therapy alone (PT; n = 18). Twenty-four SCS and PT patients responded positively to trial stimulation and underwent SCS implantation. During 12 months of follow-up, costs (routine SCS, out of pocket) and effects (pain relief by visual analog scale [VAS], health-related quality of life [HRQL] improvement by EuroQol [EQ]-5D) were assessed in both groups. Analyses were carried out up to 1 year and up to the expected time of death. SCS was both more effective and less costly than the standard treatment protocol. As a result of the high initial costs of SCS, in the first year, the treatment per patient was $4000 more than control therapy. However, in the lifetime analysis, SCS per patient was $60,000 cheaper than control therapy. In addition, at 12 months, SCS resulted in pain relief (SCS + PT [−2.7] versus PT [0.4] [p < 0.001]) and improved HRQL (SCS + PT [0.22] versus PT [0.03] [p = 0.004]). The authors found SCS to be both more
Peripheral nerve stimulation was introduced by Wall and Sweet as well as others in the mid-1960s. This technique has shown efficacy for peripheral nerve injury pain syndromes as well as CRPS, with the use of a carefully implanted paddle lead using a fascial graft to help anchor the lead without traumatizing the nerve. There are numerous potential applications for peripheral nerve stimulation including occipital, supraorbital, ilioinguinal, and genitofemoral nerves, and sacral nerve roots; however, the level of evidence for this technique has not exceeded class III. Good blinded RCTs in this domain are essential to continue this work.

Motor cortex and deep brain stimulation have been explored to treat high refractory neuropathic pain syndromes including central pain, deafferentation syndromes, trigeminal neuralgia, and others. Deep brain stimulation (DBS) has become a widely used technique for movement disorders and much less so for painful indications, although there have been many case reports on treating highly refractory central pain syndromes. Unfortunately, a multicenter study, promoted by the Food and Drug Administration (FDA), showed negative results of DBS therapy in the treatment of neuropathic pain. These findings hinder the use of DBS in clinical practice in the United States, leaving only class III level evidence for DBS for phantom limb pain, trigeminal neuralgia, and other peripheral nerve pain syndromes. Motor cortex stimulation for the treatment of pain is supported by several blinded RCTs (Class I evidence) including the most recent trial in 2009. This trial involved 16 patients who had neuropathic pain related to peripheral lesions. Patients were followed up for 12 months and evaluated by VAS, brief pain inventory (BPI), McGill Pain Questionnaire (MPQ), and Sickness Impact Profile scores. VAS and Sickness Impact Profile scores had significantly improved by 1 year postimplantation.

**Box 69.4 Principles of Neurostimulation**

- The mechanism of action for spinal cord stimulation (SCS) is not completely understood but influences multiple components and levels within the central nervous system (CNS) with both interneuron and neurochemical mechanisms.
- SCS therapy is effective for many neuropathic pain conditions. The entire painful area may experience stimulation-evoked paresthesia.
- Stimulation should be applied with low intensity, just supra-threshold for the activation of the low-threshold, large-diameter fibers, and should be of nonpainful intensity. To be effective, SCS must be applied continuously (or in cycles) for at least 20 minutes before the onset of analgesia. This analgesia develops slowly and typically lasts several hours after cessation of the stimulation.
- SCS has demonstrated clinical benefit and cost-effectiveness in limb ischemia, failed back surgery syndrome (FBSS), and complex regional pain syndrome (CRPS). Clinical effectiveness also has been shown in angina pectoris and occipital neuralgia, with favorable preliminary reports in visceral pain states.
- Multicontact, multiprogram systems improve outcomes and reduce the incidence of surgical revisions. The role of the paddle versus percutaneous leads is uncertain with islands of support for each.
- Anchoring technique is one of the most important skills to obtain. Two of the three SCS companies now have anchoring systems that lock the lead to the anchor, reducing the risk of lead migration within the anchor.
- Serious complications are exceedingly rare but can be devastating. Meticulous care must be taken during implantation to minimize procedural complications. The most frequent complications are lead breakage or migration (approximately 13% for permanent percutaneous leads and higher for paddle leads) and wound infections (approximately 3% or less).
- The frequent need for revision procedures as outlined in this chapter is important in many ways. Although the revision procedures entail relatively minimal risk, there are numerous costs and risks for the patient and health system. The patient's analgesia is interrupted, entailing the expense and time of lost work or productivity, increased medication use, SCS hardware expenses, operative expenses, and other direct costs. Correction of this high hardware failure rate must be addressed in future technology systems in the face of increased scrutiny over shrinking health care resources if this expensive therapy is to remain a viable choice.
- One of the greatest threats to the viability of this therapy is the cost of the therapy and the poor selection of appropriate patients. Poor selection results in a low trial to permanent ratio that imposes huge costs to the health care system with no benefit to the patient. A trial to permanent ratio should be on the order of 75%. Trial to permanent ratios below 50% should be empirically examined.

**Conclusion**

Spinal cord stimulation is an invasive, interventional surgical procedure that is useful in refractory chronic pain syndromes. Meyerson and Linderoth have proposed principles of neurostimulation that are cornerstones of SCS theory and practice (Box 69.4). The evidence for spinal cord stimulation in properly selected populations with neuropathic pain states is good to moderate. The evidence for SCS therapy in the FBSS patient population (who are not covered by workers’ compensation) supports a level A recommendation. The evidence for CRPS supports a level B recommendation, and the evidence for critical limb ischemia and angina is Class I and supports a level A recommendation. However, this therapy should be reserved for patients who have failed more conservative therapies and who are extremely well selected and educated regarding the goals and expectations of therapy. With appropriate selection and careful attention to technical issues, the clinical results are overwhelmingly positive. It is now time to focus on providing evidence of quality of life and overall function improvement with this therapy.
KEY POINTS

- Shealy implanted the first spinal cord stimulator device for the treatment of chronic pain in 1967.
- Stimulation of either the dorsal horn or dorsal nerve roots at intensity and frequency to selectively activate Aβ fibers reduced the spontaneous firing of wide dynamic range (WDR) neurons in animals with neuropathic injuries. This same stimulation reduced WDR responses to mechanical stimulation of normal and injured animals. Stimulation of the dorsal columns, but not the dorsal root, reduces activity-dependent neuronal excitability (wind-up).
- Patient selection is the most challenging and important step in the decision to offer neurostimulation.
- Appropriate patients for a trial of neurostimulation must meet the following criteria: (1) the diagnosis is amenable to this therapy (e.g., neuropathic pain syndromes), (2) the patient has failed conservative therapy, and (3) significant psychological issues have been ruled out.
- Schedule a 5- to 8- day trial and encourage patients to be as active as possible in their usual environment, with the exception of limiting bending and twisting movements.
- A spinal cord stimulator system is made up of three parts: (1) electrodes or leads, (2) implantable pulse generators (IPGs) or the battery, and (3) the charging and programming systems.
- Most consider 50% or more pain relief to indicate a successful trial, although the ultimate decision should include other factors such as activity level and medication intake. Some combination of pain relief, increased activity level, and decreased medication intake indicates a favorable trial.
- SCS is a cost-effective treatment modality for patients with radicular and back/neck pain following spine surgery (FBSS).

KEY POINTS—cont’d

- SCS is a cost-effective treatment modality for patients with neuropathic pain of an extremity (e.g., complex regional pain syndrome [CRPS]).
- SCS (or neuromodulation) is effective in the treatment of pain associated with angina, peripheral vascular disease, and occipital neuralgia.

REFERENCES

REFERENCES

Intrathecal drug delivery for the treatment of pain is an outgrowth of pioneering research into spinal cord mechanisms and receptors that modulate nociceptive signal transmission to and within the central nervous system. Starting in the 1970s, researchers identified the peptide substance P in small dorsal root ganglion cells and observed that opiates with a spinal action would produce selective analgesia. These findings as well as the observation that substance P release evoked from C fibers is blocked by morphine marked the beginning of the current trend toward focusing on the selective regulation of spinal afferent processing. Since then, there has been much research in this area, leading to widespread use of intrathecal therapy to treat chronic intractable pain. Although this therapy has proven to be extremely beneficial to many patients, it is also associated with high costs, high maintenance, and risks requiring careful patient selection. This chapter focuses on the patient selection, technologies used for chronic intrathecal drug delivery, system implantation, and troubleshooting.

## Intraspinal Drug Delivery Techniques

There are essentially three methods of intraspinal drug delivery: (1) externalized systems, (2) partially externalized systems, and (3) totally implanted systems. The selection of the technique will depend on the goal of therapy, ranging from short-term intrathecal trialing to long-term therapy to treat chronic pain. Each technique has associated risks and costs, which are taken into account when selecting the technique.

### Externalized Systems

An externalized intrathecal catheter is the most widely used technique for trialing intrathecal drugs. Such a system is designed for short-term (hours to days) use but has been successfully used for longer-term delivery in the terminally ill (weeks to months). The use of an externalized catheter raises the concern for a local infection at the catheter exit site or that the catheter may serve as a conduit for either epidural or intrathecal spread of infection. Using strict aseptic technique for catheter insertion can minimize the risk of insertion site infection, and the placement of a chlorhexidine impregnated catheter patch at the insertion site further reduces this risk (Fig. 70.1). There is no evidence that systemic antibiotics prevent these infections. In the terminally ill patient, the risk-benefit ratio may favor the use of an externalized catheter for intrathecal drug delivery. Some practitioners tunnel these catheters under the skin for some distance to provide stability and reduce the likelihood of inadvertent catheter withdrawal. Currently, the U.S. Food and Drug Administration (FDA) has not approved any externalized intrathecal catheters, and it is common to use epidural or lumbar drain catheters for this purpose.

### Partially Externalized Systems

Partially externalized systems are those in which the intrathecal catheter is tunneled and connected to a subcutaneous port. A needle then accesses the port percutaneously and medication is delivered with tubing connected to an external pump. Compared to an externalized system, this permits greater patient freedom of movement and reduces the risk of inadvertent catheter removal. Partially externalized systems are intended for single bolus injections. There continues to be a risk of colonization and infection of the port pocket with prolonged or repeated needle access. These systems have limited application for long-term, continuous intrathecal drug delivery.

### Implanted Intrathecal Infusion Pumps

Totally implanted systems are those with both the catheter and pump system completely internalized by surgical implantation. They have the advantages of a lower risk of infection, potential for long-term use, and much greater freedom of movement for the patient. The totally implanted systems are more expensive and require a more invasive surgical procedure than the externalized or partially externalized systems. Although it is generally recommended that implanted pumps be reserved for patients with a life expectancy of greater than 6 months, this therapy may improve quality of life in patients with life expectancy as low as 2 to 3 months. However, patients with a life expectancy of less than 6 months should be carefully selected.

There are two main types of intrathecal infusion systems, fixed-rate and variable-rate programmable pumps. All implanted pumps have two percutaneous access ports. One port is for refilling the drug reservoir, and there is a separate intrathecal catheter access port for bolus injection through, or aspiration from, the catheter. The
infusion systems are generally implanted in the lower abdominal subcutaneous fat and connected to a catheter, which is tunneled subcutaneously around the abdominal wall into the intrathecal space. However, the pumps may also be implanted subcutaneously in the lower back in rare, selected patients (see the discussion that follows). The septum puncture life of the percutaneous refill port is very high: 500 punctures for the most commonly used, Medronic Synchromed II, pump. It would be unlikely to reach this number of punctures during the life of the pump (7 years for the Synchromed II).

The first intrathecal pump, manufactured by Shiley Infusaid, became commercially available in 1982. The Infusaid and other early pumps were nonprogrammable fixed-rate infusion systems. These pumps were simple devices without batteries, in which pressurized gas pushes the drug from a reservoir through a valve and into the catheter. The chief advantage of these pumps is simplicity of design and lack of batteries. Unfortunately, they are unable to vary the dose delivered without changing the concentration of drug in the reservoir. Currently the Codman 3000 is the only fixed-rate infusion pump on the market in the United States and is no longer used with significant frequency. The pump is available in three sizes (16, 30, and 50 mL reservoir), and each size is available in three flow rates. The low and medium flow rates are 0.5 and 1 mL/day, respectively, for all sizes. The high flow rates are 1.3, 1.7, and 3.4 mL/day, respectively, for the 16, 30, and 50 mL pumps. The flow rate is controlled by a flow restrictor. Flow rates may vary for different drugs, drug combinations, and especially with high drug concentrations, based on differences in viscosity. In addition, changes in body temperature and atmospheric pressure will change flow rate by affecting the gas pressure within the system.

Programmable pumps, on the other hand, allow the clinician to vary infusion rates to increase or decrease the dose without changing the concentration of the drug or drugs in the pump. The original programmable pump was the Medtronic Synchromed, first introduced in 1991. More recent programmable pumps such as the Medtronic Synchromed II (Fig. 70.3) allow patient-controlled intrathecal bolus dosing via a remote control device. The Synchromed II uses a peristaltic roller system (Fig. 70.4) to move the drug from the reservoir to the implanted intrathecal catheter. The Synchromed II is available in a 20-mL and a 40-mL reservoir size and is FDA approved for baclofen, morphine, and ziconotide.

In 2012, the FDA gave marketing approval for the Flowonix Prometra implantable pump (Fig. 70.5). This device uses a pressurized gas chamber as the driving force. Unlike the older fixed-rate infusion pumps, a programmable flow-metering valve allows for a variable drug delivery rate. The Prometra pump’s low energy requirement is its main advantage. Since the batteries are used to control the electronics only, not to pump the drug, the battery has a 10-year life span before the need to surgically replace the pump. The Prometra is available in a 20-mL reservoir and is FDA approved for morphine. The issues with variable flow resulting from viscosity, temperature, and residual reservoir volume have been addressed by the advanced flow-metering valve.
The MedStream Programmable Infusion System is another implantable device currently FDA approved only for the delivery of intrathecal baclofen (Fig. 70.6). This implantable drug delivery system offers improved catheter technology and pump durability. Its intrathecal catheter has been designed to resist kinking and tearing (similar to the newest Medtronic catheters). The MedStream uses compressed gas as the driving force and a ceramic drive flow valve system to maintain the infusion rate. The pump has either a 20-mL or a 40-mL reservoir and measures 76 mm by 21.6 mm (20 mL) or 28.2 mm (40 mL).11,12

The Medallion is an implantable drug delivery system currently in clinical trials. The Medallion system offers safety improvements with the use of a negative pressure reservoir. The negative pressure draws medication from the syringe during pump refills rather than requiring positive pressure from the syringe plunger. This reduces the risk of inadvertent injection into the pump pocket rather than the pump reservoir. The Medallion will be available in either a 20- or a 40-mL reservoir.12

PATIENT SELECTION

PAIN TYPE

Intrathecal drug delivery systems (IDDSs) are reserved for treating severe and refractory pain in two types of patients: those with cancer pain and those with noncancer pain who have failed more conservative therapies.13 The cost and invasive nature of IDDSs necessitate a careful evaluation to determine whether each individual patient is appropriate and likely to achieve benefit. A thorough assessment includes an evaluation of pain-generating pathology, medical comorbidities, psychosocial issues, patient compliance history, economic and health care coverage, and anatomic and technical considerations.14

In advanced stages of cancer, the prevalence of pain exceeds 60%. One third of those patients report moderate to severe pain.15 Comprehensive medical management (CMM) can significantly reduce pain and manage the adverse effects of opioids and other analgesics.16 Despite aggressive therapy, however, some patients continue to endure severe pain. Others are unable to tolerate systemic opioids due to toxicity. A 2002 multicenter randomized trial compared CMM alone versus CMM plus an IDDS. They found that cancer patients receiving CMM plus an IDDS had reduced pain, fewer drug toxicities, and prolonged survival compared to controls.17 Patients with significant toxicity or with refractory pain that has been inadequately controlled by the systemic administration of opioids and other analgesics are potential candidates for an IDDS.18 Intrathecal therapy may be especially valuable in patients with neuropathic pain from tumor invasion of neural plexuses, unstable pathologic fractures, painful impending spinal
cord compression, and visceral tumors with or without autonomic dysfunction that results in gut dysmotility.

In patients with a life expectancy of less than 2 to 3 months, a percutaneous catheter and pump is generally used. These patients may be discharged from the hospital with hospice care or home-health services for the care of the catheter and infusion if appropriate services are locally available. When life expectancy is greater than 3 to 6 months, an implanted system is generally recommended.\textsuperscript{19,20}

For the patient with chronic noncancer pain, a comprehensive evaluation to establish the etiology of the pain should be performed as part of the decision process regarding whether an intrathecal pump is appropriate. The evaluation should include a detailed history, physical examination, radiologic studies, and assessment of prior therapies and their outcomes.\textsuperscript{21} Many diagnoses and painful conditions may be amenable to intrathecal drug delivery in certain cases. These include neuropathic syndromes such as spinal cord injury, diabetic peripheral neuropathy, complex regional pain syndrome, postherpetic neuralgia, and phantom limb pain. Additionally, mixed nociceptive and neuropathic conditions such as postlaminectomy pain syndrome or chronic pancreatitis as well as nociceptive pain conditions such as chronic vertebral compression fractures and severe spinal degeneration may be appropriate for an IDDS in some circumstances.\textsuperscript{14,21,22}

Implanted drug delivery therapy should be reserved for those patients who are refractory from more conservative treatment. A stepwise approach starting with the least invasive and costly therapies is recommended.\textsuperscript{13,14} This may begin with exercise programs, relaxation techniques, and over-the-counter analgesics. Subsequent steps include adjuvant analgesics, muscle relaxants, physical therapy, and psychological therapies. More invasive therapies include neuraxial somatic and sympathetic blocks and spinal cord stimulation. More aggressive medication therapy can then be introduced with oral opioids. The top tier of this stepwise treatment pyramid is reserved for the most invasive therapies, including intrathecal drug delivery and neurodestructive procedures.\textsuperscript{21,25} There are few controlled trials of intrathecal therapy for chronic noncancer pain, but observational studies suggest such therapy can provide pain relief in certain patients who have failed to achieve relief with more conservative treatments.\textsuperscript{24,25} Determining the efficacy of long-term intrathecal drug therapy remains one of the greatest challenges in chronic noncancer pain management. One of the reasons for the lack of randomized controlled trials is that the high cost and invasiveness of such treatment pose ethical challenges in designing a double-blind, placebo-controlled study. Therefore, one can only rely on the retrospective reviews of patients receiving this therapy and attempt to make conclusions on the efficacy of this treatment. Many studies have attempted to determine the efficacy of long-term intrathecal morphine therapy based on classification of the pain. However, a review of these articles reveals large discrepancies in pain classification between studies. Because pain is often multifactorial (e.g., failed back syndrome versus HIV neuropathy versus complex regional pain syndrome), it is difficult to determine what pain syndromes are the most responsive to this therapy.

**PATIENT COMORBIDITIES**

The aging chronic pain patient may experience some of the same age-related comorbidities as any individual. Many of these comorbid conditions can complicate the implantation and use of an intrathecal pump. These medical issues and their potential interaction with intrathecal therapy must be considered during the patient selection process.

### Diabetes Mellitus

*Diabetes mellitus* affects over 8% of the U.S. population and nearly 27% of those over the age of 65.\textsuperscript{26} Patients with diabetes experience poor wound healing and suffer from an increased incidence of surgical site infections.\textsuperscript{27} Implantable devices pose a special risk of surgical wound infections. With implantable intrathecal pumps, wound infections have been found to be the most common device-related complication.\textsuperscript{28}

Patients with diabetes, especially if blood glucose control is poor, should be counseled on the increased risk, and implanters should maintain extra vigilance for signs of site infections.

### Anticoagulant Therapy

*Anticoagulant therapy* has become increasingly common as more indications for anticoagulation such as coronary artery stent placement have arisen. Additionally, newer anticoagulant therapies have improved management and dosing of anticoagulants. Patients on anticoagulant therapy are at increased risk of epidural hematoma formation after placement or removal of epidural or spinal catheters.\textsuperscript{29,30}

The American Society of Regional Anesthesia publishes guidelines regarding the performance of neuraxial injection and catheter placement with concomitant administration of anticoagulants (Fig. 70.7).\textsuperscript{30} These guidelines do not specifically address the permanent implantation of intrathecal drug delivery systems. Scattered case reports of anticoagulant therapy restarted after implantation of intrathecal pumps offered no clear evidence for or against the safe use of intrathecal pumps in these patients.\textsuperscript{14}

### Infections

Any active infection puts the patient at high risk of seeding the pump with bacteria. The resulting pump pocket infection is virtually impossible to clear completely and will require explanting the entire pump and catheter system. Any active or chronic bacterial or fungal infectious

Regional anesthesia in the Society of Regional Anesthesia and Pain Medicine evidence-based guidelines (3rd ed.). *Reg Anesth Pain Med.* 2010;35:64-101.)
process, particularly with noncancer pain patients, should be regarded as an absolute contraindication to implantation.

**Pulmonary Disease**

More than 18 million Americans have obstructive sleep apnea (OSA). In addition to the risks of carbon dioxide retention and both systemic and pulmonary hypertension, the OSA patient has increased sensitivity to the respiratory depressant effects of opioids. There are no studies of intrathecal opioid use in OSA patients. However, case reports suggest that chronic use of oral opioids in those with OSA may increase apnea duration and hypoxia severity. Chronic obstructive pulmonary disease (COPD) also results in carbon dioxide retention and increased risk of respiratory depression with administration of opioids. A retrospective case-controlled study of postoperative COPD patients administered opioids found an increased risk of respiratory events (odds ratio [OR] 5.09; 95% confidence interval [CI]) compared to patients without chronic lung disease. Most of these events occurred within 24 hours of surgery. The long-term risk of intrathecal opioid administration in patients with severe pulmonary disease is unknown. However, known risks of perioperative opioid administration in this population warrant careful monitoring during trialing as well as after implantation and initiation of therapy.

**PSYCHOLOGICAL SCREENING**

The Centers for Medicare and Medicaid Services require a psychological assessment prior to the implantation of spinal cord stimulator systems. No such requirement exists for IDDS. Although not required, it is widely accepted that a pre-procedure psychological assessment is warranted and is at least as important for appropriate patient selection for an IDDS as spinal cord stimulation. Ideally, a psychological evaluation would aid in predicting positive response to an implantable therapy. In reality, there is limited evidence regarding the efficacy of psychological screening to predict long-term success. Much of the literature in this area concerns implantable spinal cord stimulators, and it is from this body of literature that guidelines regarding the use of psychological evaluation for IDDS have been extrapolated.

The presence of suicidal or homicidal ideation, uncontrolled depression, active psychosis, severe cognitive deficits, and active drug abuse are absolute contraindications to implantation. In a study by Celestini and colleagues, certain psychological factors and traits were associated with poor analgesic outcome after implantation. These include somatization, depression, anxiety, and poor coping skills. However, a study by Doleys and Brown found that those with mild abnormality on the Minnesota Multiphasic Personality Inventory (MMPI) personality profiles had better long-term analgesic efficacy than those with more normal scores. Consensus guidelines have recommended the use of some form of psychological assessment in the selection process for IDDS candidates but caution against using the results to categorically rule out implantation in patients with psychological issues.

The psychological evaluation should be used to identify factors that may affect the outcome of a trial or long-term therapy, either positively or negatively. In addition to identifying severe psychopathology, the screening examination can evaluate for cognitive deficits, coping mechanisms, social supports, patient expectations, and comprehension of treatment goals that may affect therapy. This screening may also identify the need for psychological treatment that can improve the outcome of therapy. The psychologist should not be asked to give “clearance” but rather act as an additional source of information as to whether IDDS therapy is appropriate, the patient has rational expectations, and this therapy is likely to succeed for an individual patient.

**TRIALING**

Some type of therapy trial prior to permanent system implantation has been commonly performed and is often required by insurance (Medicare). Trial options include a single bolus intrathecal injection, multiple bolus injections, or a continuous infusion via percutaneous intrathecal or epidural catheter. Unfortunately, there are no commonly accepted guidelines regarding how to perform a trial. Further, the data are limited, suggesting that trialing can accurately predict efficacy after implantation. An expert consensus statement regarding guidelines for selection of patients for noncancer pain recently recommended against the requirement of a pre-implant trial because of the trial’s unsubstantiated predictive value.

The selection of a trialing method for noncancer pain will be made largely based on physician preference along with payer requirements. The majority of trials are performed in a hospital inpatient setting via epidural or intrathecal infusion. The advantage of epidural infusion is simplicity of catheter placement and a much lower risk of postdural puncture headache (PDPH). The development of a PDPH during trial may impair the patient’s ability to determine the efficacy of the trial. An intrathecal trial more closely mimics the permanent implant conditions. Both of these options are more costly than single or multiple intrathecal injections. Although injections, whether single or multiple, provide simplicity with a low incidence of PDPH, they fail to mimic the chronic infusion conditions of a permanent implant.

Trials for cancer pain are performed in a similar fashion. However, the lack of prognostic evidence for trials calls into question their value in patients with rapidly progressive disease near the end of life. According to one consensus guide to intrathecal therapy for cancer pain, the risks associated with the trial and delay of therapy may not outweigh the alleged prognostic benefits. Other experts have recommended the use of a trial in the event of cancer pain in order to give the patient and physician the opportunity to evaluate potential responses as well as possible side effects.

Trials of baclofen therapy for spasticity are considerably more straightforward than those for cancer and noncancer pain. There are clear, objective outcome measures of spasticity that can be assessed to determine response. The commonly used criterion for a successful trial is a 2-point reduction on the Modified Ashworth Scale for grading spasticity (Fig. 70.8). Patients may also demonstrate improvements in joint range of motion.

The baclofen trial consists of a bolus intrathecal injection of 25 to 50 mcg of baclofen and is performed in an outpatient setting. The onset of effect occurs in 1 to 3 hours and may last 6 to 8 hours. The patient is then evaluated with serial examinations to determine response. If the patient fails to respond, the trial may be repeated on a subsequent day at a higher dose.
Most patients that reach the level of intrathecal therapy to treat chronic pain are on some amount of systemic opioids. It is controversial whether to detoxify patients off of the opioids prior to trialing. There are many advantages to detoxifying the patient prior to a trial. First, the drug holiday will provide the opportunity to observe the patient without the systemic opioids and allows a better assessment of addiction. There is often a gray area between addiction and treating chronic pain, as there is frequently some overlap between treating valid chronic pain complaints and the presence of addiction that needs to be assessed prior to implant. Second, the drug holiday will reduce tolerance, allowing for a better assessment of response to intrathecal therapy during the trial. Third, weaning patients off of the opioid prior to implant will likely result in lower doses of intrathecal opioids in the long term. Patients that are titrated up on intrathecal opioids as they are being weaned from systemic opioids often experience withdrawal symptoms resulting in overly aggressive increases in the intrathecal dose. One disadvantage to weaning the systemic opioid prior to trialing includes the pain and suffering that the patient may experience during the drug holiday. There is currently no clear consensus on whether to wean or maintain the systemic opioid prior to trialing. The decision should be based on a discussion between the physician and patient. An addictionology consult may be considered for patients who are unable to wean from the opioids because of severe withdrawal symptoms.

**LOCATION OF PUMP PLACEMENT**

There are several considerations when choosing where to locate the pump. Patient comfort is of primary importance. The pump must be located away from bony prominences, including the iliac crest and ribs, to avoid rubbing. The amount of subcutaneous fat is also important. In the average-sized patient there may be too little space and tissue in the flank, whereas in the morbidly obese patient there may be too much subcutaneous fat in the abdomen. Have the patient sit up to mark the site to ensure that the pump will not lie below the belt line. Discuss the patient’s sleeping habits to determine if the patient is a side sleeper. If so, then place the pump in the contralateral abdomen. In the majority of cases, the most appropriate location for pump placement is in either the left or right lower quadrant of the abdomen. Unlike spinal cord stimulator pulse generators, the size of intrathecal pumps makes placement in the flank or upper gluteal region uncomfortable for average-sized patients. Placement of the pump pocket in the abdomen necessitates positioning the patient in lateral decubitus for the surgical procedure. Proper attention to positioning is necessary to ensure that both the pump site and catheter insertion site are accessible without breaking scrub and repositioning.

Patients who have had multiple abdominal surgeries may pose a challenge in locating the pump pocket. If an abdominal site is impossible, a smaller 20-mL pump may be placed in the superior gluteal region. In larger patients, there may also be room to place the pump in the flank midway between the 12th rib and the iliac crest. A consultation with a plastic surgeon may be helpful in patients with limited implant site options. When re-implanting a pump after previous pump site infection, it is best to use a new location such as the contralateral abdomen to minimize re-infection risk. Placement of a pump into scar tissue is not recommended, as the blood supply can be erratic, limiting the flow of antibiotics to the area during implantation. This is evident with pump re-implantations for battery failure in which the capsule surrounding the pump has minimal bleeding when opened. In these cases, meticulous care must be taken with sterile technique to minimize the risk of infection with the re-implant.

**ANESTHESIA FOR PUMP IMPLANTATION**

Intrathecal pump implantation can be performed under local anesthesia with sedation, spinal anesthesia, or general anesthesia. The anesthesia method of choice is to place the catheter under local anesthesia followed by either a spinal anesthetic or local anesthetic infiltration for catheter anchoring, tunneling, and pump placement. This method allows for communication with the patient during catheter placement to minimize the risk of nervous system injury. It is also acceptable to use general anesthesia, but the risks must be disclosed to the patient. The choice of anesthesia will depend on surgeon and patient preference. Nonsurgically trained pain physicians may be more comfortable with an awake patient under local anesthesia who can communicate with the implanter during needle and catheter placement and allow for the assessment of neurologic status. Orthopedic and neurosurgeons may be more accustomed to a patient under general anesthesia. In addition, general anesthesia may be more comfortable and better tolerated by some patients. If implanting under spinal anesthesia, the implanter will first place the Tuohy needle into the intrathecal space under local anesthesia. The implanter can then thread the intrathecal catheter through the Tuohy, communicating with the patient to make sure there is no pain or paresthesias. Once the catheter is confirmed to be in the intrathecal space radiographically and by free flow of cerebrospinal fluid (CSF), injection of 20 to 30 mg of preservative-free lidocaine will achieve adequate spinal anesthesia for both the posterior midline incision and abdominal pump pocket incision.

**PATIENT POSITIONING**

Most commonly the pump will be located in the abdomen, which necessitates either a lateral decubitus position or

repositioning of the patient from prone to supine midway through the surgery. Most implanters use the lateral decubitus position to avoid the time delay and potential infection risk of repositioning. Careful positioning with pressure points padded and an axillary roll in place is necessary for patient comfort and to avoid intraoperative nerve compression injuries. The use of sticky rolls to support the upper abdomen or posterior thorax may assist in positioning the patient in a true lateral decubitus. Taking the time to ensure the patient is well supported and the sagittal axis is perpendicular to the operating room table will ensure a true anterior-posterior (AP) view with fluoroscopy. Position the patient’s arms to avoid interfering with fluoroscopic visualization. As stated before, it is critical to mark the pump implantation site with the patient in the sitting position because tissue will shift when in the lateral position. Marking the patient while in the lateral position risks having the pump end up in an uncomfortable location.

**SURGICAL TECHNIQUE**

**STERILE TECHNIQUE**

Good sterile technique and pre-operative antibiotics are the two most important controllable factors in preventing wound infections. In a study of primary implantations and revisions of intrathecal baclofen pumps in pediatric and adult patients, an infection rate of 4% to 5% was found. In more than half of the infections, the primary organism was *Staphylococcus aureus*. In a multicenter prospective study of intrathecal pump implantations for both pain and spasticity, Follett found that the most common complication was infection, with an incidence of 7%. Most surgical site infections in clean surgeries are due to skin microorganisms. Careful cleansing of both the surgeon’s hands and the patient’s skin at the operative site with either a chlorhexidine-alcohol or povidone-iodine scrub reduces skin bacterial counts. Scrubs of 2 to 3 minutes are superior to shorter scrub times. Several studies have suggested that chlorhexidine-alcohol scrubs may be superior to povidone-iodine scrubs. Body hair should be removed only if excessive, and removal should be performed with clippers instead of shaving. Shaving results in microtrauma of the skin, resulting in the inability of the antiseptics to reach the cracks and crevices that may be hiding bacteria. Use of chlorhexidine skin preparation of the surgical site followed by the use of povidone-iodine-impregnated adhesive skin drapes is recommended, as this produces another barrier between the skin flora and wound. If using these drapes, allow extra time for the skin prep to dry so that the adhesive will stick firmly to the skin. Adherence to the patient’s skin is necessary for the antiseptic effect. Surgeons and assistants should double glove to reduce the infection risk associated with glove puncture. Prophylactic systemic antibiotics against the most likely pathogens (skin flora) should be administered within 60 minutes of skin incision. If patient allergy to cephalosporins and penicillin precludes their use, one recommended alternative is clindamycin. There is no evidence supporting the postoperative administration of oral antibiotics to prevent wound infections.

Additional practices that may reduce the risk of infection include (1) soaking the pump in a mixture of saline and povidone-iodine solution, (2) packing the wounds with povidone-iodine-soaked sponges for a few minutes, (3) painting the edge of the wound with povidone-iodine and redraping the edge of the wound prior to placing the pump into the wound, and (4) regloving after surgical dissection is complete and before handling the pump. These practices may reduce the risk of skin flora colonization of the pump and pocket.

**CATHETER PLACEMENT AND ANCHORING**

Prior to needle insertion, the spinous processes of the levels of insertion should be marked on the skin. This will identify the midline incision to be used for dissection and anchoring. Insert the introducer needle using a shallow-angle, paramedian oblique technique (Fig. 70.9). An angle of approximately 30 degrees off of the spine is ideal. For an average-sized patient, the skin entry point will be 1 to 2 cm lateral to the midline on the side of the intended pump pocket, and 1 to 1.5 vertebral levels caudad to the targeted interlaminar entry site. The typical entry site will range from the L2 to L4 interlaminar spaces unless anatomic considerations or previous surgery dictates otherwise.

With the stylet in place, the introducer needle should be advanced to the superior edge of the caudad lamina for the target space. After touching the lamina to gauge depth, the needle is then walked off the edge to the midline of the interlaminar space and, using the loss of resistance technique, the epidural space should be identified (Fig. 70.10). It is best to enter the epidural space just lateral to the midline. Further advancement into the intrathecal space will then be more midline. Once the epidural space is identified, the bevel of the needle is rotated 90 degrees toward the midline so that the needle bevel will be parallel to the longitudinal fibers of the dura. This will spread rather than cut the fibers to reduce the chance of postdural puncture headache. The fluoroscopic view should then be rotated to the lateral view to monitor the needle depth as it is advanced into the intrathecal space. With gentle aspiration, the needle is advanced until there is a return of CSF. If there is no return of CSF in spite of adequate depth on lateral fluoroscopic view, rotate the needle...
back 90 degrees to the original position, which may result in CSF return. If there is no CSF return, rotate 90 degrees and gently advance the needle. Periodically rotate the needle if no CSF returns. Keeping the patient awake and communicating provides an increased margin of safety. Replace the needle stylet to stop CSF flow until ready to place the catheter. Turn the bevel tip cephalad. Ensure that the catheter guidewire is fully advanced into the catheter and is in place during insertion and positioning of the catheter. Advance the catheter through the introducer to the desired level under fluoroscopic guidance (Fig. 70.11). Once the catheter tip is beyond the distal portion of the needle, extreme caution should be used should the catheter need to be withdrawn, as catheter sheering or damage may occur. If there is the slightest resistance when attempting to withdraw the catheter through the needle, it is recommended that the needle and catheter be removed together and the process restarted with needle placement.

Leaving the needle in place to protect the catheter, make an incision in the midline over the spinous processes medial to the needle entry site down to the supraspinous ligament. The incision must be large enough to create a pocket for anchor placement, approximately 5 cm. Undermine the edges of the incision laterally to expose the fascial plane for anchor placement and fully expose the traversing introducer needle (Fig. 70.12).

With the catheter guide wire still in place, carefully remove the needle. To prevent inadvertent withdrawal of the catheter, hold the catheter steady just proximal to where it enters into the needle. Once the needle is removed, hold the catheter firmly at the entry site into the fascia at the level of the supraspinous ligament, and withdraw the guide wire. Recheck the catheter position under fluoroscopy to ensure proper placement (Fig. 70.13). Injection of a small amount of contrast may be necessary to make the catheter visible under fluoroscopy. While still holding the catheter at the fascia, bring the external portion of catheter through the skin into the posterior pocket (Fig. 70.14). Clamp the end of the catheter with a rubber
shod clamp to prevent CSF loss while anchoring and tunneling. Using nonabsorbable suture, tie a purse string suture through the fascia around the catheter to prevent CSF leak tracking back along the catheter. Place an 0 silk suture into the supraspinous ligament next to the catheter as it penetrates the fascia and tie the suture. Next, place the butterfly (V-wing) anchor onto the catheter and advance it to the fascial entry site (Fig. 70.15). Use the 0 silk suture placed in the ligament to close the anchor wings together. A second 0 silk suture is then tied around the neck of the anchor, making sure the suture fits in the groove on the anchor (Fig. 70.16). This will ensure a tight fit to hold the catheter. Make sure the anchor is attached firmly to the supraspinous ligament and not to subcutaneous fat and that the distal tip of the anchor is as close as possible to the catheter entry point into the fascia. Catheter migration out of the intrathecal space may occur if the anchor is not firmly attached to fascia. Extra catheter between the anchor and fascial entry point may also increase the risk of catheter migration. Catheter migration distal to the anchor can further be avoided by bringing a layer of tissue together over the anchor and suturing with absorbable suture (discussed later).

**PUMP POCKET**

Once the catheter is securely anchored, the implanter can then turn attention to creating a subcutaneous pocket for
the pump. Anesthesia for this and subsequent portions of the surgery can be achieved by injecting spinal lidocaine through the catheter. Alternatively, local anesthetic infiltration into the site can be used. At the abdominal site previously marked, make an incision down through the scarpas fascia to subcutaneous fat. Obtain hemostasis with electrocautery as necessary and extend the incision to a depth of at least 1.5 cm but no more than 2.5 cm. Using careful scissor dissection, undermine along a horizontal plane to create a pocket that just fits the pump. An oversized pocket increases the risk of seroma and shifting or flipping of the pump. The pocket should be undermined predominantly cephalad or caudad to the incision so that the final incision does not lie directly over the refill port of the pump. After ensuring proper fit of the pump, place 0 silk sutures into at least three corners of the pocket for anchoring the pump (Fig. 70.17). These sutures should be firmly anchored to the fascia if possible. However, in obese patients this may not be possible, so using a large needle, take big bites of fat and gently tie the knot. The scaring that subsequently results around the sutures will eventually anchor the pump.

TUNNELING
Once the pocket is prepared, the catheter must be tunneled from the posterior incision to the pump pocket (Fig. 70.18). The supplied tunneling device may be bent in a gentle curve to facilitate passage subcutaneously from posterior to anterior trunk. Start at the posterior pocket with pressure and a gentle twisting motion to begin passing the tunneling device toward the pump pocket. Place one hand on the skin surface over the tunneling device tip. The tip should be palpable without piercing the skin throughout the course to ensure it is neither too deep nor too superficial. Once the introducer has entered the pump pocket, remove the handle and begin passing the catheter through the introducer toward the pocket. Remove the introducer from the pump pocket side. Excess catheter length will be coiled beneath the pump. Once the catheter has been tunneled, irrigate each pocket with copious amounts of normal saline with or without bacitracin.

Unclamp the catheter tip and ensure patency by observing CSF flow from the catheter. Attach the catheter to the provided catheter connector. The connector is then attached to the pump. Ensure that it is firmly connected. Access the side port using the appropriate side port access needle and gently aspirate to make sure there is a flow of CSF. Insert the pump into its pocket and use the previously placed 0 silk sutures to tie it down in three of the corner suture loops. Make sure the catheter is not entangled in these sutures to prevent kinking. Tying the pump down will prevent it from flipping over in the pocket. Place coils of excess catheter behind the pump and ensure that the pump refill port is facing up (Fig. 70.19).

CLOSURE
Before closure of the posterior pocket, pass one 2-0 Vicryl suture through the dorsolumbar fascia alongside the anchor, then cross the suture over the anchor and through the fascia on the opposite side (Fig. 70.20). Pull the two sides together to tightly cover the anchor site and tie down (Fig. 70.21). This tight pocket over the anchor will help prevent catheter migration out of the intrathecal space. For deep incisions, the deep fascia may need to be closed.
using interrupted inverted absorbable sutures. For shallower incisions, only the subcutaneous fascia will need to be closed, using interrupted inverted sutures with the spacing close enough that a fingertip placed between sutures is unable to pass below the fascia into the subcutaneous fat. For the pump site, only the subcutaneous fascia will require closure, using interrupted inverted absorbable sutures similar to the back incision closure technique. Skin closure of both incisions may be performed with a running subcuticular closure of 3-0 Monocryl with Steri-strips or with staples. For dressings, place Telfa directly over the incision, followed by 4×4 gauze, then a clear occlusive dressing.

**COMPLICATIONS**

**PERIOPERATIVE COMPLICATIONS**

The implantation of an IDDS exposes the patient to risks similar to those of other surgical or invasive procedures such as bleeding, infection, wound dehiscence, and neurologic injury. In addition there is a risk of CSF leakage, migration of the intrathecal catheter, and pump site complications such as seroma formation.

**BLEEDING**

Intraoperative bleeding is most likely to be problematic in patients with a history of bleeding diathesis or hepatic disease, or those on anticoagulant therapy. Patients with suspected coagulation disorders should be evaluated carefully prior to implantation. The American Society of Regional Anesthesia and Pain Medicine guidelines regarding anticoagulants for neuraxial analgesia should be followed to reduce the risk of potentially catastrophic spinal or epidural hematoma formation.

**INFECTION**

The incidence of infection following intrathecal pump implantation has been reported to be between 2.5% and 9%. The majority of infections occur at the pump pocket site and present within 15 to 45 days after implantation. Pediatric patients implanted for treatment of spasticity have been found to have slightly higher rates of postimplantation infections. In addition to local infection at the pump site, there is a risk of infection spreading to the CSF with resulting meningitis. This risk necessitates good infection control practices to prevent surgical site infections as well as careful evaluation of any suspected infection (discussed previously). In the majority of cases, a pump pocket infection will require explanting both the device and the catheter.

The clinical presentation of a local pump pocket infection may include increased pain, fever, erythema, tenderness, swelling, purulent drainage, and warmth at the pump site. In the case of CSF infection and meningitis, the patient may present with nuchal rigidity, headache, nausea, vomiting, and fever. In either case the patient may have an elevated
white blood count (WBC), C-reactive protein, or erythrocyte sedimentation rate. The formation of a seroma within the pump pocket may mimic a local infection with swelling and erythema. Percutaneous drainage and culture of fluid may assist in making the diagnosis. The most common pathogens implicated are *Staphylococcus.*

If an infection is suspected, the pump and catheter should be removed immediately. Antibiotics should not be administered until the pump is removed and wound cultures are obtained. Antibiotics administered before cultures are obtained can make it difficult to identify the bacteria, thus committing the patient to a longer course of broad coverage antibiotic therapy.

### CEREBROSPINAL FLUID LEAKS

Cerebrospinal fluid leaks may occur around the catheter via the dural puncture site or as a result of disconnection, fracture, or puncture of the catheter. The leakage of CSF may result in a postdural puncture headache. Generally, CSF leaks that are not due to catheter fracture or disconnection are self-limiting and may be treated conservatively. However, if the leak and symptoms persist, an epidural blood patch may be performed under fluoroscopic guidance in order to avoid damage to the catheter. Severe CSF leaks may result in CSF fluid collections in the posterior catheter site pocket. These can be difficult to treat, and if an epidural blood patch does not resolve the leak, injection of 1 mL of fibrin glue at the dural entry site under fluoroscopy can be considered. If this does not resolve the leak, explantation of the system may be necessary.

Persistent or recurrent fluid collection in the pump pocket after percutaneous drainage should raise the suspicion of a catheter disconnect from the pump with a CSF leak into the pump pocket. Percutaneous side port access with injection of contrast under fluoroscopy can diagnose this complication.

### CATHETER COMPLICATIONS

Catheter-related problems are the most common complications following implantation of an intrathecal drug delivery system. Although the reported occurrence varies, Follet and Naumann found a rate of 18.6% in a prospective study of catheter-related complications. These problems include fracture, puncture, disconnection, migration, or dislodgement from the intrathecal space. Among these, catheter migration is the most common and usually is the result of improper anchoring of the catheter to the fascia. Catheter failures may present as inadequate analgesia, CSF leaks, or withdrawal symptoms. Evaluation of catheter complications starts with accessing the side port. If CSF can be aspirated freely, then a fluoroscopic evaluation with injection of contrast may help identify leaks and the location of the catheter within the intrathecal space. If CSF cannot be aspirated, one must fill the pump with saline and clear the catheter of the drug before injecting contrast in order to avoid bolus injection of drug intrathecally. Contrast studies may not detect small leaks, kinks, or breakage. A computed tomography (CT) myelogram following injection of contrast through the side port may be required to identify the location of a leak or the formation of a granuloma at the catheter tip.

### GRANULOMA FORMATION

Granulomas are aseptic inflammatory masses composed of macrophages, neutrophils, and monocytes with granulation tissue. The formation of a granuloma at the catheter tip may cause a loss of analgesic efficacy, progressive neurologic symptoms resulting from a mass effect on the spinal cord, and permanent neurologic injury. In a study of granulomas reported to the manufacturer of one pump system, the authors calculated an incidence of 0.49% of implanted systems. Because many granulomas go undetected or unreported, the actual incidence is likely much higher. The most commonly reported symptoms are decreased efficacy of analgesia and pain. Neurologic symptoms reported include weakness, numbness, and incontinence. Risk factors for granuloma formation include a high dose and high concentration infusion of opioids (all except fentanyl). The most commonly implicated drug has been morphine, but other opioids and, rarely, baclofen have been associated with granuloma formation. Imaging by magnetic resonance imaging (MRI) with contrast or CT myelogram can aid in the evaluation of a suspected granuloma. However, in the authors’ experience, CT myelogram is superior, as catheter identification can be difficult with MRI, and we have seen two cases where MRI with contrast failed to demonstrate a granuloma whereas subsequent CT myelogram diagnosed the granuloma. The treatment employed will depend on the presence and severity of any neurologic symptoms. Options include replacement of the intrathecal infusate with saline, removal of the catheter, or surgical exploration and mass resection.

### CONCLUSION

Since the 1980s, intrathecal drug delivery of opioids and nonopioid analgesics has become a promising option when more conservative therapies have failed. There are an increasing number of choices with regard to implanted intrathecal pump systems for the management of spasticity as well as cancer and chronic noncancer pain. The challenges involved in the successful use of intrathecal therapy start with patient selection. Understanding the issues in selecting an appropriate candidate with cancer pain, chronic noncancer pain, or spasticity will go a long way toward ensuring adequate therapy once the system is implanted. The main risks associated with implantation of an intrathecal system are infection and catheter migration. Careful attention to good sterile technique during the surgical implantation as well as catheter anchoring can minimize these risks.

### KEY POINTS

- Intrathecal analgesia therapy has proven to be extremely beneficial to many patients; it is also associated with high costs, high maintenance, and risks requiring careful patient selection.
- The cost and invasive nature of an intrathecal drug delivery system (IDDS) necessitate a careful evaluation to determine whether each individual patient is appropriate and likely to achieve benefit.
KEY POINTS—cont’d

- A 2002 multicenter randomized trial compared comprehensive medical management (CMM) alone versus CMM plus an IDDS. The researchers found that cancer patients receiving CMM plus an IDDS had reduced pain, fewer drug toxicities, and prolonged survival compared to controls.
- The psychologist should not be asked to give “clearance” but rather act as an additional source of information as to whether IDDS therapy is appropriate, the patient has rational expectations, and the treatment is likely to succeed for an individual patient.
- Granulomas are aseptic inflammatory masses composed of macrophages, neutrophils, and monocytes with granulation tissue. The formation of a granuloma at the catheter tip may cause loss of analgesic efficacy, progressive neurologic symptoms due to a mass effect on the spinal cord, and permanent neurologic injury.

REFERENCES

Intra-articular (IA) joint and bursa injections are used to treat pain in the joint and surrounding structures. Musculoskeletal system disorders, including osteoarthritis, are some of the most common medical conditions for which patients seek care. Musculoskeletal diseases are associated with high levels of disability and significant economic costs.1,2 Osteoarthritis, a noninflammatory rheumatologic condition, is the most prevalent form of arthritis. It is projected that more than 59 million individuals in the United States (18% of the population) will suffer from osteoarthritis by 2020.3

In the 1950s, Hollander introduced the IA corticosteroid injection for the treatment of rheumatoid arthritis (RA).4-6 In 1958, the first clinical trial for IA joint injections for osteoarthritis was performed.7 Currently, joint injections continue to be used extensively in a multimodal treatment platform for musculoskeletal conditions. In the updated American College of Rheumatology (ACR) guidelines for the medical management of osteoarthritis, IA injections were recommended as alternative and augmentative treatment approaches to oral medications and physical therapy.8

This chapter provides an updated review of IA joint injections. Four major areas are covered: (1) pharmacology of common injectable agents, (2) indications for treatment, (3) image-guided injection techniques, and (4) IA injection-associated adverse effects and complications. The three major joints addressed are the shoulder, hip, and knee. Assessments of the accuracy and therapeutic efficacy of each technique are provided.

PHARMACOLOGY OF AGENTS UTILIZED FOR JOINT INJECTIONS

Intra-articular needle placement is routinely used to deliver therapeutic agents to reduce pain and improve function. The three agents routinely employed for IA injections are local anesthetics, corticosteroids, and viscosupplements.

LOCAL ANESTHETICS

INDICATIONS AND MECHANISM OF ACTION

Local anesthetics (LAs) are often utilized in combination with corticosteroids for IA and extra-articular injections. The rationale for utilizing LAs includes providing pain relief for the needle insertion itself and diagnostic purposes as well as diluting and distributing the steroid preparation within the joint.

Local anesthetics act by reversibly binding to sodium channels on neuronal cell membranes, thereby blocking nerve conduction.9 Local anesthetics also have transient anti-inflammatory effects and inhibit several leukocyte functions.10

LOCAL ANESTHETIC AGENT SELECTION (STRUCTURE AND FUNCTION)

Local anesthetics commonly employed for joint injections include the short-acting LA, lidocaine, and the long-acting LAs, bupivacaine and ropivacaine.

ADVERSE EFFECTS AND Complications ASSOCIATED WITH LOCAL ANESTHETIC INJECTION

Local anesthetics are associated with both local and systemic side effects. Local effects of LAs include myotoxicity and chondrotoxicity. Myotoxicity can occur from LA administration in or around muscle tissue, although it is usually not clinically relevant and muscle regeneration occurs.11 Bupivacaine is more myotoxic than lidocaine and ropivacaine. Local anesthetics produce myonecrosis through the lytic degeneration of the sarcoplasmic reticulum and mitochondria. The addition of corticosteroids to LA injection amplifies the muscle damage and prolongs the recovery phase.12 Myonecrosis rarely presents any clinically discernible manifestations in the course of routine use of local anesthetics for IA joint injections.

Local anesthetics are also chondrotoxic.13-17 Most reported cases of chondrolysis occurred after use of continuous IA local anesthetic infusions to manage postoperative pain rather than single IA injections.17 In vitro studies have demonstrated that LAs cause mitochondrial dysfunction and apoptosis in human chondrocytes.14 Chondrotoxic effects are influenced by the LA type and concentration. Grishko and colleagues14 demonstrated that 2% lidocaine caused massive necrosis of cultured chondrocytes after 24 hours of exposure, whereas 1% lidocaine caused a detectable but insignificant decrease in cell viability. For longer-acting LAs, in vitro studies indicate that 0.5% ropivacaine is significantly less chondrotoxic to cultured human articular cartilage than 0.5% bupivacaine.15 Similar to myotoxicity, combining LA with corticosteroids amplifies chondrotoxicity.18 Further studies are needed to determine the clinical significance and exact mechanisms of LA toxicity to cartilage cells.

When combining LA with corticosteroids, flocculation—aggregation of the particles of steroid—may occur.19 Indeed, dilution with either saline or LA may influence the size of corticosteroid particles.20 Betamethasone sodium phosphate/betamethasone acetate (Celestone Soluspan) should not be mixed with LAs that contain the excipients methylparaben, propylparaben, or phenol because of an increased risk of flocculation.19 Flocculation leads to larger particles that may
clog smaller bore needles, preventing injection. The effect of flocculation of the injected steroid on its therapeutic effect is unclear; theoretically, the change in the size of the microaggregates of the steroid could significantly alter the bioavailability of the steroid over time as well the distribution within the joint after injection, altering the therapeutic effect.

Systemic effects of LAs include allergic reactions and central nervous system and cardiac toxicity.23 When appropriate steps are taken to avoid intravascular injection, including frequent aspiration and using small volumes for musculoskeletal injections, the incidence of these occurrences are low. Allergic reactions are more common with amino-ester LAs secondary to the production of metabolites related to para-aminobenzoic acid. Allergic reactions may also be due to the preservatives contained within the carrier solution (e.g., methylparaben). Cross-sensitivity does not exist between LA structural classes. The American Society of Regional Anesthesia published a practice advisory on local anesthetic toxicity and provided a checklist for managing local anesthetic toxicity (Fig. 71.1).

CORTICOSTEROIDS
INDICATIONS AND MECHANISM OF ACTION
Corticosteroids are often used for pain associated with symptomatic arthritis and soft tissue conditions (e.g., tendinitis, bursitis, and tenosynovitis). Numerous guidelines with specific focus on osteoarthritis of the knee recommend IA corticosteroid injection for short-term pain relief.24,25 Intra-articular steroid injections should be part of a multimodal treatment plan that includes aerobic and muscle-strengthening programs. Contraindications to IA injection are shown in Box 71.1.

The exact mechanism of action of corticosteroids in reducing arthritic joint pain has not been completely defined. Corticosteroids placed in the joint exert both local and systemic effects.19,25 In individuals with RA, changes in the non-injected knee thermographic index, a quantitative measure of radiated energy from a defined area of the joint surface, have been demonstrated after IA prednisolone and MPA levels were suppressed for up to 1 week after injection.25 The systemic effects are further confirmed by reduction of systemic inflammatory marker levels, including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).19

Corticosteroids have significant anti-inflammatory and immune effects and are active at the cellular level by combining with receptors to alter the rate of messenger RNA synthesis and specific protein production. Specifically, corticosteroids result in increased synthesis of annexin-1 (lipocortin-1). Annexin-1 has phospholipase A2-inhibitory activity that reduces production of multiple inflammatory mediators, including eicosanoids, lysosomal enzymes, interleukin-1, leukotrienes, and prostaglandins.26-28 The clinical response to IA steroids is accompanied by histologic improvement and decreased expression of genes that are involved in articular cartilage destruction.29 Additionally, corticosteroids reduce microvascular permeability and synovial perfusion, and they increase synovial fluid viscosity.30

Corticosteroids seem to exert greater therapeutic effects with IA injection versus either systemic or intramuscular (IM) administration. Injection of corticosteroid into multiple joints in RA patients greatly improved ACR criteria, patient disease activity, number of tender points, and reduced systemic side effects, when compared to equivalent IM dosing.31

CORTICOSTEROID SELECTION (STRUCTURE AND FUNCTION)
The first steroid used for IA injection was hydrocortisone.32,33 Although over the past 50 years pharmacologic developments have resulted in the advancement of steroid preparations, substantial variation still exists for agent selection. However, there remains a paucity of randomized controlled trials comparing the efficacy of different corticosteroids for osteoarthritis. Thus, evidence-based recommendations to guide steroid selection cannot be made. In 1994, a survey of ACR members indicated that agent selection was usually determined empirically and was strongly influenced by the geographic region of training. The three most commonly utilized agents were MPA, TH, and triamcinolone acetonide (TA).32

Table 71.1 lists commonly utilized corticosteroids that have been certified by the United States Food and Drug Administration (FDA) for IA injection. The only other corticosteroid approved for IA injection is dexamethasone. Dexamethasone, a highly water soluble, nonparticulate steroid preparation, exerts primarily systemic effects even after IA injection and is not routinely utilized for IA injections.19,20

The selection of a depot corticosteroid can be based on cost and multiple pharmacologic properties including solubility as well as crystal and molecular structure. Chemical structures important to depot steroids include the presence of an ester group and the addition of a fluorine group. Ester groups decrease corticosteroid solubility.33 Inserted fluorine groups increase corticosteroid absorption and increase steroid potency.19

Corticosteroid solubility may influence duration of action, although published studies are conflicting. Triamcinolone hexacetonide is the most insoluble injectable corticosteroid. Some IA injection studies have demonstrated prolonged duration of activity with TH compared to other corticosteroids with higher solubility. Derendorf and associates34 demonstrated that TH was associated with lower levels of systemic absorption and higher synovial levels than similar IA administration of TA. Comparison of TH and MPA for knee osteoarthritis did not support steroid solubility as the only factor influencing drug duration of action and therapeutic efficacy.35 After 3 weeks, TH was more effective but at 8 weeks only MPA resulted in continued improvement in pain and disability scores. Another study comparing TH and MPA for RA treatment demonstrated a longer therapeutic effect with TH.36 Thus, available data are conflicting.

The adverse-effect profile of a corticosteroid should also be considered. Methylprednisolone acetate may be utilized for both joint and soft tissue injections, whereas TH is not recommended for soft tissue injections because of the higher risk of calcification, necrosis, and atrophy of soft tissues.9,33,37
The Pharmacologic Treatment of Local Anesthetic Systemic Toxicity (LAST) Is Different from Other Cardiac Arrest Scenarios

- Get Help
- Initial Focus

- **Airway management**: ventilate with 100% oxygen
- **Seizure suppression**: benzodiazepines are preferred; AVOID propofol in patients having signs of cardiovascular instability
- **Alert** the nearest facility having cardiopulmonary bypass capability

- **Management of Cardiac Arrhythmias**
  - **Basic and Advanced Cardiac Life Support (ACLS)** will require adjustment of medications and perhaps prolonged effort
  - **AVOID** vasopressin, calcium channel blockers, beta blockers, or local anesthetic
  - **REDUCE** individual epinephrine doses to <1 mcg/kg

- **Lipid Emulsion (20%) Therapy** (values in parentheses are for 70 kg patient)
  - **Bolus 1.5 mL/kg** (lean body mass) intravenously over 1 minute (~100 mL)
  - **Continuous infusion 0.25 mL/kg/min** (~18 mL/min; adjust by roller clamp)
  - **Repeat** bolus once or twice for persistent cardiovascular collapse
  - **Double** the infusion rate to 0.5 mL/kg/min if blood pressure remains low
  - **Continue infusion** for at least 10 minutes after attaining circulatory stability
  - **Recommended upper limit**: Approximately 10 mL/kg lipid emulsion over the first 30 minutes

- **Post LAST events** at www.lipidrescue.org and report use of lipid to www.lipidregistry.org

**BE PREPARED**
- We strongly advise that those using local anesthetics (LAs) in doses sufficient to produce local anesthetic systemic toxicity (LAST) establish a plan for managing this complication. Making a Local Anesthetic Toxicity Kit and posting instructions for its use are encouraged.

**RISK REDUCTION (BE SENSIBLE)**
- Use the least dose of LA necessary to achieve the desired extent and duration of block.
- **Local anesthetic blood levels** are influenced by site of injection and dose. Factors that can increase the likelihood of LAST include: advanced age, heart failure, ischemic heart disease, conduction abnormalities, metabolic (e.g., mitochondrial) disease, liver disease, low plasma protein concentration, metabolic or respiratory acidosis, medications that inhibit sodium channels. Patients with severe cardiac dysfunction, particularly very low ejection fraction, are more sensitive to LAST and also more prone to "stacked" injections (with resulting elevated LA tissue concentrations) due to slowed circulation time.
- **Consider** using a pharmacologic marker and/or test dose, e.g. epinephrine 5 mcg/mL of LA. Know the expected response, onset, duration, and limitations of "test dose" in identifying intravascular injection.
- **Aspirate** the syringe prior to each injection while observing for blood.
- **Inject** incrementally, while observing for signs and querying for symptoms of toxicity between each injection.

**DETECTION (BE VIGILANT)**
- Use standard American Society of Anesthesiologists (ASA) monitors.
- **Monitor** the patient during and after completing injection as clinical toxicity can be delayed up to 30 minutes.
- **Communicate** frequently with the patient to query for symptoms of toxicity.
- **Consider LAST** in any patient with altered mental status, neurological symptoms or cardiovascular instability after a regional anesthetic.
- **Central nervous system signs** (may be subtle or absent)
  - **Excitation** (agitation, confusion, muscle twitching, seizure)
  - **Depression** (drowsiness, obtundation, coma or apnea)
  - **Non-specific** (metallic taste, circumoral numbness, diplopia, tinnitus, dizziness)
- **Cardiovascular signs** (often the only manifestation of severe LAST)
  - **Initially may be hyperdynamic** (hypertension, tachycardia, ventricular arrhythmias), then
  - **Progressive hypotension**
  - **Conduction block, bradycardia or asystole**
  - **Ventricular arrhythmia** (ventricular tachycardia, torsades de points, ventricular fibrillation)
- **Sedative hypnotic drugs** reduce seizure risk but even light sedation may abolish the patient’s ability to recognize or report symptoms of rising LA concentrations.

**TREATMENT**
- **Timing** of lipid infusion in LAST is controversial. The most conservative approach, waiting until after ACLS has proven unsuccessful, is unreasonable because early treatment can prevent cardiovascular collapse. Infusing lipid at the earliest sign of LAST can result in unnecessary treatment since only a fraction of patients will progress to severe toxicity. The most reasonable approach is to implement lipid therapy on the basis of clinical severity and rate of progression of LAST.
- There is laboratory evidence that epinephrine can impair resuscitation from LAST and reduce the efficacy of lipid rescue. Therefore it is recommended to avoid high doses of epinephrine and use smaller doses, e.g., <1 mcg/kg, for treating hypotension.
- **Propofol should not be used** when there are signs of cardiovascular instability. Propofol is a cardiovascular depressant with lipid content too low to provide benefit. Its use is discouraged when there is a risk of progression to cardiovascular collapse.
- **Prolonged monitoring** (>12 hours) is recommended after any signs of systemic LA toxicity, since cardiovascular depression due to local anesthetics can persist or recur after treatment.

ASRA hereby grants practitioners the right to reproduce this document as a tool for the care of patients who receive potentially toxic doses of LAs. Publication of these recommendations requires permission from ASRA.

American Society of Regional Anesthesia and Pain Medicine checklist for managing local anesthetic toxicity: 2012 version. Reg Anesth Pain Med. 2012;37:16-18.)
in performing IA injections close to the surgical date.\textsuperscript{43} Retrospective comparative studies demonstrated increased risk for deep infection in individuals who received IA corticosteroid injections shortly before the surgical replacement procedure.\textsuperscript{44,45} However, Joshy and colleagues\textsuperscript{46} did not observe increased deep infection rates for individuals who underwent IA injections shortly prior to total knee replacement.

**ADVERSE EFFECTS AND COMPLICATIONS ASSOCIATED WITH CORTICOSTEROID INJECTION**

The adverse effects and complications of corticosteroid injections can be divided into local and systemic effects. Local adverse effects include tissue (skin or fat) atrophy, Nicolau’s syndrome, tendon rupture, cartilage damage, postinjection flare, hemorrhage, joint destruction, avascular necrosis, and septic arthritis.\textsuperscript{9,33,47,48} Local tissue atrophy is one of the most common local adverse effects occurring in 1% to 8% of cases and is often associated with superficial injection, inaccurate placement, and less soluble agents (e.g., triamcinolone compounds). Skin atrophy typically develops between 1 and 4 months after injection.\textsuperscript{30,47} Methylprednisolone acetate is less frequently associated with soft tissue atrophy. Another common adverse effect is postinjection flare in pain, with a prevalence of 2% to 25%. Postinjection flare typically presents within a few hours of injection and resolves within 1 to 3 days.\textsuperscript{33}

Concern also exists for corticosteroid-specific effects on cartilage, tendon, and bone. Current data on corticosteroid effects on cartilage are conflicting. Animal studies have been inconsistent, with some demonstrating cartilage destruction and others revealing a cartilage-protective effect during acute inflammatory events.\textsuperscript{49-55} Clinical studies suggest that cartilage loss may occur more frequently with repeated injections in large numbers.\textsuperscript{9} Avascular necrosis has also been reported after joint injections, with the hip being the most commonly affected joint. This complication typically occurs after multiple joint injections within a short period of time and is seen more often in individuals who are concurrently taking oral steroids.\textsuperscript{47} Tendon disruption has also occurred following corticosteroid injection and care should be taken to avoid direct injection within tendons.\textsuperscript{47,56}

Hemorrhage and septic arthritis are two infrequent complications that carry significant morbidity. No specific guidelines exist for performance of IA steroid injections in individuals on anticoagulants, and surveys have demonstrated substantial practice variation.\textsuperscript{57} A small study demonstrated a low risk of hemorrhage in individuals taking warfarin sodium who received IA injections.\textsuperscript{58} Septic arthritis has a reported incidence ranging from 1 in 3000 to 1 in 50,000.\textsuperscript{19,59,60} To limit this adverse event it is important to understand contraindications to injection (see Box 71.1) and utilize a stringent aseptic technique. When performing a joint injection, if synovial fluid appears abnormal, the aspirated fluid should be sent for a complete white blood cell (WBC) count including differential, crystal analysis, Gram stain, and culture. Steroid should not be placed until the synovial fluid analysis (Table 71.2) has been reviewed and interpreted. Septic arthritis is a medical emergency and can result in cartilage destruction, septicemia, and death within a few days if untreated. When septic arthritis is suspected, orthopedic surgery and infectious disease specialists should
be consulted immediately. Arthrocentesis and synovial fluid analysis (see Table 71.2) are mandatory for diagnosis and to guide treatment. Blood tests including a WBC, erythrocyte sedimentation rate, and CRP are neither sensitive nor specific in diagnosing or excluding septic arthritis. Broad-spectrum antibiotics are initially started after obtaining the synovial fluid, and antibiotic selection is further guided by culture and sensitivity results. Septic arthritis has also been reported following viscosupplementation injections. Systemic adverse effects of IA corticosteroids include endocrine, metabolic, and vascular effects. The most common and predictable endocrine effect is rapid suppression of endogenous cortisol production. Maximal suppression of serum cortisol levels occur by 24 to 48 hours after IA injection; adrenocorticotropic hormone (ACTH) levels typically return to normal between 1 and 4 weeks, indicating recovery of normal endogenous steroid production. Metabolic effects include elevation of blood glucose levels in diabetic patients. Triamcinolone administration is associated with a higher rate of facial flushing.

### VISCOSUPPLEMENTATION

#### INDICATIONS AND MECHANISM OF ACTION

Viscosupplementation refers to IA administration of synthetic hyaluronic acid (HA). Intra-articular HA administration (IAHA) is recommended by numerous specialty guidelines, including the ACR, Osteoarthritis Research Society International (OARSI), and European League Against Rheumatism (EULAR), as a treatment option for the management of knee osteoarthritis. Intra-articular HA administration is approved by the FDA only for knee osteoarthritis. Off-label application of IAHA has been reported for the shoulder, hip, and ankle. Selection criteria include unresponsiveness to standard noninvasive treatment programs with clinical and radiologic signs of knee osteoarthritis. Osteoarthritis severity may be an important predictor in determining the magnitude of clinical response to IAHA injection. In general, IAHA seems most beneficial in individuals with early osteoarthritis and radiographic evidence of joint space preservation.

(Data from references 170-172.)
Although the exact mechanism of action is unknown, the treatment goal is to restore the viscoelastic properties of synovial fluid.\textsuperscript{73} Observed treatment benefits are not entirely explained by IA residence time, which is considerably shorter than the duration of clinical benefit. Several in vitro and preclinical studies have proposed additional mechanisms of action for IAHA, including inhibition of inflammation and cartilage degradation, reduction of pain mediators, and induction of in vivo HA synthesis.\textsuperscript{74,75}

### VISCOSUPPLEMENTATION AGENT SELECTION (STRUCTURE AND FUNCTION)

Viscosupplementation formulations differ in their origin, method of production, molecular weight, treatment schedule, and physicochemical properties.\textsuperscript{76} Six hyaluronic acid preparations are approved for knee osteoarthritis in the United States (Table 71.3). Formulations are classified as cross-linked or non-cross-linked and are further defined by chemical modifications and production method (avian versus non-avian-derived products). Non-avian products are produced by bacterial fermentation. All available avian preparations are derived from rooster combs and are purified natural products. The sole exception is hylan G-F 20, which is chemically modified (cross-linked HA) to increase the molecular weight to more closely replicate the properties of native synovial fluid and to lengthen IA residence half-life.\textsuperscript{76} No conclusive evidence exists that differences in viscosupplement physical properties translate into superior clinical efficacy.\textsuperscript{77}

### DOSING AND POSTINJECTION PROTOCOLS

The recommended dosing regimens for particular viscosupplementation products are based on the physical properties and the manufacturers’ prescribing recommendations. Currently, there is insufficient evidence to guide the appropriate injection frequency and dosing intervals. Common recommendations are either for a single injection or a total of three to five weekly injections based on the selected product (see Table 71.3), but these are solely based on the manufacturer’s recommendations that arose from the premarketing registry trials for each product.\textsuperscript{78} Evidence-based recommendations do not exist for interval timing for repeating treatment. Insurance providers typically require a minimum of 6 months between repeated treatment courses. Pre-injection synovial fluid aspiration and avoidance of excessive weight bearing activities for 48 to 72 hours postinjection may yield better outcomes.\textsuperscript{70,72,79}

### ADVERSE EFFECTS AND COMPLICATIONS ASSOCIATED WITH VISCOSUPPLEMENTATION INJECTION

In general, viscosupplementation is well tolerated with more local reactions but fewer systemic side effects compared to other medical interventions for the management of knee osteoarthritis.\textsuperscript{80} Frequently reported local adverse effects include injection site pain, short-term erythema, and joint effusion development. These effects are typically mild and resolve within 24 to 48 hours.

Other infrequent local adverse effects include pseudosepsis and pseudogout.\textsuperscript{81} Pseudosepsis, a severe acute inflammatory reaction (SAIR), is considered an extreme local adverse reaction. It is characterized by a large effusion, severe pain, and cellular infiltration occurring within 24 to 72 hours after the injection. Pseudosepsis often requires clinical intervention such as arthrocentesis, IA corticosteroids, and systemic analgesics.\textsuperscript{82} Pseudosepsis may be misdiagnosed as septic arthritis.\textsuperscript{82} The proposed mechanisms of pseudosepsis include an immune reaction to cross-linked products. Inappropriate injectate placement has also been suggested as a causative factor in pseudosepsis.\textsuperscript{70,83} When pseudosepsis is suspected, it is imperative that other clinical conditions such as septic arthritis are ruled out.

Pseudogout is a type of crystal-induced arthropathy characterized by calcium pyrophosphate crystal deposition. Individuals with pseudogout present with acute pain, joint swelling, and decreased function. The pathophysiology leading to pseudogout after IAHA is not clearly understood. Pseudogout occurs more frequently in patients with preexisting chondrocalcinosis; therefore, IAHA should be used with a caution in these individuals.\textsuperscript{84,85} Pseudogout may also be mislabeled as pseudosepsis. Synovial fluid analysis is helpful in making the correct diagnosis (see Table 71.2).

JOINT INJECTION TECHNIQUES

Three injection techniques (palpation, ultrasound guided, and fluoroscopy guided) may be used for the placement of drugs into the IA space. Palpation-guided IA injections are associated with inappropriate needle placement rates as high as 50% to 60%. Fluoroscopy- and ultrasound-guided methods have evolved to increase injection accuracy. Although both techniques allow for needle visualization, ultrasound guidance has advantages. Benefits of ultrasound-guided injection include dynamic real-time multiplanar imaging of relevant anatomic structures, direct visualization of injected therapeutic agents, and absence of ionizing radiation.

Improved injection accuracy with visually guided techniques ensures correct IA compound placement and may significantly influence clinical outcomes. In a randomized control trial evaluating clinical outcomes in individuals who received either anatomic palpation-guided or ultrasound-guided IA joint injections, the benefit of accurate IA placement was demonstrated. A total of 148 joint injections were studied with 95% of injections occurring in large joints (knee, hip, shoulder, elbow, wrist, and ankle). The remaining 5% of the injections occurred in small joints (interphalangeal or metacarpophalangeal joints). Intra-articular knee injections represented the largest category at 42%. Sonographic needle guidance was found to be statistically superior in multiple areas. In comparison to palpation-guided injections, ultrasound-guided injections resulted in a 43% reduction in procedural pain, 58.5% reduction in absolute pain scores at 2 weeks, 26% increase in responder rate, and 62% reduction in the nonresponder rate. Sonographic needle placement also improved detection of joint effusion by 200% and increased aspirated fluid volume by 337%. The authors concluded that sonographic guidance for IA injections is associated with significant short-term clinical advantages.

In this section we will describe the injection techniques for the three major joints: shoulder, hip, and knee. Emphasis will be placed on the visual-guided techniques. The efficacy for IA and viscosupplementation will also be discussed. Strict aseptic technique should be utilized for all injections.

SHOULDER

ANATOMY

The shoulder is a complex anatomic structure allowing multidirectional movement. The shoulder girdle refers to several articulations associated with important muscle groups that provide a wide range of shoulder movement. Three important shoulder joints are the glenohumeral, acromioclavicular, and sternoclavicular. The glenohumeral joint is a ball and socket joint that allows abduction, adduction, flexion, extension, rotation, and circumduction. The acromioclavicular joint is situated superficially between the lateral end of clavicle and acromion process of scapula. The rotator cuff muscles include the supraspinatus, infraspinatus, teres minor, and subscapularis. The subacromial bursa is positioned within the subacromial space between the overlying deltoid muscle and the underlying supraspinatus tendon, and it provides rotator cuff lubrication.

Injection techniques for the shoulder include palpation (anatomic landmarks) and visually guided (ultrasound and fluoroscopy) approaches. We will focus the discussion on visually guided techniques for the three major anatomic locations for shoulder injections: (1) subacromial/subdeltoid bursa, (2) glenohumeral joint, and (3) acromioclavicular (AC) joint. Shoulder injection using only anatomic landmarks may be inaccurate, which may adversely affect short-term clinical outcomes.

SUBACROMIAL/SUBDELTOID BURSA INJECTIONS

INDICATIONS AND MUSCULOSKELETAL PATHOPHYSIOLOGY

Subacromial injections are used to diagnose and treat various shoulder conditions including rotator cuff pathology, subacromial bursitis, and subacromial impingement. Impingement refers to the narrowing of space available for the rotator cuff resulting in compression of rotator cuff tendons against the undersurface of the coracoacromial arch. Rotator cuff impingement may result in the development of bursitis, subacromial inflammation, secondary tendinitis, and degenerative tears.

Clinical outcomes following subacromial injections have been linked to the accuracy of injection, the severity of imaging findings, and the duration of symptoms. Specifically, a magnetic resonance imaging (MRI) finding of isolated bursitis without rotator cuff tear, younger age, and shorter duration of symptoms (less than 1 year) are associated with better postinjection clinical outcomes.

PALPATION-GUIDED ANATOMIC INJECTION TECHNIQUE

Commonly utilized portals for palpation-guided subacromial injections include the posterior-lateral and anterior-lateral approach. In the posterior approach, the needle is inserted 1 to 2 cm inferior to the posterior-lateral aspect of the acromion process. The needle is directed anteriorly and cephalad. In the anterior approach, the needle is inserted approximately 1 cm inferior to the anterior/inferior aspect of the acromion process. The needle is directed posteriorly and cephalad. The posterolateral approach is preferred because of the existence of a larger subacromial space.

FLUOROSCOPY-GUIDED INJECTION TECHNIQUE

Limited information exists detailing subacromial joint injections performed under fluoroscopic guidance. The utilization of fluoroscopy with radiographic contrast IA injection has been employed as a confirmatory adjunct to palpation-guided injections, to ensure appropriate needle and injectate placement.

ULTRASOUND-GUIDED INJECTION TECHNIQUE

The patient sits in the upright position with the shoulder extended, elbow flexed, and palm of the hand placed over the ipsilateral back pocket (modified Grass position). Initially the IA portion of the biceps tendon is identified over the anterior shoulder with a high frequency linear-array ultrasound probe. The probe is oriented in the coronal plane and is moved superiorly and posteriorly until it is aligned with the supraspinatus tendon longitudinal axis. The supraspinatus tendon in this position has a typical beak-shaped appearance. The subacromial-subdeltoid bursa is visualized as a thin hypoechoic band outlined by highly

972 PART 7 — INTERVENTIONAL TECHNIQUES
reflective lines corresponding to peribursal fat between the deltoid muscle and supraspinatus tendon (Fig. 71.2). Other structures visualized include the acromion process at the medial end and the greater tuberosity at the lateral end of the scan plane. The lateral end of the transducer is marked for the skin entry. A procedure needle is advanced with an in-plane technique into the subacromial-subdeltoid bursa. After confirming needle position within the bursa, the desired medication is injected slowly while noting the expansion of the bursa. Injection without bursa distention suggests intramuscular or intratendinous needle insertion and requires needle tip repositioning.

**Glenohumeral Joint Injections**

**INDICATIONS AND MUSCULOSKELETAL PATHOLOGY**

Glenohumeral joint injections are used as a nonoperative management technique for glenohumeral arthrosis or adhesive capsulitis (frozen shoulder).

**FLUOROSCOPY-GUIDED INJECTION TECHNIQUE**

The patient is placed in the lateral decubitus position with the head resting on the nontargeted arm with the targeted shoulder in the nondependent position. A bolster is placed in front of the patient and then the patient rotates onto the bolster with the targeted arm internally rotated until the glenohumeral joint space is aligned under the fluoroscopic anterior-posterior view (Fig. 71.3). The skin entry site is marked over the inferiomedial quadrant of the humeral head. A 22-gauge needle is advanced with a coaxial fluoroscopy-guided technique to the humeral head. After negative aspiration, radiographic contrast is injected to confirm IA needle placement. Although the posterior approach is commonly used, additional fluoroscopic techniques have been described utilizing the anterior and rotator cuff interval approaches.

**ULTRASOUND-GUIDED INJECTION TECHNIQUE**

The patient is placed in either the semiprone position resting on the contralateral shoulder or in an upright sitting position with the ipsilateral arm placed on the contralateral shoulder to open up the glenohumeral joint space. A high-frequency linear-array probe facilitates visualization of superficial structures including the infraspinatus muscle, glenoid cavity, glenohumeral joint, and associated labrum. The probe is positioned over the infraspinatus fossa inferior and parallel to the scapular spine. The field of view is adjusted to encompass the posterior glenoid rim and the glenohumeral junction (Fig. 71.4). The posterior glenoid labrum appears as a triangular structure. The lateral end
of the transducer is marked for the skin entry. A 22-gauge needle is advanced with an in-plane approach into the joint deep to the infraspinatus tendon, between the posterior glenoid labrum and the hypoechoic humeral articular cartilage.\textsuperscript{109} Resistance at the time of injection suggests a needle tip position within articular cartilage or labrum and necessitates needle repositioning. Alternative techniques include the anterior\textsuperscript{110} and rotator cuff interval approaches.\textsuperscript{111}

**ACROMIOCLAVICULAR JOINT INJECTION**

**INDICATIONS AND MUSCULOSKELETAL PATHOLOGY**

AC joint injections are employed for diagnostic and therapeutic purposes for AC joint arthritis.\textsuperscript{94,112}

**FLUOROSCOPY-GUIDED INJECTION TECHNIQUE**

Few reports exist describing fluoroscopically guided AC joint injections. With the patient in the supine position, a 25-gauge needle is advanced into the AC joint using either an anterior or superior approach. Less than 0.5 mL of radiographic contrast is utilized to confirm IA placement.\textsuperscript{113,114}

**ULTRASOUND-GUIDED INJECTION TECHNIQUE**

Both in-plane\textsuperscript{115} and out-of-plane\textsuperscript{95,104,116} ultrasound-guided techniques have been described. However, the out-of-plane technique is preferred due to this joint’s small size and superficial location.\textsuperscript{95} The patient is positioned in the sitting position, and a high-frequency linear-array probe is placed in an anatomic coronal plane over the superficially located AC joint (Fig. 71.5). The acromion process, clavicle, joint capsule, and wedge-shaped fibrocartilaginous disk are visualized. A 25-gauge needle is advanced using an out-of-plane technique. Because of the shallow AC joint depth, needle insertion must be carefully controlled to avoid misplacement into the subacromial space.\textsuperscript{95,112}

**GENERAL EFFICACY OF SHOULDER INJECTIONS**

**GENERAL EFFICACY OF SUBACROMIAL/SUBDELTOID BURSA INJECTIONS**

Evidence for the efficacy of subacromial/subdeltoid bursa injections is conflicting. This incongruity may correlate with the lack of selection of specific shoulder diagnoses in some study populations or inaccurate injectate placement.\textsuperscript{95,98,117} A randomized controlled trial of palpation-guided subacromial injections demonstrated greater short-term pain reduction and functional outcome improvement at 1 and 6 weeks with the combined subacromial injection and exercise protocol versus exercise alone.\textsuperscript{118} However, the study did not demonstrate continued differences in clinical outcomes at 12 weeks. Predictors of success following subacromial injections have been investigated. MRI findings consistent with low-grade impingement and bursitis without evidence of a rotator cuff tear are positive predictors of injection response.\textsuperscript{98}

**GENERAL EFFICACY OF GLENOHUMERAL JOINT INJECTIONS**

The majority of available evidence for therapeutic gleno- humeral joint injection relates to adhesive capsulitis.\textsuperscript{117} A systematic review evaluated the efficacy of repeated IA corticosteroid injections in treating adhesive capsulitis.\textsuperscript{119} Nine randomized controlled trials were included in this review. This review concluded that multiple injections improve pain and range of motion in the short term (6 to 16 weeks). Another systematic review investigated the efficacy of IA glenohumeral joint corticosteroid injection compared to other treatments including oral corticosteroid, subacromial injection, joint manipulation, joint distension, and physical therapy. This review concluded that IA corticosteroid injection improves pain and range of motion in the short term, with no significant long-term differences in comparison to other treatments.\textsuperscript{120} Limitations to the studies included in these reviews were use of diverse outcome measures, injection techniques (palpation versus image guidance), injection site (concurrent subacromial and AC joint injection in some studies), drug types and preparations, and physical therapy regimens. Future studies with improved design are required to definitively assess IA glenohumeral injection efficacy for shoulder joint disorders.

**GENERAL EFFICACY OF ACROMIOCLAVICULAR JOINT INJECTIONS**

To date, no randomized controlled trials have been published evaluating the effectiveness of AC joint injections. Retrospective case series and prospective cohort studies reported short-term improvement.\textsuperscript{121,122} In studies examining pain relief beyond 3 months, decreasing levels of efficacy were documented with only 14% to 19% of patients reporting sustained pain relief.\textsuperscript{123,124} In one study, a predictor of short-term procedural success was capsular hypertrophy (more than 3 mm) on MRI.\textsuperscript{114}

**COMPARISONS OF ACCURACY AND EFFICACY FOR SPECIFIC SHOULDER JOINT INJECTION TECHNIQUES**

**ACCURACY AND EFFICACY OF SUBACROMIAL/ SUBDELTOID BURSA INJECTION TECHNIQUES**

When directly comparing visually guided techniques to palpation-guided techniques, Naredo and associates\textsuperscript{95} demonstrated improved technique accuracy and outcomes...
(shoulder functional assessment) with ultrasound-guided injection versus palpation-guided injection. Palpation-guided injection resulted in a 30% accuracy rate when validated with ultrasound confirmation of injectate placement. Although fluoroscopic confirmation of injectate placement has been described in other clinical studies, no direct comparative data have been presented with regard to fluoroscopy- versus palpation-guided injection techniques. In a systematic review, image-guided (fluoroscopy or ultrasound) injection had an average accuracy rate of 100% compared to an average accuracy rate of 72% for palpation-guided injections. When examining individual studies for palpation-guided anatomic injection techniques, clinical and cadaveric studies have reported variable accuracy rates in the range of 29% to 91%. Improved injection accuracy resulting from ultrasound guidance or fluoroscopic confirmation positively affects short-term clinical outcomes.

Studies directly comparing the efficacy and safety of various image-guided techniques have not been conducted. However, Mathews and coworkers questioned the reliability of fluoroscopy-guided injections in a cadaveric study. Approximately 7% of injections considered to be accurately placed under fluoroscopic guidance were found to be placed inaccurately on subsequent cadaveric dissection. Because of the complex soft tissue anatomic structures of the shoulder joint, fluoroscopic guidance may not guarantee accurate needle placement in the subacromial space. Better visualization of soft tissues using ultrasound guidance potentially favors this method for subacromial joint injections and diagnostic shoulder imaging.

Diagnostic evaluation of rotator cuff tears with high-resolution ultrasound has been shown to be comparable in utility to MRI.

**COMPARISON OF ACCURACY AND EFFICACY FOR GLENOHUMERAL INJECTION TECHNIQUES**

When directly comparing ultrasound-guided techniques to palpation-guided techniques, Cunningham and colleagues demonstrated that junior trainees with basic ultrasound skills achieved higher IA injection accuracy rates using ultrasound-guided (63%) compared to palpation-guided (40%) approaches. No studies exist that directly compare fluoroscopy- versus palpation-guided glenohumeral injection techniques. In one review, image guidance (fluoroscopy, ultrasound, and MRI) had an average accuracy rate of 95% compared to an average accuracy rate of 79% with palpation guidance. When examining individual studies for palpation-guided anatomic injection techniques, clinical and cadaveric studies have reported variable glenohumeral injection accuracy rates in the range of 27% to 100%.

Improved glenohumeral injection accuracy resulting from ultrasound guidance or fluoroscopic confirmation significantly enhances short-term clinical outcome. In a study involving multi-joint interventions, Sibbitt and colleagues demonstrated that ultrasound guidance significantly improves clinical outcome. When directly comparing ultrasound guidance with fluoroscopic guidance, Rutten and colleagues demonstrated that ultrasound guidance improved procedural outcomes. Ultrasound guidance resulted in a first pass accuracy rate of 94% compared to 72% obtained with fluoroscopic guidance, and it also comparatively reduced procedural time and patient discomfort levels.

**HINDGLOSSES AND MUSCULOSKELETAL PATHOLOGY**

Intra-articular injections are used to diagnose and treat the symptoms of inflammatory and non-inflammatory arthropathies of the hip joint. Osteoarthritis is a significant cause of hip pain and disability. Intra-articular hip injections are used as a nonoperative treatment for hip osteoarthritis. Intra-articular hip injections are also utilized for diagnostic purposes to assist in determining and distinguishing IA hip pathology from extra-articular sources of pain. Clinical predictors of a successful response include the presence of joint effusion and lack of an atrophic radiologic pattern. The radiographic severity of hip arthritis does not predict pain relief outcome for therapeutic IA hip injection.

**PALPATION-GUIDED ANATOMIC INJECTION TECHNIQUE**

Multiple hip joint injection techniques are described in literature including palpation- (anatomic landmarks) and visually (fluoroscopy and ultrasound) guided techniques. Palpation-guided injections include both anterior and lateral approaches. Intra-articular hip injections using anatomic landmarks are often inaccurate due to the joint’s deep location. Here we focus on descriptions of visually guided techniques, which are associated with improved injection accuracy.
Fluoroscopy-Guided Intra-Articular Hip Injection Techniques

Anterior Approach

The patient is placed in the supine position on the fluoroscopy table. First, the femoral artery is identified with palpation along the inguinal crease. With fluoroscopy under an anterior-posterior view, the lateral aspect of the femoral head/neck junction is identified. A needle is then directed coaxially under fluoroscopic guidance to the lateral femoral head/neck junction while avoiding the previously marked femoral artery. After reaching the lateral aspect of the femoral head/neck junction, the needle is slightly withdrawn. Following negative aspiration, radiographic contrast agent is injected to confirm intracapsular needle placement. Corticosteroids, often with local anesthetics, are then injected (see Table 71.1).

Lateral Approach

The patient is placed in the supine position on the fluoroscopy table. First, the femoral artery is identified with palpation along the inguinal crease. With fluoroscopy under an anterior-posterior view, the lateral aspect of the femoral head/neck junction is identified. A needle is then directed coaxially under fluoroscopic guidance to the lateral femoral head/neck junction while avoiding the previously marked femoral artery. After reaching the lateral aspect of the femoral head/neck junction, the needle is slightly withdrawn. Following negative aspiration, radiographic contrast agent is injected to confirm intracapsular needle placement. Corticosteroids, often with local anesthetics, are then injected (see Table 71.1).

Ultrasound-Guided Intra-Articular Hip Injection Techniques

The patient is placed in the supine position on the procedure table. Typically, a low frequency curvilinear probe is employed to allow for adequate penetration and a larger field of view. The femoral neurovascular bundle is identified in the short axis view. In the anterior-oblique-sagittal (anterior-longitudinal) view, the femoral neck, femoral head, acetabular rim, and anterior synovial recess should be visualized. The anterior synovial recess, at the femoral head/neck junction, is the target location. In this view, the femoral neurovascular bundle is located 20 to 30 mm medial to the desired needle trajectory. Power or color Doppler is utilized to identify any overlying vascular structures such as the ascending branch of lateral femoral circumflex artery. The ultrasound view is adjusted to provide a needle trajectory that is clear of any vascular structures. A 22-gauge needle is advanced with an in-plane approach into the anterior synovial recess (Fig. 71.7). After confirming needle position within the synovial recess, the medication is injected slowly while noting expansion of anterior hip capsule.

Efficacy of Intra-Articular Hip Injections

Limited data exist that evaluate the efficacy of IA hip injections for osteoarthritis. Efficacy data for IA knee injections cannot be extrapolated to the IA hip injections because of differences in anatomic and functional characteristics. Three prospective randomized controlled studies suggest short-term efficacy for pain relief and functional outcome with visually guided (ultrasound or fluoroscopy) administration of corticosteroids.
ACCURACY AND EFFICACY FOR INJECTION
TECHNIQUE COMPARISONS

Although multiple studies have recommended image guidance to improve accuracy, no studies to date have directly compared image-guided versus palpation-guided techniques. Conventional palpation-guided IA injections may result in inaccurate needle placement. The femoral neurovascular bundle is the primary anatomic structure at risk of injury. Accuracy rates of 60% to 80% for IA injectate may result in inaccurate needle placement. The femoral neurovascular bundle is the primary anatomic structure at risk of injury. Accuracy rates of 60% to 80% for IA injectate placement have been documented with palpation-guided techniques.

Ultrasound-guided IA hip injections have demonstrated accuracy rates of 97% to 100%, which are comparable to the accuracy rates associated with computed tomography (CT)- or fluoroscopy-guided injections. Given the paucity of clinical outcome studies, no conclusive relationship can be established between improved accuracy rates and clinical and functional outcomes. One study demonstrated that ultrasound guidance significantly improved performance and clinical outcomes for small and large joint IA injections. Further evaluation is warranted regarding the safety and efficacy of IA hip injections, with direct comparison necessary between fluoroscopy- and ultrasound-guided techniques.

KNEE

ANATOMY

The knee joint is a synovial joint composed of three bones: the patella, femur, and tibia. The four major ligaments providing stability to the knee are the anterior cruciate, posterior cruciate, medial collateral, and lateral collateral.

The medial and lateral menisci are fibrocartilaginous structures that provide stability, lubrication, and nutrition to the joint space. Meniscal tears occur three times more frequently in the medial meniscus. Knee flexion and extension are the main motion planes. The knee is divided into three major compartments: medial, lateral, and patellofemoral. Knee arthritis typically occurs in two or more compartments.

INDICATIONS AND MUSCULOSKELETAL PATHOLOGY

Intra-articular knee injections with either corticosteroids or viscosupplements are part of nonoperative management of knee osteoarthritis. In 1997, viscosupplementation was approved in the United States to treat knee osteoarthritis. For knee osteoarthritis, clinical predictors of a positive response to IA corticosteroids have not been conclusively identified. Multiple attempts have been made to identify clinical predictors of response to IA corticosteroids. Jones and Doherty were not able to identify clinical predictors. Gaffney and colleagues reported greater improvements in pain relief when there was clinical evidence of an effusion and aspiration of synovial fluid at the time of injection. Based on these data, it is difficult to determine whether an effusion predicts clinical response or if synovial fluid is just a surrogate marker for appropriate needle placement.

PALPATION-GUIDED ANATOMIC KNEE INJECTION

TECHNIQUES

Commonly utilized knee portals for IA injections include superior anteromedial, superior anterolateral, inferior anteromedial, inferior anterolateral, and lateral and medial midpatellar approaches. Multiple studies have examined different injection techniques in specific populations. In individuals without knee effusions, confirmation of appropriate needle placement can be difficult when using a palpation-guided technique. Jackson and colleagues demonstrated that the lateral midpatellar approach resulted in a higher accuracy rate (93%) in comparison with both the anteromedial (75% accuracy) and anterolateral (71% accuracy) approaches. The anteromedial and anterolateral injections were performed inferior to the patella with the affected leg over the side of the examination table and the knee flexed to approximately 90 degrees.

A cadaver study compared four different IA injection sites (anteromedial, anterolateral, lateral midpatellar, and medial midpatellar). The midpatellar approaches were performed with the knee extended on an examination table. The anteromedial and anterolateral injections were performed inferior to the patella with the leg over the side of the examination table and the knee flexed to approximately 90 degrees. The accuracy rate was highest for the anterolateral approach (85%) and lowest in the medial midpatellar approach (56%).

Wind and Smolinski examined injection portals superior to the patella (superolateral and superomedial) for low-volume (2 to 3 mL) injections, consistent with viscosupplementation treatment. Injections were performed with the knee extended. In this study, the lateral joint line injection was unreliable and resulted in IA placement less than 50% of the time.

FLUOROSCOPY-GUIDED KNEE INJECTION

TECHNIQUES

Techniques have been described for both fluoroscopic needle advancement and fluoroscopic confirmation of appropriate injectate location following palpation-guided IA injection. The fluoroscopy-guided injection technique can be performed above (Fig. 71.8), below, or at the level of the patella. When the injection is performed at the patellofemoral joint with either a medial or lateral approach, the patella is manually displaced away from the needle and the needle is advanced into the joint. In individuals with severe patellofemoral joint arthritis, access into the joint may be difficult with this technique.

Anterior approaches have also been described. Moser and associates assessed the infrapatellar anterolateral and anterior paramedian needle insertion approaches for technical success and patient tolerance levels during knee arthrography. For the anterior paramedian approach, the knee is flexed to 60 degrees and the needle is introduced just lateral to the inferior patellar ligament and directed cephalad and medial toward the femoral notch. For the anterolateral approach, the knee is flexed to 90 degrees and the joint space is located. The needle is placed at the joint line and directed posteriorly and slightly medial toward the lateral femoral articular condyle.

For the fluoroscopy-guided techniques, radiographic contrast agent may be injected to confirm appropriate needle placement. If radiographic contrast cannot be utilized, IA placement has also been verified by mini-air arthrography. For the superior patellar approach, mini-air arthrography is able to confirm IA placement when
a sharply defined shadow of air is found in the suprapatellar pouch after 0.5 to 5 mL of air is injected. Extra-articular placement is suggested when the air is found diffusely in the surrounding tissues. Although air arthrography has been suggested as a safe procedure, the Doppler function for ultrasound or a negative aspiration for fluoroscopy-guided injections should be utilized prior to injecting air to prevent an intravascular injection and the possible development of an air embolism.

**ULTRASOUND-GUIDED INJECTION TECHNIQUES**

Ultrasound-guided approaches include the midpatellar lateral, the midpatellar medial, and the suprapatellar synovial recess approaches. With both the medial and lateral midpatellar approaches, the patella prevents direct visualization of the needle and injectate in the IA space. Therefore, the preferred technique is the suprapatellar synovial recess approach. This approach also minimizes the risk to soft tissue structures and the articular cartilage.

One disadvantage of this approach is that the suprapatellar synovial recess can be difficult to visualize in individuals without knee effusions.

For the suprapatellar approach, the patient is in the sitting or supine position with the knee flexed approximately 20 to 30 degrees. The knee can be supported with a pillow. A high-frequency linear-array probe is utilized. First the knee is scanned with the transducer parallel to the longitudinal axis of the quadriceps tendon (Fig. 71.9). Then the skin and subcutaneous tissues, quadriceps tendon, patella, quadriceps fat pad, prefemoral fat pad, femur, and suprapatellar synovial recess are identified. The suprapatellar synovial recess is located between the prefemoral and quadriceps fat pads, and it communicates directly with the knee joint. It is important that transducer pressure is minimized to prevent compression of the synovial recess. In some individuals, a significant effusion will be visualized in the synovial recess. Next the transducer is rotated 90 degrees to the axial (transverse) plane for the short axis view (Fig. 71.10), and the same structures are identified. The needle is advanced in the short axis view with an in-plane technique from lateral to medial into the suprapatellar synovial recess. Synovial fluid may be aspirated. Then the injectate is placed into the joint under direct ultrasound visualization. The Doppler function can also be utilized to enhance visualization of the injected fluid.

The suprapatellar synovial recess injection may also be performed with the ultrasound transducer along the
femoral condyles. 164,165 For the suprapatellar synovial recess, the needle is advanced in-plane in the long axis. This approach may be advantageous when it is difficult to view the suprapatellar synovial recess in the short axis (transverse) plane.

GENERAL EFFICACY OF INTRA-ARTICULAR KNEE INJECTIONS

One review evaluated the efficacy of IA-injected corticosteroids for treating knee osteoarthritis. 166 Twenty-eight trials were included in the analysis. Corticosteroids were compared to placebo, viscosupplementation (hyaluronic acid and hylan derivatives), and joint lavage. For pain relief at 1 week, injected corticosteroids were found to be superior to placebo with a number needed to treat (NNT) of three. Increased pain reduction by injection versus placebo lasted up to 3 weeks. From 4 to 24 weeks there was a lack of evidence to support prolonged therapeutic efficacy. Functional outcomes were difficult to evaluate secondary to a lack of data. Corticosteroid injection and viscosupplementation benefits were similar between 1 and 4 weeks postinjection. From weeks 5 to 13, viscosupplementation was assessed as superior, with improvements maintained in functional and pain outcomes.

A systematic review of viscosupplementation for the treatment of osteoarthritis evaluated 76 trials. 160 In comparison to placebo, viscosupplementation was found to be superior. From 5 to 13 weeks postinjection, viscosupplementation improved pain relief from baseline by 28% to 54%, and enhanced function by 9% to 32%. Although slower in onset, viscosupplementation appears to have a more prolonged therapeutic effect than IA corticosteroids. 167 Comparisons between different formulations of viscosupplementation could not be made secondary to differences in study designs and outcome measures. 80

COMPARISONS OF ACCURACY AND EFFICACY FOR INTRA-ARTICULAR KNEE INJECTION TECHNIQUES

In direct comparison of visually guided techniques to palpation-guided techniques for IA knee injections, numerous studies have demonstrated greater accuracy with visually guided methods. 87,165,165,168 For the suprapatellar approach, ultrasound-guided IA injection resulted in greater accuracy rates (96% to 100%) than palpation-guided injections (55% to 84% accuracy). 164,165 For the medial patellar portal, injection accuracy increased from 77% for blind injections to 96% for ultrasound-guided injections. 163 Improvement in accuracy from ultrasound needle guidance positively and significantly influences clinical outcomes and cost effectiveness. 87,168 Improvement in outcomes using ultrasound guidance for arthrocentesis of the effusive knee included a 48% reduction in procedural pain and a 183% increase in aspirated synovial fluid volumes. 169 Short-term pain outcomes were also improved at 2 weeks postinjection. Although fluoroscopic guidance assists with needle placement, data have not yet been presented that demonstrate improvements in clinical or functional outcomes.

CONCLUSION

Joint injections are an important part of multimodal treatment for painful musculoskeletal conditions. Ultrasound- and fluoroscopy-guided IA injections assist in improving the accuracy of needle placement. Ultrasound is particularly helpful for interventional musculoskeletal procedures, offering advantages for specific procedures due to its ability to visualize periarticular soft tissues and provide real-time needle tracking without using ionizing radiation. The improvement in the accuracy of needle placement with ultrasound guidance for some joints is associated with significant clinical outcome benefits when compared with palpation-guided techniques. Future comparative studies are needed to develop guidelines for selecting the most appropriate IA corticosteroid and viscosupplementation agents and selecting the best methods to deliver these agents. Particular attention must be paid to the efficacy and adverse effects associated with treatment of each particular joint and underlying musculoskeletal condition. Furthermore, optimal protocols for the timing of injection, postprocedure activity, and specific dosing regimens need to be defined. For some joint injections, larger-scale studies are needed to directly compare the safety and efficacy of ultrasound-guided IA techniques with traditional landmark-based and fluoroscopy-guided techniques.

KEY POINTS

- Musculoskeletal diseases, including symptomatic arthritis and soft tissue conditions, are associated with high levels of disability and significant economic costs. Osteoarthritis is the most prevalent form of arthritis.
- When joint injections are used, they should be incorporated into a multimodal treatment plan.
- Agents utilized for joint injections include corticosteroids, local anesthetics, and viscosupplements.
- Multiple corticosteroid and viscosupplementation formulations exist with differing pharmacologic properties.
- Viscosupplementation seems to have a more prolonged analgesic effect than intra-articular corticosteroids.
- It is important to understand the adverse effects and complications associated with each injectate class. Appropriate management strategies should be employed when these events occur.
- Joint injections may be performed with palpation, ultrasound-guided, or fluoroscopically guided injection techniques.
- Visually guided techniques (ultrasound and fluoroscopy) have been shown to improve the accuracy of needle placement.
- Ultrasound offers advantages for specific procedures because of its ability to visualize periarticular soft tissues and to provide real-time needle tracking without ionizing radiation.
- Appropriate intra-articular placement with ultrasound has been shown to positively influence clinical and economic outcomes.
SUGGESTED READINGS

Peterson C, Hodler J. Evidence-based radiology (part 2): is there sufficient research to support the use of therapeutic injections into the peripheral joints? Skeletal Radiol. 2010;39:11-18.

Pain practitioners have come to rely on fluoroscopy and, to a lesser but growing extent, on computed tomography (CT) to facilitate image-guided pain treatment techniques. Understanding the physics and biology underlying the biologic effects of ionizing radiation will help pain practitioners to minimize radiation exposure to their patients, other involved personnel, and themselves during image-guided injection. The basic elements of the fluoroscopy unit are illustrated in Figure 72.1. X-rays emanate from an x-ray tube, typically positioned beneath the table and the patient to minimize radiation exposure. The x-rays pass through the table and the patient to strike the input phosphor of the image intensifier, where they are converted to visible light and, in turn, detected by an output phosphor that transfers the signal to a digital camera for visual display on a monitor or transfer to film. The size and shape of the x-ray beam can be adjusted after exiting the x-ray tube and before entering the patient, from side to side by an adjustable linear collimator or in a circular, concentric fashion by an iris collimator. The C-arm allows variation in the axis of the x-ray beam in numerous planes relative to the patient.

The use of CT has become more commonplace, particularly among radiologists. With the advent of fluoroscopy units that can rotate around the patient and reconstruct the images in multiple planes, the distinction between CT-fluoroscopy and traditional CT has become blurred. These CT-fluoroscopy units yield data that can be reformatted in multiple planes and produce final images rivaling the quality of conventional CT. However, acquiring images in multiple planes with either CT-fluoroscopy of conventional CT requires significantly greater radiation exposure than conventional fluoroscopy.1 In most instances, the superior anatomic information provided does not warrant the routine use of these advanced imaging modalities (see the further discussion of radiation dose later in this chapter). Patients undergoing high-risk procedures where small variations in anatomy can alter the risk/benefit ratio of a given technique may benefit from CT-fluoroscopy or conventional CT guidance.

Radiation is energy radiated or transmitted as rays, waves, or in the form of particles. X-rays are one portion of the spectrum of electromagnetic radiation. As x-rays pass through matter, they impart enough energy to dislodge electrons (ionizing radiation), yielding free radicals that can lead to harmful biologic effects. In radiography, it is the x-rays that penetrate the body without effect that emerge to strike an image intensifier where they are converted to visible light and can be displayed on a monitor or transferred to film, producing an image based on x-ray penetrability of various tissues.

Several factors and definitions are central to any basic understanding of radiation safety. The biologic effects of ionizing radiation are proportional to the time of exposure, whereas radiation exposure is inversely proportional to the square of the distance from the radiation source. Radiation exposure is expressed as roentgen (R) or coulomb per kilogram, whereas the energy absorbed from radiation is expressed as radiation absorbed dose (rad) or as gray (Gy). Because different types of radiation can have different biologic effects, units of exposure are converted from rad to radiation equivalent in man (rem) or Sievert (Sv). The units used to express radiation exposure are listed in Table 72.1.2 For x-rays, 1 R ~ 1 rad ~ 1 rem.

The electrical input to the tube that generates the x-rays can be varied to produce x-rays that differ in number and energy. Increased current applied to the x-ray tube (expressed as milliamps or mA) produces more x-rays, and the more x-rays that strike the image intensifier, the darker the image. Lengthening the exposure time will also increase the number of x-rays reaching the image intensifier, thus variations in current and exposure time are expressed as mAs (mA x seconds). Increased voltage (expressed as kilovoltage peak or kVp) applied to the x-ray tube results in x-ray emission at higher energy levels (i.e., with greater ability to penetrate). In general, high kVp (75 to 125 kVp) and low mA (50 to 1,200 mA) are employed for fluoroscopy with short exposure times. This combination optimizes image quality while minimizing radiation exposure. High kVp/low mA combinations expose the patient to significantly less radiation than low kVp/high mA combinations. Modern fluoroscopy units typically employ automatic brightness control (ABC), which automatically adjusts kVp and mA to yield optimal brightness and contrast.
The x-rays generated during fluoroscopy are a form of ionizing radiation and have the potential to produce significant biologic effects. Small doses of ionizing radiation can produce molecular changes that take years to manifest in the form of cancerous transformation. Exposure to low doses of ionizing radiation is likely inconsequential because normal cellular mechanisms repair the damage. The International Committee on Radiation Safety Protection (ICRP) has produced estimates of the maximum permissible dose (MPD) of annual radiation to various organs (Table 72.2). Exposure below these levels is unlikely to lead to any significant effects, but the ICRP recommends that workers should not receive more than 10% of the MPD.

Use of fluoroscopy for interventional procedures grew rapidly during the late 1980s, leading to increased concerns about radiation exposure. In 1994, the U.S. Food and Drug Administration (FDA) issued a public health advisory about serious radiation-related skin injuries.
resulting from some fluoroscopic procedures. Today’s equipment and techniques have reduced the risks of radiation exposure dramatically. Radiation exposure during a typical epidural steroid injection carried out with fluoroscopy and assuming the practitioner is at least 1 meter from the x-ray tube has been reported to be as low as 0.03 mR. In contrast, the typical entrance skin exposure during fluoroscopy ranges from 1 to 10 R per minute. A typical single chest radiograph leads to a skin entrance exposure of 15 mR. Thus, 1 minute of continuous fluoroscopy at 2 R per minute is equivalent to the exposure during 130 chest radiographs. Minimum target organ radiation doses that lead to pathologic effects are shown in Table 72.3. Radiation dermatitis still occurs in fluoroscopists with unknown long-term consequences. Estimates of the relative radiation dose to the patient during use of fluoroscopy in comparison to other common diagnostic radiologic procedures are shown in Table 72.4.

combining optimal technique and shielding to minimize patient and personnel exposure.5,6 Because no dose of ionizing radiation is without biologic effects and can be considered absolutely safe, radiographs should be used only when necessary, and the dose and exposure time should be limited. Dose is a factor of both the number of x-rays (proportional to mA × seconds of exposure) and the energy of the x-rays (proportional to kVp).7 Modern fluoroscopy units employ ABC, which automatically controls mA and kVp settings to optimize brightness and contrast while minimizing dose. However, if you choose to use fluoroscopy in the manual mode (e.g., to increase penetration in an obese patient), the kVp should be increased while minimizing mA. For an equivalent increase in exposure, the mA must be doubled, whereas the kVp must be raised only 15%. When using ABC mode, the only element under practitioner control is the exposure time, and this should be held to the minimum required to complete the procedure. Short pulses of exposure rather than continuous exposure should be employed whenever feasible. Continuous fluoroscopy in the form of movies (cineradiography) and digital subtraction exposes patients to markedly higher doses than brief spot images (see Table 72.4). Many modern units include an option termed pulsed mode for use in place of a continuous technique. This mode substitutes brief, periodic spot images separated by an interval without exposure (e.g., a new image is displayed one to two times per second). Use of this mode in place of continuous fluoroscopy can reduce overall exposure dramatically and is suitable for procedures in the pain clinic where continuous fluoroscopy is needed (e.g., while threading an epidural catheter or spinal cord stimulation lead; see Fig. 72.2).

**OPTIMIZE THE POSITION OF THE X-RAY TUBE**

Radiation exposure to the patient is best minimized by ensuring optimal distance between the patient and the x-ray tube (Fig. 72.3). When the x-ray tube is positioned close to the patient, a small area of skin will be exposed to radiation, but because of the close proximity of the x-rays, the dose that this smaller area will be exposed to is much higher. When the tube is positioned further from the patient, a larger area is exposed to a smaller dose of radiation. The x-ray tube should be positioned as far from the patient as possible, without including unnecessary structures in the field of view.

**EMPLOY SHIELDING WHENEVER POSSIBLE**

The use of lead shielding can prevent exposure of regions adjacent to the area that is to be imaged from being exposed to any ionizing radiation. Small lead shields can be placed on the table underneath the patient, directly in front of
the x-ray beam before it penetrates the patient to protect the gonads or the fetus in the rare instance where fluoroscopy is necessary in a pregnant patient. Although lead shields should be readily available in the fluoroscopy suite, they are seldom practical for use during image-guided injection of the lumbosacral spine because the shield would lie directly in the path of the structures to be imaged.

**EMPLOY COLLIMATION**

Fluoroscopy units have built-in mechanisms that allow the emitted x-ray beam to be reduced in size and changed in shape (or collimated) so the area of the patient exposed is minimized. All units have both linear and circular collimation. Linear collimation employs shutters that can be moved in from either side of the exposure field and are helpful in imaging long, thin structures such as the spine (Fig. 72.4). Circular or iris collimation can be helpful when a small, circular area is to be imaged (Fig. 72.5). Collimation is also helpful in optimizing image quality because the ABC mode attempts to optimize the image quality by taking into account the exposure needed across the entire field of exposure; it is often difficult to visualize radiodense and radiolucent areas in the same image. Useful employment of collimation can exclude areas of greatly varying radiodensity to improve image quality by reducing the range of densities included in the field. Two good examples are imaging of the thoracic spine, where the large density differences between the spine and the adjacent air-filled lungs can make it difficult to see the bony elements of the spine with any resolution. Linear collimation to limit the field to the spine itself will dramatically improve the image quality. Likewise, imaging in the cervical spine is fraught with the same difficulties when the air on either side of the neck is included in the x-ray field (see Fig. 72.4). Either linear collimation or circular collimation (see Fig. 72.5) can be used to limit the field to the area of interest, improving image quality and reducing radiation exposure. Modern fluoro units may also allow for magnification of the image by electronically magnifying the area of interest. Magnification allows better visualization of a smaller area but leads to increased radiation exposure as the system increases output to compensate for losses in gain. To minimize the dose to the patient, the largest field of view, in conjunction with the tightest collimation, should be employed.

**MINIMIZING PRACTITIONER EXPOSURE**

**EMPLOY PROPER SHIELDING**

Only the personnel needed to conduct the procedure should be in the fluoroscopy suite. All personnel should be shielded with lead aprons before use of fluoroscopy begins. The practitioner using the fluoroscopy unit should alert everyone in the room that he or she is about to begin and ensure that personnel are shielded. Routine use of thyroid shields can minimize the long-term risk of thyroid cancer. Although protective lead gloves can reduce the exposure of the hands to radiation, they can produce a false sense of security. When leaded gloves are employed and the practitioner’s hands are in the field of exposure, units with ABC will increase their output to compensate for the radiodense leaded gloves and negate their protective effects. Using
techniques that eliminate the practitioner’s hands from direct exposure within the x-ray field should be used at all times. Protective eyeglasses are available that dramatically reduce eye exposure during fluoroscopy; leaded eyewear is recommended for practitioners who accumulate monthly readings on collar badges above 400 mrem (4 Sv). Levels of exposure in this range are typically encountered only in areas where continuous cineangiography is conducted frequently (e.g., the cardiac catheterization laboratory).

**PRACTITIONER POSITION**

The practitioners must understand the geometry of the radiation path as it passes from the x-ray tube to the image intensifier and adopt positions that minimize their exposure during fluoroscopy (Fig. 72.6). The dose drops proportionally to the square of the distance from the x-ray source. Thus, standing as far from the x-ray tube as practical is the first means to minimize exposure. Using an intravenous extension tube and taking a step back from the table during periods where contrast is injected under continuous or live fluoroscopy will reduce exposure. When the x-ray tube is rotated to obtain a lateral image, the practitioner should step completely away from the table beneath the x-ray tube and out of the path of the x-ray beam or move to the side of the table of the image intensifier. Inverting the C-arm so the x-ray tube is above the table and the image intensifier is below the table is a means some practitioners use to increase the C-arm’s range of lateral movement beyond the typical 45 to 55 degrees allowed by the unit. This practice dramatically increases exposure to both patient and practitioner by bringing them in close proximity to the x-ray source.

**OPTIMIZING IMAGE QUALITY**

Modern fluoroscopy units use ABC, which automatically adjusts mA and kVp to optimize image brightness and contrast while minimizing radiation exposure. These controls can be adjusted separately. Increased kVp produces x-rays of higher energy that penetrate without attenuation, thus the resulting image is brighter with less contrast between different tissues, thereby reducing image detail. The clarity of small structures, or image detail, can be improved by lowering kVP, reducing the distance between the patient and the image intensifier, and by using collimation to limit the field of exposure to only those structures of interest. Fluoroscopic images also have less sharpness at the periphery of the image because of a fall off in brightness and spatial resolution, a phenomenon called *vignetting*. Placing the structure of interest in the center of the image will yield maximum image detail. Finally, *pin cushion distortion* occurs toward the periphery of the image because the x-rays emanate from a spherical surface and are detected on a flat surface. This results in an effect much like a fisheye camera lens with a splaying outward of objects toward the periphery of the image. This can lead to particular difficulties when attempting to advance a needle using a coaxial technique if the needle is toward the periphery of the image. Within the past several years, several manufacturers have developed electronic flat plate detectors to replace conventional image intensifiers. Flat plate detectors employ a gridlike

---

**Figure 72.6** Radiation exposure dosage during fluoroscopy. A, During routine use in the anterior-posterior plane, the x-ray tube (source) should be positioned below the patient and the detector above the patient to minimize radiation exposure to both the patient and the practitioner. B, The oblique projection results in markedly increased exposure to the practitioner. C, During use in the lateral projection, the practitioner should step completely behind the x-ray tube (source) to minimize radiation exposure. When it is necessary to work close to the patient during lateral fluoroscopy, the practitioner should step away from the x-ray tube and move to the side of the table opposite the x-ray tube to minimize exposure. D, Radiation exposure to both patient and practitioner is dramatically increased when the x-ray tube (source) is inverted above the patient. Some practitioners invert the C-arm to allow for more extreme lateral angle (e.g., rotation beyond 35 to 45 degrees oblique to the side opposite the C-arm is not possible without inverting the C-arm on some units). Radiation exposure can be reduced by rotating the patient on the table and keeping the x-ray source below the table. (Reproduced with permission from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. 2nd Edition. Philadelphia: Lippincott Williams & Wilkins; 2012, Figure 2-6.)
electronic detector that eliminates both vignetting and pincushion distortion, providing optimum image quality from the center to the peripheral portions of each image. Flat plate digital detectors are rapidly replacing traditional image intensifiers. Digital flat plate detectors are capable of dramatically reducing radiation while improving image quality and eliminating the distortion of the image at the periphery of the detector that occurs with traditional image intensifiers.

**OVERVIEW OF RADIOGRAPHIC CONTRAST MEDIUM**

Iodine is the only element that has proven satisfactory as an intravascular radiographic contrast medium (RCM).\(^8\,^9\) Iodine produces the radiopacity whereas the other portions of the molecule act as the carriers for the iodine, improving solubility and reducing the toxicity of the final compound. Organic carriers of iodine are likely to remain in widespread use for the foreseeable future.\(^10\) During image-guided injection, injection of RCM can prove invaluable in determining the final location and distribution of the injectate (Figs. 72.7 to 72.9). Use of RCM can improve the safety of many techniques by allowing for detection of intravascular (Figs. 72.10 and 72.11), subdural (see Fig. 72.8), or intrathecal (see Fig. 72.9) needle location before local anesthetic or steroid is placed.

**PHARMACOLOGY OF RADIOGRAPHIC CONTRAST MEDIA**

Currently, there are four chemical varieties of iodinated RCM in widespread use: ionic monomers, nonionic monomers, ionic dimers, and nonionic dimers.\(^11\) On intravascular injection, all four are redistributed rapidly via capillary permeability to the extravascular space, they do not enter the interior of blood or tissue cells, and they are rapidly excreted, more than 90% eliminated via glomerular filtration within 12 hours of administration. None of the four varieties have marked pharmacologic actions. All RCM agents come in a range of concentrations that vary in their radiopacity and viscosity. Because iodine is the element that is responsible for the radiopacity, the iodine concentration...
in milligrams per milliliter represents the radiopacity. The nonionic monomers are now used almost exclusively in pain medicine; the nonionic dimers offer increased radiopacity at low osmolar concentrations but are not in widespread clinical use and offer questionable clinical advantages.

Several important chemical properties determine the characteristics of RCM in clinical use. Osmolality depends on the number of particles of solute in solution and is highest for the ionic contrast agents. Adverse reactions, particularly discomfort on injection, have been reduced dramatically with the advent of low-osmolar RCM. Contrast media with osmolality below 500 mOsm per kg of water are virtually painless. Radiopacity depends on the iodine concentration of the solution and, therefore, on the number of iodine atoms per molecule and the concentration of the iodine-carrying molecule in solution. Digital subtraction electronically enhances the image, reducing the amount of contrast medium needed by twofold to threefold. With the use of digital subtraction, RCM with as little as 150 to 200 mg per mL of iodine can be used even for intra-arterial use. Ionic molecules dissociate into cation and anion in solution. Non-ionicty, or a molecule that does not dissociate in solution, is essential for myelography or use along the neuraxis, where inadvertant placement within the cerebrospinal fluid (CSF) is possible during injection. The chemical properties of common RCM used in clinical practice are compared in Table 72.5.

The most frequently used ionic monomers are diatrizoate (Urografin), iothalamate (Conray), and metrizoate (Isopaque). All ionic monomers are the salts of meglumine or sodium as the cation and a radiopaque tri-iodinated fully substituted benzene ring as the anion. The ionic monomers are still used for intravenous pyelography and similar applications; however, they have been completely replaced by the low-osmolar, nonionic RCM for many applications, including intrathecal administration. The most common nonionic...
monomers in clinical use include iodixanol (Visipaque), iohexol (Omnipaque), iopamidol (Isovue), and ioversol (Optiray); only iohexol and iopamidol are labeled for intrathecal use. The nonionic monomers appeared in the 1970s and now represent the most common RCM in clinical use. They are more stable in solution and less toxic than the ionic monomers.

### ADVERSE REACTIONS TO RADIOGRAPHIC CONTRAST MEDIA

Modern contrast agents have reduced, but not eliminated, the risk of adverse reactions. To minimize the risk, RCM should be used in the smallest concentrations and in the smallest total dose that will allow adequate visualization.

### IDIOSYNCRATIC ANAPHYLACTOID REACTIONS

Idiosyncratic reactions are the most feared and most serious complications associated with RCM. At present, we cannot predict or prevent this type of reaction reliably, and they

*The ionic, high-osmolar agent diatrizoate and the nonionic, low-osmolar, agents iohexol and iopamidol. Iohexol and iopamidol are commonly used in image-guided pain treatment. These agents provide a nonionic low-osmolar RCM that balance a low risk of adverse reaction, demonstrated safety for intrathecal use, and sufficient radiopacity for identifying intravascular and intrathecal placement. RCM, radiographic contrast media.*
Severe ADR (%)*  
% of ADR*  
RCM can reach several times that of physiologic osmolality - high-osmolar contrast media, where the osmolality of the contrast medium is 300 mOsm per kg H2O (see Table 72.5). Osmotoxic reactions were much more common with the use of ionic and non-ionic contrast media: a report from the Japanese Committee on the Safety of Contrast Media. Radiology. 1990;175:621-628.

Nonidiosyncratic reactions can be divided into chemotoxic reactions (chemical reactions to the iodine-carrying molecule) and osmotoxic reactions (those caused by high osmolality of the contrast medium). These nonidiosyncratic reactions are dose dependent; therefore, this type of reaction should be exceedingly rare in patients receiving the small volumes of RCM required to facilitate needle localization during image-guided pain treatment.

Chemotoxic reactions are rare and may result in direct organ toxicity and include cardiac (direct and prolonged decrease in cardiac contractility), neurologic (seizures), and renal toxicity (oliguria, impaired creatinine clearance, and reduced glomerular filtration rate that may progress to acute renal failure). Osmotoxic reactions were much more common with the high-osmolar contrast media, where the osmolality of the RCM can reach several times that of physiologic osmolality of 300 mOsm per kg H2O (see Table 72.5). Osmotoxic reactions have been dramatically reduced with the advent of low-osmolar, nonionic agents such as iohexol and should be exceedingly rare after administration of the small volumes used in pain medicine applications. Hyperosmolar reactions include erythrocyte damage (hemolysis), endothelial damage (capillary leak and edema), vasodilation (flushing, warmth, hypotension, cardiovascular collapse), hypervolemia, and direct cardiac depression (reduced cardiac contractility). The relative incidence of various adverse reactions to RCM is listed in Table 72.7.

Reactions can be generally grouped as mild, moderate, or severe. The incidence of these reactions following the use of RCM used in pain medicine has not been reported, but the incidence following intravenous administration of larger volumes of contrast is given here. Mild reactions occur in 5% to 15% of those receiving intravenous contrast and include flushing anxiety, nausea, arm pain, pruritus, vomiting, headache, and mild urticaria. These are generally mild and self-limiting, and require no specific treatment. Occasionally, an oral antihistamine (diphenhydramine 25 mg) can be useful in managing pruritus and anxiety. More serious reactions occur in 0.5% to 2% of those receiving intravenous contrast and include more pronounced severity of mild symptoms, as well as moderate degrees of hypotension and bronchospasm. Suggested treatments for moderate reactions are given in Table 72.8.

Severe reactions are life threatening, occur in less than 0.04% of those receiving intravenous RCM, and include convulsions, unconsciousness, laryngeal edema, severe bronchospasm, pulmonary edema, severe cardiac arrhythmias, and cardiovascular collapse. Treatment of these life-threatening reactions is urgent, necessitating the immediate

*ADR following intravenous injection of low-osmolar, nonionic radiographic contrast media.

ADR, adverse drug reaction.

Severe reactions are life threatening, occur in less than 0.04% of those receiving intravenous RCM, and include convulsions, unconsciousness, laryngeal edema, severe bronchospasm, pulmonary edema, severe cardiac arrhythmias, and cardiovascular collapse. Treatment of these life-threatening reactions is urgent, necessitating the immediate...
availability of full resuscitation equipment and trained personnel, along with a practiced routine for responding to these rare events. The airway must be secured, and oxygen, mechanical ventilation, external cardiac massage, and electrical cardiac defibrillation must be administered as required. Epinephrine is the drug of choice for the treatment of anaphylaxis; the usual adult starting dose is 0.01 mg/kg (maximum of 0.5 mg) subcutaneously, intravenously, or intramuscularly. Death may ensue following this type of severe adverse reaction; the incidence is not known with accuracy but likely lies between 1/14,000 to 1/170,000 intravenous administrations of RCM.

### PREVENTION OF REACTIONS TO RADIOGRAPHIC CONTRAST MEDIA

Recognition of the factors that predispose patients to adverse reactions when receiving RCM is the first step in prevention (see Table 72.6). The risk of reaction is increased in those with previous reaction to RCM (sixfold), in asthmatics (eightfold), in allergic and atopic patients (fourfold), and in patients with advanced heart disease (threelfold). If there is any chance that the injectate will end up in the subarachnoid space, then a low-osmolar, nonionic contrast agent must be used. Infrequent deaths have been reported following the inadvertent intrathecal administration of ionic RCM. Most pain medicine practitioners have adopted the universal use of a low-osmolar, nonionic RCM in a moderate concentration (e.g., iohexol 180 mg/mL or iopamidol 41%) for all applications.

There is no known premedication regimen that can reliably eliminate the risk of severe reactions to RCM. The most common strategies suggested combine pretreatment with corticosteroids (e.g., oral prednisone 50-mg doses 12 and 2 hours before RCM administration) and antihistamines (e.g., oral diphenhydramine 50-mg doses 1 to 2 hours before RCM administration). Some authors recommend the addition of H2-antagonists (e.g., oral ranitidine). This approach has proven to reduce the incidence of subsequent adverse reactions in those with a history of previous reaction to high-osmolar contrast agents; however, it is less clear whether prophylactic treatment is needed prior to the use of a low-osmolar, nonionic contrast agent such as iohexol. Patients believed to be at greater than usual risk are listed in Box 72.1. It has been our practice to avoid radiographic contrast altogether in those at elevated risk for adverse reaction. Most procedures in pain medicine can be carried out safely without use of radiographic contrast. In some instances (e.g., epidural placement), the location can be established using loss of resistance alone, and final needle position can be verified using anterior-posterior and lateral radiography without contrast. However, some injections should not be attempted without radiographic contrast injection (e.g., transforaminal injection); in this case, injection of contrast under live or real-time fluoroscopy (with or without digital subtraction) is the only means to detect intra-arterial needle location (see Figs. 72.10 and 72.11) and to prevent catastrophic injection of particulate steroid directly into critical vessels supplying the spinal cord. Performing interlaminar epidural steroid injection without contrast may well be a safe and effective alternative to transforaminal injection in the patient with a greater than usual risk for adverse reaction to RCM.

### USE OF GADOLINIUM AS AN ALTERNATIVE TO IODINATED RADIOGRAPHIC CONTRAST MEDIA

Gadolinium chelates, such as gadopentetate dimeglumine (Magnevist), are commonly used intravenous contrast agents used to enhance vascular structures during diagnostic magnetic resonance imaging. Gadolinium chelates also have an intrinsic ability to attenuate x-rays and have been used successfully in place of iodinated contrast media for angiography and spinal injections used in image-guided...
pain treatment. They have also been used as an alternative to iodinated contrast agents in patients with known contrast allergy. The radiopacity of gadolinium is less than that of iodinated contrast agents, resulting in a less conspicuous appearance on fluoroscopic images (Fig. 72.12, A, B). Nonetheless, 1 to 3 mL of undiluted gadopentetate dimeglumine (Magnevist) has been used successfully and reliably for identification of the epidural space; the visualization can be further enhanced through the use of digital subtraction in combination with gadolinium (Fig. 72.12, C). Limited experience with intrathecal administration of gadolinium chelates suggests that it is safe when administered directly within the CSF.18 Use of gadolinium-based contrast agents has been linked to the subsequent development of nephrogenic systemic fibrosis in patients with renal disease.19 The risk depends on the degree of renal dysfunction, dose of contrast agent, and severity of concomitant illness and varies from negligible in healthy patients to up to 2% to 5% in select high-risk patients. The use of gadolinium-based contrast is contraindicated in patients with GFR < 30 mL/min/1.72 m², and caution is recommended in patients with moderately reduced kidney function (30 to 60 mL/min).20 Given the small dose of gadolinium used in most pain treatment applications, the risk of renal toxicity should be negligible, making gadolinium a viable and readily available alternative in those at risk of reaction to iodinated agents.

ACKNOWLEDGMENTS

Much of the material in this chapter was originally prepared and published by the author in Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine, 2nd edition, Philadelphia, Lippincott Williams & Wilkins, 2012. I am grateful to Lippincott Williams & Wilkins, the original publisher, and Brian Brown, executive editor with Lippincott, for providing permission for the material to appear here in a modified format.

KEY POINTS

- The biologic effects of ionizing radiation are proportional to the time of exposure, whereas radiation exposure is inversely proportional to the square of the distance from the radiation source.
- Modern fluoroscopy units typically employ automatic brightness control (ABC), which automatically adjusts kVp and mA to yield optimal brightness and contrast.
- The International Committee on Radiation Safety Protection (ICRP) has produced estimates of the maximum permissible dose (MPD) of annual radiation to various organs. Exposure below these levels is unlikely to lead to any significant effects, but the ICRP recommends that workers should not receive more than 10% of the MPD.
- A minute of continuous fluoroscopy at 2 R per minute is equivalent to the exposure during 130 chest radiographs.
- Practitioners using ionizing radiation should adhere to the ALARA principle (“as low as reasonably achievable”), combining optimal technique and shielding to minimize patient and personnel exposure.
- The x-ray tube should be positioned as far from the patient as possible, without including unnecessary structures in the field of view.
- To minimize the dose to the patient, the largest field of view, in conjunction with the tightest collimation, should be employed.
- Although protective lead gloves can reduce the exposure of the hands to radiation, they can produce a false sense of security.
- Leaded eyewear is recommended for practitioners who accumulate monthly readings on collar badges above 400 mrem (4 Sv).
KEY POINTS—cont’d

- Iodine is the only element that has proven satisfactory as an intravascular radiographic contrast medium (RCM). Iodine produces the radiopacity, whereas the other portions of the molecule act as the carriers for the iodine, improving solubility and reducing the toxicity of the final compound.
- Digital subtraction electronically enhances the image, reducing the amount of contrast medium needed by twofold to threefold.
- Of the common nonionic monomers in clinical use, only iohexol and iopamidol are labeled for intrathecal use.
- The most common premedication regimen to reduce the risk of severe reactions to contrast media combines pretreatment with corticosteroids and antihistamines; some recommend the addition of H2-antagonists.
- Gadolinium chelates have been used as an alternative to iodinated contrast agents in patients with known contrast allergy. Its use has been linked to the subsequent development of nephrogenic systemic fibrosis in patients with renal disease.

REFERENCES

Sickle cell disease (SCD) refers to a related group of genetic hemoglobin disorders. Sickle hemoglobin has a single mutation resulting in the replacement of glutamine with valine at the sixth amino acid position in the beta-globin subunit. Molecules of this abnormal hemoglobin polymerize upon deoxygenation into long polymers that physically deform the erythrocyte into the characteristic sickle shape and ultimately obstruct blood flow. This polymerization largely ceases when sickle hemoglobin is combined with adult hemoglobin, so-called sickle trait, or with high levels of fetal hemoglobin, resulting in a relatively benign condition. In contrast, this polymer formation is promoted to varying degrees by the co-occurrence of sickle hemoglobin with other abnormal hemoglobins, such as hemoglobin C, D, E, or Oarab, or mutations that reduce the production of normal hemoglobin, resulting in sickling disorders of varying degrees of severity.

The sickle mutation is believed to have arisen independently many thousands of years ago in several areas of Africa and the Middle East or Indian subcontinent. Its prevalence was maintained and expanded in these areas by reproductive advantage as sickle trait provided some degree of protection from severe malaria. Thus, most of the 100,000 to 150,000 individuals with SCD in the United States trace their ethnic origins to Africa, the Middle East, or the Mediterranean where malaria was endemic; the slave trade to the Caribbean and South America also led to the spread of the sickle mutation to many individuals of Hispanic ethnicity. The pathophysiology of vaso-occlusive pain in SCD is quite complex (Fig. 73.1) and involves mechanisms beyond sickle polymer formation, especially the adhesion of sickled erythrocytes, and perhaps other cellular elements including leukocytes and platelets, to abnormal vascular endothelium. As part of the vicious cycle of sickling, the subsequent ischemic injury from initial vaso-occlusion results in the accumulation of endogenous factors released from cells that reside within or infiltrate into the injured area (including mast cells, basophils, platelets, macrophages, neutrophils, endothelial cells, keratinocytes, and fibroblasts). Collectively, these factors, referred to as the “inflammatory soup,” represent a wide array of signaling molecules, including neurotransmitters, peptides, eicosanoids and related lipids, neurotrophins, cytokines, and chemokines, as well as extracellular proteases and protons, which damage local nociceptive nerves leading to increased spontaneous firing that is perceived as acute pain.

Although considerable further research is needed to confirm this process, the intense and repetitive nature of vaso-occlusive events and resulting chronic tissue/bone damage likely drive the experience of chronic pain in adults with SCD (Fig. 73.2) through a process termed central sensitization, which represents an activity- or use-dependent form of functional synaptic plasticity that can occur after intense repetitive noxious stimuli. Central sensitization with its augmented pain response occurs by complex processes involving changes in neurotransmitters, receptors, ion channels, and signaling pathways in spinal cord and cortical neurons that change the response elicited by normal sensory inputs, including those that usually evoke innocuous sensations, resulting in the sensation of persistent pain. Further changes in the pain experienced in chronic pain disorders occur as a result of anatomic and functional connectivity changes in various brain regions and can reverse with treatment.

**EPIDEMIOLOGY OF VASO-OCCCLUSIVE PAIN**

SCD is a relatively unique pain disorder, as pain can begin early in the first year of life as levels of fetal hemoglobin decline in susceptible individuals. Most children reported to have pain in the first year of life have pain locations (hands/feet) and signs/symptoms (swelling or tenderness) consistent with dactylitis, often referred to as “hand-foot syndrome,” which becomes progressively less prevalent in older children and rare after 5 to 7 years of age. Almost all children with SCD experience increasingly frequent pain throughout childhood and into adolescence and young adulthood; however, the majority of these painful episodes are managed at home rather than in acute care settings. Most episodes are relatively brief, typically 2 to 3 days, with pain of moderate intensity located in a small number of body sites, usually the lower legs, back, and chest wall. However, a small number of children transition, often in their early adolescent years, from a pattern of sporadic episodes of brief acute pain to frequent, recurrent, acute pain or chronic pain, and these individuals represent the majority of pediatric patients hospitalized for acute pain. Pain is a more complex experience in adults with SCD, with features of both acute recurrent and chronic pain and is more often managed in an acute care setting compared to pain in children. Family characteristics and mental health issues are often comorbidities contributing to frequent health care utilization in SCD adults with chronic pain.

**OTHER PAIN ETIOLOGIES IN SCD**

Vaso-occlusive pain in SCD remains a clinical diagnosis as laboratory and imaging studies largely show nonspecific
increases in inflammatory markers and increased hemolysis. Other pain syndromes distinct from vaso-occlusive episodes are not uncommon and always need to be considered when evaluating an individual with SCD and pain (Table 73.1). Children and, occasionally, young adults can experience acute left-upper-quadrant visceral pain from rapid enlargement of the splenic capsule consistent with acute splenic sequestration, an often life-threatening trapping of sickled erythrocytes and platelets in the spleen. Almost all children with SCD will experience episodic right-upper-quadrant colicky abdominal pain and jaundice from cholelithiasis or bile duct obstruction and ultimately require cholecystectomy, as chronic hemolysis results in bilirubin accumulation in the gallbladder and the subsequent production of pigment stones. Avascular necrosis in the vertebral column, shoulder, or hips can be a source of acute pain as well as chronic pain in adolescent and young adult patients, who often respond to physical therapy for initial symptom management of hip pain; some patients, however, have progressive collapse, particularly in the head of the femur, that will ultimately require joint replacement for relief of chronic pain or to improve physical functioning. Although uncommon in the pediatric age group, leg ulcers, typically over the medial malleolus of either or both ankles, can be a source of considerable pain and disability and are difficult to manage. Headaches, as an isolated pain syndrome or as part of a vaso-occlusive event, can occur but are not well characterized. Some have features characteristic of migraine headaches, others may be more typical of tension-type headaches, and a small number of individuals satisfy current diagnostic criteria for chronic daily headache. Use of the triptan class of medications to treat migraine-like headaches in SCD individuals is contraindicated because of cardiovascular concerns.

**SCD PAIN MANAGEMENT**

**EDUCATION IS THE FOUNDATION**

A lifespan approach is most applicable for these sickling disorders, as pain will likely be experienced throughout childhood and adult life. A focus on the family is essential for children, whereas adolescents must be encouraged and supported to accept progressively more responsibility for their own pain management so that they can function appropriately in the adult health care system. Thus, initial disease and pain management education involves parents and other caregivers for young children and broadens to include the school system in older children; finally, organized transition programs starting in early adolescence focus on self-management skill education. Self-management skill development should include learning psychological approaches to pain management, similar to other pediatric chronic pain disorders for which one meta-analysis indicated the superiority of cognitive-behavioral interventions (multi-component, relaxation, and biofeedback approaches) for pain management.

**HOME MANAGEMENT: “IT TAKES A VILLAGE”**

A number of studies in children and adults suggest the preference to manage vaso-occlusive pain at home. The home setting is likely to be more comfortable for children...
and less disruptive to the families’ normal activities and routines. Surprising to most health care providers, many SCD individuals avoid care in acute care settings, as they frequently encounter negative attitudes toward patients with SCD and a pervasive fear among health care providers of catering to opioid addiction, which often compromises analgesic therapy. Successful home management requires a parent or other caregiver skilled in pain assessment and administration of appropriate analgesic medications. Extended family also is critical for psychological and physical support, as most pain episodes may last for several days and usually require around-the-clock medication for adequate management. Support by trusted medical health professionals with experience in SCD and pain management also facilitates home management and appropriate emergency department utilization. Clergy and local complementary and alternative medicine practitioners and mental health professionals also can facilitate the use of both medical and psychological interventions to assist with the management of pain symptoms. Several studies of caregivers of children with SCD have found that a large percentage of families use prayer, spiritual healing, massage, and relaxation in addition to medication to manage their child’s pain at home. In both studies, complementary medicine approaches were used more frequently with higher levels of pain or medication use.

Low-potency analgesics, such as acetaminophen and ibuprofen, are recommended as initial therapy at the onset of typical vaso-occlusive pain and are often adequate for mild to moderate pain, particularly in younger children. These analgesics are often chosen out of concern for the adverse consequences of opioid analgesics and have the advantage of less sedation and subsequent disruption of age-appropriate activities. A substantial number of oral hydrocodone and oxycodone analgesics of varying potency, often in combination with acetaminophen, are available in liquid and tablet formulations for management of more intense pain in children with SCD. There has been some shift away from the use of codeine containing analgesics because of pharmacogenetic issues of excessive toxicity or inadequate efficacy.

Although labeled dose amounts and frequency of potent oral opioid analgesics are usually prescribed, the enhanced hepatic and renal clearance of morphine in this population and the potential impact of prevalent pharmacogenetic genotypes impacting morphine metabolism suggests that the dose and frequency of these opioids may need to be further individualized.

There have been few comparative studies of adjunctive nonopioid analgesic medications in this population. A study using pharmacy claims data suggested that pharmacologic treatments for sickle pain consisted mainly of nonsteroidal anti-inflammatory drugs (NSAIDs) and weak opioids. Significantly more severe SCD patients, those with more than three yearly inpatient or emergency department (ED) visits for pain management, were prescribed more potent opioids, antidepressants, or anticonvulsants. Prescription of both stronger opioids and antidepressants or anticonvulsants was significantly associated with lower frequencies of acute sickle pain visits. Further clinical trial data are needed in SCD individuals to support these observations and to establish comparative efficacy and safety data for various analgesic and anticonvulsant or antidepressant combinations, particularly as many of these classes of medications are not currently labeled for use in pediatric age groups.

Authoritative guidelines have been published for the management of severe SCD pain in the acute care setting, but they are somewhat outdated. However, a number of pediatric hospitals have published more contemporary single site pain management practices and an update of the National Institutes of Health’s Sickle Cell Treatment Guidelines will be available in 2013. Nurse-initiated ED analgesic protocols for adults with SCD also have been developed and their implementation has been shown to improve pain relief over the period of ED treatment.

CHAPTER 73 — THE MANAGEMENT OF PAIN FROM SICKLE CELL DISEASE
Intravenous doses of potent opioids, usually morphine or hydromorphone, are the typical initial treatment for vaso-occlusive pain in both adults and children, as all are assumed to have failed a course of oral analgesics at home prior to arrival in the ED. In some pediatric centers, intravenous nalbuphine is also used, as it is often associated with fewer complaints of nausea and pruritus, but it is seldom used for SCD adults because it may precipitate opioid withdrawal symptoms in opioid tolerant individuals. The use of oral and subcutaneous routes of opioid administration is increasing in adults with limited intravenous access. Administration of opioids by patient-controlled analgesia (PCA) devices is not a common practice in the ED, but where available it allows more frequent dosing, which can be problematic in a busy ED.

The concurrent use of a parenteral NSAID, usually ketorolac, is a widespread clinical practice in the ED setting as an additional analgesic, and it may have additional benefit as an anti-inflammatory agent given the increased evidence for the role of inflammation in SCD pathophysiology. Parenteral NSAID doses administered to SCD adults are often reduced for renal insufficiency, which is not uncommon.

SCD PAIN MANAGEMENT IN THE INPATIENT SETTING

A snapshot of current analgesic practice, across a large number of pediatric and adult hospitals that participated in an observational study after hospitalization for sickle pain management, documented the widespread use of opioid-based PCA. Opioid doses varied over a wide range but appeared to be somewhat higher for individuals receiving PCA compared to scheduled opioid dosing, as well as for those receiving hydromorphone compared to morphine. The relationship between opioid dosing and prior daily opioid usage was not described in this cohort, but adult chronic pain patients with chronic opioid use have been shown to report higher postoperative pain scores after surgery and have a slower rate of pain resolution; a similar pattern is likely in SCD. A small clinical trial of opioid PCA dosing suggested that adult SCD individuals have a more rapid improvement in pain when using PCA largely delivered by continuous infusion rather than demand dosing, likely because individuals with severe pain had difficulty obtaining adequate pain relief with frequent demand doses. Parenteral NSAIDs, usually ketorolac, are commonly used as an additional analgesic. Evidence of efficacy of other adjuvant analgesics for acute sickle pain, as have been proposed for post-operative pain, have not been subjected to controlled trials. Refractory sickle pain that persists beyond 3 to 5 days can present a difficult management problem, particularly in adolescents and young adults. The use of concurrent low-dose ketamine infusions has been described for this situation, as has the use of epidural anesthesia, but further research and clinical experience are needed.

Nausea, pruritus, and constipation are common opioid-related adverse effects and require symptomatic management during the course of hospitalization, with constipation often being quite problematic. The use of concurrent administration of low doses of an opioid antagonist (naloxone) has been shown in several small pediatric cohorts to ameliorate many central nervous system (CNS) opioid-related symptoms without altering analgesia, and it may be of particular importance in SCD where respiratory depression may increase the risk for symptomatic hypoxia and SCD pulmonary complications, such as acute chest syndrome. Common opioid-related adverse effects of nausea and constipation can be ameliorated by peripherally acting nonabsorbable opioid antagonists, such as methylnaltrexone, but they have not been studied in SCD and are not yet approved for children. Similar to its use for other critically ill patients, transdermal or oral clonidine, an α2-adrenergic agonist, is often used in SCD adolescents and adults with prolonged hospitalizations and opioid exposure to reduce symptoms of opioid withdrawal after discharge, which otherwise might result in a subsequent readmission.

MANAGEMENT OF PERIOPERATIVE PAIN IN SCD

Pre-operative management of individuals with SCD relies on adequate, usually overnight, intravenous hydration and red blood cell transfusion if the hemoglobin is less than 10 grams/dl. In some low-risk surgeries, transfusion may not be necessary, and in some high-risk surgeries, individuals with higher hemoglobin levels may require exchange transfusion. Intra-operative management focuses on the prevention of sickling by maintaining adequate hydration, oxygenation, and ambient temperature. Effective pain control is a primary goal in the perioperative management of patients with SCD and may require additional analgesics compared to that used to treat other patients. For example, postoperative pain scores after laparoscopic cholecystectomy, one of the most common surgeries in SCD, were higher in SCD patients than in controls, and morphine consumption was more than double that compared to control children, as was the duration of PCA use. SCD children also had a longer duration of postoperative hospital stay (3.4 ± 1.6 days versus 1.5 ± 0.5 days). These differences likely reflect alterations in pain perception from frequent vaso-occlusive episodes, enhanced clearance of opioids, and psychosocial variables.

MANAGEMENT OF CHRONIC PAIN IN SCD: LARGELY UNCHARTED TERRITORY

The management of chronic daily pain, which is likely prevalent in adolescents and young adults, is largely uncharted territory with few case series or clinical trials to guide therapy selection. Currently, pain management in SCD has largely relied on the use of long-acting opioid preparations, sometimes using very large daily doses and putting these individuals at risk for opioid tolerance and opioid-induced hyperalgesia. Studies focusing on the U.S. population suggest that daily opioid usage is more frequent in individuals with comorbid psychological and psychiatric disorders, and clinical experience suggests similar findings in the SCD population. Adolescents and young adults with SCD started on daily opioids should also receive concurrent psychosocial and psychiatric support given the negative role that emotional, social, and psychiatric issues play in an individual’s pain experience.
strategies may benefit from extrapolations from other chronic pain syndromes where antidepressants and anticonvulsants have proven track records of efficacy, but further research and clinical experience are again needed before definitive treatment recommendations can be made.

**SUMMARY**

SCD is unique as a lifelong pain disorder with features of acute recurrent pain in childhood that often transforms in adolescents or young adults into a chronic pain syndrome complicated by exacerbations of acute pain. Health providers and patients often have difficulty changing treatment goals and strategies during this transformation, which can be further complicated by transitioning from pediatric to adult health care systems. As with other chronic pain syndromes, mental health problems are frequent comorbidities; poverty and health disparities unique to urban minority populations are additional challenges. Pain management optimally requires a multidisciplinary team of hematologists, psychologists, physical therapists, alternative medicine practitioners, and pain specialists. Further clinical collaborations are also important for expanding the evidence base for acute and chronic pain management in this population, which currently is distressingly limited. A further understanding of the pathophysiology of pain in this complex pain syndrome, likely driven by peripheral and central sensitization from repeated ischemic insults and chronic inflammation, could lead to the identification of new therapeutic targets and agents to ameliorate the pain and suffering currently experienced by individuals with SCD.

**KEY POINTS**

- The pathophysiology of sickle vaso-occlusion in sickle cell disease (SCD) involves intracellular polymer formation and related biochemical changes, a host of cellular interactions, and multiple inflammatory pathways, making the development of targeted therapeutics challenging.
- Pain from sickle vaso-occlusion likely represents acute nociceptor stimulation by inflammatory mediators from hypoxia and reperfusion injury, as well central sensitization from repeated episodes of severe pain.
- SCD is a relatively unique pain disorder, as pain can begin early in the first year of life and almost all children with SCD experience increasingly frequent pain throughout childhood and into adolescence and young adulthood.
- Pain is a more complex experience in adults with SCD, with features of both acute recurrent and chronic pain.
- Mental health issues are often comorbidities contributing to frequent health care utilization in SCD adults with chronic pain.
- Other pain syndromes distinct from vaso-occlusive episodes are not uncommon in children and adults with SCD, and they always need to be considered when evaluating an individual with SCD and pain.

**KEY POINTS—cont’d**

- Low-potency analgesics, such as acetaminophen and ibuprofen, are recommended as initial therapy at the onset of typical vaso-occlusive pain, and they are often adequate for mild to moderate pain, particularly in younger children, whereas oral hydrocodone and oxycodone analgesics, often in combination with acetaminophen, are available in liquid and tablet formulations for the management of more intense pain in children with SCD.
- Cognitive-behavioral approaches—specifically deep breathing and progressive muscle relaxation, guided imagery, and calming self-talk—are effective psychological therapies for SCD pain in children and adolescents.
- Support by trusted medical health professionals with experience in SCD and pain management facilitates home management and appropriate emergency department utilization.
- Intravenous doses of potent opioids, usually morphine or hydromorphone, are the typical initial treatment for vaso-occlusive pain in both adults and children, as most have failed a course of oral analgesics at home prior to arrival in the emergency department (ED).
- The concurrent use of a parenteral nonsteroidal anti-inflammatory drug (NSAID), usually ketorolac, is a widespread clinical practice in the ED setting as an additional analgesic, and it may have additional benefit as an anti-inflammatory agent.
- The efficacy of adjuvant analgesics for acute sickle pain has not been subjected to controlled trials, and refractory sickle pain that persists beyond 3 to 5 days is a difficult management problem with few new therapeutic options.
- Chronic daily pain, which is likely prevalent in SCD adolescents and young adults, is currently managed with long-acting opioid preparations.
- Adolescents and young adults with SCD started on daily opioids should also receive concurrent psychosocial and psychiatric support and may benefit from antidepressants and anticonvulsants, but further research and clinical experience are needed.

Management of pain from burns is extremely challenging for the clinician due in part to the complex physiology and potential chronic nature of burn pain. Although there may be variability in the etiology and extent of burn pain, the treatment options of pain management are similar. While traditional analgesic agents such as opioids are a mainstay for the treatment of different types of burn pain, adjuvant agents and nonpharmacologic techniques also play important roles in the management of burn pain. A multidisciplinary approach involving not only pain management but also psychological support and physical rehabilitation may be the ideal method for treating patients with burns.

Attempts have been made in the past to present a reasonable approach for managing the complex pain associated with burn injuries. However, because evidence continues to evolve in our understanding of the mechanisms of pain therapeutics in burns, evidence-based treatment regimens and algorithms for burn pain management remain limited. Despite this evolution in our knowledge, practice standards for burn pain management have remained and continue to remain inadequate, inconsistent, and mostly unchanged in many centers since the 1990s, with opioid- and benzodiazepine-based regimens as the mainstay of therapy in the acute setting.

**EPIDEMIOLOGY**

Burn injuries occur in approximately 1.25 million people in the United States alone each year, with up to 71,000 people requiring hospitalization. The majority of burns are a result of flame-related (55%) or scald burns (40%). The age of the person correlates with the type of injury, with scald burns occurring more frequently in children and flame-related burns more common in adults. Burns disproportionately affect people in developing countries with an estimated 90% of the global burns occurring in low- and middle-income countries. Globally, there are also gender differences in burn injuries with a greater proportion of women injured in fires from cooking/heating fuels in the developing world and a predominance of men injured in fires from industrial accidents in developed nations.

A national review of burn data (approximately 140,000 cases) in the United States revealed that 58% were Caucasian, 17% were African American, 13% were Hispanic, 2% were Asian, and 0.6% were native American (the remainder had missing data). Approximately 16% of cases had a burn surface area (BSA) of greater than 20%. The elderly (age > 70 years) accounted for 8% of reported burns. Of the 60% of cases with a defined etiology for the burn injury, fire/flame accounted for 44%, followed by scald (36%), contact with a hot object (8%), electrical (4%), and chemical (3%).

**PATHOPHYSIOLOGY**

Depending on the location and extent of the insult, burn injury (which may originate from different sources such as heat, cold, electricity, or chemicals/radiation) is a potentially traumatic event that may result in a systematic inflammatory response affecting all organ systems. At the molecular level, there is a massive activation of toxic inflammatory mediators, including histamine, prostaglandins, thromboxane, bradykinin, serotonin, catecholamines, platelet aggregation factor, angiotensin II, vasopressin, oxygen radicals (superoxide, hydrogen peroxide, hydroxyl ion), and corticotropin-releasing factor. At the cellular level there is protein denaturation and coagulation with surrounding tissue hypoperfusion and capillary vasoconstriction. These may lead to disruption of structures deep to the skin (e.g., dermal tissue, muscle). When combined, these local responses to burn trauma become systemic and manifest as myocardial dysfunction, increased systemic vascular resistance, increased pulmonary vascular resistance, increased pulmonary capillary wedge pressure, organ ischemia, peripheral capillary leak causing interstitial and pulmonary edema secondary to hypoproteinemia, temperature dysregulation from loss of body heat, and increased evaporative water loss. If severe enough, they may then result in potentially fatal systemic complications such as infection, respiratory distress, shock, or multiple organ failure.

**PHASES OF BURN RECOVERY**

Recovery from burn injuries can be broadly divided into four phases (Table 74.1). The first phase is the initial evaluation and resuscitation that occurs over 1 to 3 days postinjury. This is when the patient often requires large volume fluid resuscitation. The second phase is when the burn wounds are excised and temporarily closed with auto- or allografting of skin to accelerate the natural healing process. This generally occurs over weeks to months, depending on the size of the burn injury. The third phase occurs with definitive wound closure and reconstruction. Finally, the last stage of recovery is rehabilitation and reconstruction, which eventually leads to discharge and reintegration into society.

**TYPES OF PAIN IN BURN PATIENTS**

Acute postburn injury pain is often severe and extremely challenging to treat, usually necessitating powerful doses of opioids for analgesia. Burn depth, total body surface area

affected, mechanism of injury, and various patient factors play a significant role in acute burn pain. Differences in the mechanism of burn injury may also alter the severity and complexity of pain experienced. For example, pain from a partial-thickness (second-degree) burn results from loss of dermis and epidermis exposing raw nerve fibers. In contrast, nerves are also burned with the upper skin layers in full-thickness (third-degree) burns and result in lower levels of acute pain. Pain from burns may be both nociceptive and neuropathic in origin. Pain in burn patients can be divided into four different categories, which may intensify as tissues heal:

1. Rest pain. Constant, dull background pain.
2. Breakthrough pain. Intermittent, short duration, rapid onset/offset, sometimes excruciating pain.
3. Procedural pain. Short duration, greatest intensity, occurring with certain activities (i.e., wound cleaning, debridement, dressing changes, joint range of motion exercises).

**PAIN MANAGEMENT OPTIONS**

Modern day clinical burn injury care necessitates a multifaceted approach to effective burn pain management, using both pharmacologic and nonpharmacologic methods. There are many pharmacologic agents (Table 74.2) available to manage the various types of pain related to burn injuries. Because these have been presented in greater detail elsewhere in this text, we will only provide a cursory review of the various agents in context appropriate for burn pain management.

**PHARMACOLOGIC ANALGESIA**

**OPIOIDS**

Opioids including morphine, hydromorphone, and fentanyl have been the cornerstone of effective burn pain management for decades. They are widely available, can be administered by a variety of routes (e.g., oral [PO], intravenous [IV], transdermal) are inexpensive, and have a relatively ubiquitous familiarity among healthcare providers. In experimental studies utilizing burn injury, opioids (μ-receptor agonists) have been shown to produce antinociceptive effects, although there may be reduced efficacy of morphine antinociception in chronic burn injury.10,11 Opioid doses required by patients in the acute phase of burn injury to control pain may be many times greater than maximum recommended doses. An early negative consequence of (and possibly result from) this rapid and massive dose escalation is the development of acute opioid tolerance. A later consequence of this opioid escalation may be opioid-induced hyperalgesia. Longer-acting opioids, such as methadone, may mitigate or even reverse this acute tolerance and hyperalgesia, as might using other nonopioid analgesics, including ketamine, dextromethorphan, and clonidine. Although opioids are an important modality for the treatment of burn pain, clinicians should be aware of the side effects (including respiratory depression and hyperalgesia) associated with their use in any patient. For burn patients, the immunosuppressive effects of opioids could theoretically lead to an increase risk of infectious complications, although opioids should not be withheld in patients with burn-related pain.12

Methadone is a unique opioid because of its receptor binding properties. It is both a μ-opioid and N-methyl-D-aspartate (NMDA)-receptor antagonist, and it also has serotonin and norepinephrine reuptake inhibitor properties. Administration can occur via oral, parenteral, and rectal routes. However, because of variable and unpredictable potency, dosing efficacy is dependent on chronicity. The long-acting analgesia provided by methadone makes this an ideal opioid for maintenance in burn pain management.1 Further, the NMDA antagonist properties may be responsible for reducing or reversing opioid tolerance and hyperalgesia from other shorter-acting opioids, as well as modulating neuropathic pain. Methadone may be a viable option for some burn patients who are opioid tolerant and have developed chronic neuropathic pain unrelieved by conventional pharmacotherapies.13

Fentanyl is a synthetic lipophilic opioid analog with high potency. These properties facilitate rapid onset of action and quick redistribution from the central circulation. Lipophilicity allows for transmucosal absorption via nasal or buccal routes with rapid onset and peak effect similar to that achieved by IV administration. Although fentanyl is generally administered intravenously, it can be given orally or intranasally. These properties make this opioid a useful
adjunct for procedural burn care activities, such as dressing changes and hydrotherapy. The use of oral transmucosal fentanyl citrate and patient-controlled intranasal fentanyl for procedural wound care in burn patients has been reported.

**N-METHYL-D-ASPARTATE (NMDA)-RECEPTOR ANTAGONISTS**

NMDA antagonists such as ketamine and dextromethorphan may be valuable agents for the treatment of burn pain, as the NMDA receptor plays a central role in neuropathic pain processing and tolerance. In an experimental human study, ketamine significantly reduced the area of secondary hyperalgesia resulting from local first-degree burn injury. Similarly, dextromethorphan reduced the magnitude of secondary hyperalgesia from experimentally produced burn injuries.

Ketamine is a noncompetitive NMDA-receptor antagonist with antihyperalgesic and anti-allodynia properties. It reduces NMDA-R-mediated central transmission and processing of pain, thereby inhibiting central wind-up. Thus, there are many benefits to initiating ketamine early in the course of burn wound care. When administered with opioids, ketamine has synergistic effects with superior pain relief and reduced opioid consumption compared to placebo. When administered with opioids, ketamine appears to have a synergistic analgesic effect on experimentally induced wind-up–like pain in humans. At analgesic doses, it has significantly less risk of respiratory depression and negligible psychomimetic or dissociative effects.

Analgesic maintenance dosing ranges from about 1 to 3 mcg/kg/min (or 0.05 to 0.15 mg/kg/hr or 4 to 10 mg/hr). Furthermore, there appears to be no risk of developing tolerance to the drug, even with extended-duration infusion at analgesic doses. A survey of 188 European burn centers noted that ketamine was preferred for analgesia in 12% and for sedation in 13% of all substances used. A systematic review of studies investigating intravenous ketamine as an analgesic agent for burn pain suggested that ketamine demonstrated analgesic efficacy for burn injuries with attenuation of secondary hyperalgesia and that no subjects withdrew from the studies as a result of ketamine-related side effects.

Delivery of ketamine via patient-controlled analgesia for burn dressing changes has been reported. Ketamine has been used for long-term sedation and analgesia in burn patients. Finally, ketamine may be an effective analgesic agent for painful procedures in the pediatric burn patient.

Dextromethorphan (DXM) is a noncompetitive NMDA-receptor antagonist that acts by reducing excitatory transmission of primary afferent pathways and is effective in managing challenging neuropathic/wind-up pain in patients who, for a variety of reasons, may be unable to receive ketamine. It has a reduced affinity for the NMDA-receptor compared to ketamine, and it also has a significant first-pass effect in the liver via CYP2D6 microsomal enzymes. Clinically, DXM has synergistic effects when administered with opioids and has superior analgesic and opioid-reducing effects when compared to placebo. Most studies describe doses in the 60 mg twice a day to 90 mg three times a day range. It is effective in 70% to 90% of patients but has been shown to have better efficacy at lower doses when coadministered with a CYP2D6-inhibitor such as quinidine. There are virtually no psychomimetic effects at the doses used clinically. Clinically, however, ketamine appears to be used more frequently than dextromethorphan.

**NONSTERoidal ANTI-INFLAMMATORY AGENTS (NSAIDs)**

Analgesia from nonsteroidal anti-inflammatory drugs (NSAIDs) occurs by reducing inflammation and inflammatory mediators via cyclooxygenase-specific inhibition (COX-1 and COX-2). In the burn trauma population, NSAIDs may be useful adjuncts to help reduce the neurogenic inflammatory pain and fever associated with burns. In the acute setting, however, their use should be time and dose limited as they may present increased risks of bleeding.
from platelet dysfunction, gastric ulcers and gastrointestinal bleeding from COX-1 inhibition in the setting of acute stress, and renal dysfunction in the setting of reduced renal perfusion, especially in patients with larger total body surface area (TBSA) burns. COX-2–specific inhibitors (i.e., celecoxib) may offer a better overall safety profile compared to nonspecific COX inhibitors like ibuprofen and ketorolac, but data in the burn patient population are lacking and the subject needs to be better studied. NSAIDs may be especially useful for the treatment of burn pain, as experimental studies suggest that intrathecal or local administration of NSAIDs may decrease postburn hyperalgesia and reduce hypersensitivity in skin sensitized by ultraviolet burn. Intravenous ketorolac administered to volunteers increased the pressure pain tolerance threshold and attenuated secondary hyperalgesia from an experimental skin burn injury. In addition, experimental animal studies suggest that NSAIDs may enhance tissue perfusion and reduce edema formation after burns. Few studies have specifically examined NSAIDs or acetaminophen alone in the treatment of burn pain as the majority of these agents have been used as part of a multimodal approach to pain management in burn patients. A prospective, multicenter, randomized, double-blind trial evaluating intravenous ibuprofen for treatment of fever and pain in burn patients found that use of intravenous ibuprofen was associated with a significant reduction in fever and that use of the maximum daily recommended dose (800 mg every 6 hours) over 5 days was well tolerated. Finally, acetaminophen (also called paracetamol, or APAP) may be useful in the management of background postburn pain in children at doses in the 10- to 15-mg/kg/4 hr range. It is available for administration via oral, rectal, and intravenous routes. In one observational study 50% of children received only acetaminophen to control background pain.

GABAPENTINOIDS

The gabapentinoids gabapentin and pregabalin are lipophilic structural analogs of γ-aminobutyric acid (GABA) that selectively block Ca²⁺ channels containing the α₂δ-1 subunit. In injured dorsal root ganglion neurons, gabapentin has been shown to selectively silence spontaneous discharges but failed to block propagation of normal impulses. In peripheral nerve injury, as occurs in burn trauma, gabapentin activates and enhances the efficacy and release of descending noradrenergic neuronal activity from the locus coeruleus. By using central neuronal plasticity, it induces more spinal noradrenaline release after nerve injury, suppresses transmission of pain signals to the brain, and may facilitate a more natural sleeplike state in the acute setting owing to the upregulation of activity in the locus coeruleus. Gabapentinoids may be effective for the treatment of burn pain, as experimental studies demonstrate that oral gabapentin (in humans) may decrease primary mechanical allodynia in acute inflammation following a thermal injury and that intrathecal gabapentin (in rats) may produce a dose-dependent reversal of thermal hyperalgesia evoked by mild thermal injury.

Despite the potential benefits of gabapentinoids in the treatment of burn pain especially considering the presence of neuropathic pain in burn patients, few studies have actually been undertaken to examine the analgesic efficacy of this modality. One of the few double-blind, randomized placebo-controlled trials examining the analgesic efficacy of pregabalin found that administration of pregabalin (up to 300 mg twice a day over a period of 28 days) significantly reduced several aspects of the neuropathic pain and pain associated with procedures. A relatively small retrospective review of pregabalin noted that 69% of patients in a burn outpatient clinic experienced some reduction in pain score after treatment with pregabalin. Observational data also suggest that gabapentin may be useful in reducing neuropathic burn-related pain, as administration of gabapentin rapidly reduced the severity of the neuropathic burn pain and decreased opioid consumption. Another potentially useful role for gabapentin is for the treatment of postburn pruritus in patients where pruritus is not relieved with antihistamines.

Na⁺-CHANNEL BLOCKERS: LOCAL ANESTHETICS

Sodium channel blockers such as local anesthetics have been shown to reduce primary and secondary hyperalgesia from experimental heat trauma in humans. Human experimental studies indicate that intravenous lidocaine may attenuate long-term inflammation-induced tissue responses to thermal injury, and it has been shown to attenuate cytokine-induced cell injury in endothelial and vascular smooth muscle cells. Local anesthetics for analgesia can be administered via nerve blocks or intravenously in some cases.

Intravenous lidocaine has been used as an analgesic agent for postoperative pain control and for the treatment of neuropathic pain. There is only one randomized controlled trial and a few observational reports describing the use of intravenous lidocaine for the treatment of burn pain. The sole randomized controlled trial examining intravenous lidocaine (versus placebo) in 43 severely burned patients undergoing wound care procedures on two consecutive days. Subjects were randomized to either the intravenous lidocaine or control on the first dressing day and crossed over to the alternate treatment on the second dressing day. Although pain scores were significantly lower for lidocaine, there were no significant differences with regard to opioid consumption or satisfaction. A systematic Cochrane review was unable to recommend routine use of intravenous lidocaine in burn pain management at this time.

Neuraxial and peripheral regional nerve blockade have been used as analgesic techniques in the treatment of postoperative pain; however, these techniques have not been widely used for the treatment of burn pain. A variety of single-injection regional analgesic techniques have been described in burn patients, typically for reducing pain at skin graft donor site. One case report described using double continuous peripheral nerve block catheters in a child who had suffered a burn injury. Despite the potential benefits that peripheral and neuraxial catheter blocks can offer, clinicians should be aware of the potential infectious complications associated with continuous regional analgesic techniques, especially if indwelling catheters are used for any duration.

α₂-ADRENERGIC AGONISTS

Clonidine and dexmedetomidine are both highly selective central and peripheral α₂-adrenergic agonists that decrease
noradrenalinerelease at presynaptic receptor sites causing sympatholysis, thereby reducing autonomic outflow. Both drugs significantly reduce pain intensity and have a morphine-sparing effect.55 Other potential benefits include anti-inflammatory effects, improved macrophage function, antiapoptotic activity, reduced delirium, and reduced mortality by approximately ~70% for dexmedetomidine when compared to using benzodiazepines for sedation in critically ill patients.56 Analgesic dosing for these agents depends on the route of administration. For clonidine, dosing regimens may include 2 to 5 mcg/kg PO, 0.1 to 0.3 mcg/24 hr TTD, or 30 mcg to 300 mcg IV for procedural sedation in chronic opioid/chronic pain patients. Dexmedetomidine is given exclusively IV as an infusion at 0.2 to 1 mcg/kg/hr but may be bolused intermittently in small doses of 4 to 8 mcg IV push with minimal side effects. In terms of nociception, α2-adrenergic agonists may have a role in the prevention or treatment of burn pain. Experimental data suggest that α2-adrenoceptor-mediated mechanisms may be involved in nociceptor sensitization to heat stimuli in normal skin and produce antinociceptive effects in a thermal hyperalgesia model.57 Clinically, α2-adrenergic agonists may be used for analgesia and sedation in burn patients. A report of oral clonidine in a burn patient who had severe pain noted that administration of clonidine resulted in improved analgesia and sedation.58 The addition of low-dose intravenous clonidine in a child with severe burns requiring large doses of morphine causing severe opioid-related side effects resulted in a significant decrease in morphine consumption with attendant improvement in ventilatory, gastrointestinal and psychological functions.59 When administered to burn patients, dexmedetomidine is typically used for sedation for procedures or in critically ill mechanically ventilated patients.60

### NONPHARMACOLOGIC ANALGESIA

Although management of burn pain is typically achieved primarily by pharmacologic agents, nonpharmacologic techniques (Table 74.3) may be particularly helpful in the treatment of burn pain, especially considering the long-term nature of rehabilitation and possible development of chronic pain and stress-related disorders. A variety of nonpharmacologic modalities (e.g., cognitive therapies, relaxation techniques) have been examined, although there are significant methodological limitations in many available studies.

### VIRTUAL REALITY

Virtual reality utilizes computer-simulated environments that primarily incorporate sight to simulate physical presence in an alternate environment. The application of virtual reality may be most useful during painful procedures, and it is typically used in conjunction with pharmacologic analgesic agents (rather than as a sole modality for analgesia). By distracting a patient’s attention from the real world (and possibly decreasing processing of incoming nociceptive signals), virtual reality may potentially reduce pain from procedures by approximately 35% to 50% with a corresponding decrease in pain-related brain activity as documented by functional magnetic resonance imaging (fMRI).61 A systematic review of virtual reality for burn pain revealed that use of virtual reality (mostly for wound dressing changes) as an adjunct to systemic analgesics was associated with a significant reduction in procedural pain.62 Although virtual reality can be used for patients in any age group, this technique may be especially useful for pediatric patients.63 Depending on the type of virtual reality system used, there may be a significant time commitment from staff for implementation of such a system.64

### MUSIC THERAPY

Although in some sense music therapy can be considered a form of virtual reality, in some ways it should be examined separately, as virtual reality generally implies a visual rather than an auditory input in most virtual reality studies in burn patients. There is some evidence suggesting that the use of music may be of benefit in decreasing pain, especially during dressing changes or debridement procedures.65,66 Music may attenuate some measures of the cognitive and physiologic component of the stress response with a lower heart rate and anxiety in subjects who listened to music versus those who did not.67 However, not all data have demonstrated a decrease in burn pain with music therapy,68 and reporting guidelines for music-based interventions have been proposed.69 Nevertheless, music therapy may be a valuable nonpharmacologic intervention for the treatment of procedural pain after burn injury.

### RELAXATION TECHNIQUES

Relaxation techniques (e.g., breathing relaxation techniques) may be a useful adjunct to pharmacologic agents for the treatment of burn, as these techniques in essence do not increase patient risk, are easily mastered and implemented, and generally do not require expensive equipment.70 A systematic review of simple relaxation techniques for burn pain was unable to definitively determine the efficacy of simple relaxation techniques for the treatment of burn pain, although concentration on breathing, in combination with jaw relaxation, was suggested to be the most promising technique. Future research should address some of the methodological limitations of currently available studies in this area.71

### SUMMARY

Pain following burn injuries requires an aggressive multimodal and multidisciplinary approach to analgesia. Typically, burn pain consists of both nociceptive and

neuropathic components and the use of pharmacologic agents to address each component as part of a multimodal approach is optimal. Unfortunately, there are few large-scale randomized controlled trials to guide our analgesic management for burn patients, and we currently are guided by our pathophysiologic understanding of the nociceptive processing of burn pain. Nevertheless, we recognize that both pharmacologic and nonpharmacologic modalities are needed for the successful treatment of pain in burn patients.

KEY POINTS—cont’d

- Peripheral regional nerve blockade may be useful for reducing pain at the skin graft donor site, but it should be used with care due to potential issues of infection.
- Dexmedetomidine may reduce mortality by approximately 70% when compared to benzodiazepines for sedation in critically ill patients.
- Nonpharmacologic techniques, including cognitive therapies, relaxation techniques, music therapy, and virtual reality, may be particularly helpful in the treatment of burn pain.

SELECTED READINGS

The references for this chapter can be found at www.expert-consult.com.

Emergency physicians provide acute care for an extraordinarily broad range of illnesses and injuries, the majority of which involves some degree of pain. Emergency providers also cause pain in the course of therapeutic and diagnostic procedures. This chapter considers the prevalence of pain in the emergency department (ED), barriers to its adequate treatment, and a variety of treatment modalities. Space limitations prohibit a discussion of the wide variety of specific painful conditions that present to the ED. These can be found in other chapters of the text.

### PREVALENCE AND ASSESSMENT OF PAIN IN THE EMERGENCY DEPARTMENT

The prevalence of pain among emergency department (ED) patients is as high as 78%, and among those with pain, underlying chronic pain conditions are present in 40%. A national survey suggests that 24 million adults with chronic pain visit the ED annually and that 12 million visits are due to exacerbations of chronic pain syndromes. Although arriving at a diagnosis and choosing the appropriate therapy to treat underlying conditions are principal goals for physicians, those who present to the ED with pain also desire recognition of their pain and rapid, effective pain treatment.

Patients face many barriers in their efforts to obtain superior medical care, especially in regard to pain. The ED serves as a fail-safe mechanism for our fragmented health care system, and pain is but one of the many conditions in which we not only face the problem of acute clinical presentations but also care for those with chronic pain who are seeking access to specialized pain care.

Notwithstanding the issue of providing compassionate care, pain that is not acknowledged and managed appropriately causes anxiety, depression, sleep disturbances, increased oxygen demands with the potential for end-organ ischemia, and decreased movement with an increased risk of venous thrombosis. Failure to recognize and treat pain may also result in dissatisfaction with medical care, hostility toward the physician, unscheduled returns to the ED, delayed complete return to full function, and an increased risk of litigation.

Pain is inherently subjective and inevitably complex. Our patients experience pain and suffering as individuals; we assess it only indirectly. The ED’s task is to use a commonly understood vocabulary and classification system in assessing pain so that our findings can be communicated consistently. Only by quantifying the pain experience in meaningful ways can we move beyond myth and opinion toward a scientific approach to our many questions regarding the pain experience. This challenge is at the root of our difficulties in treating pain; thus issues surrounding pain assessment have primacy in our approach to understanding. Only when we use comparable methods in assessing pain can we begin to accumulate the scientific evidence that should drive our practice.

The most common response of physicians confronted by patient pain reports is skepticism. The validity of patient self-reports is often questioned, and attempts to “objectify” the pain experience are sought. This search is bound to disappoint the querulous clinician, as neither blood tests, tissue pathology, diagnostic imaging, physical assessments, nor patient behavior reliably reflects the internal pain experience.

A number of practical pain assessment tools are available. The subjective nature of pain makes such instruments necessary, and revised standards of The Joint Commission (TJC) have fostered their widespread use. Pain intensity should be assessed for all patients presenting to the ED with either an 11-point numeric rating scale (NRS) or a graphic rating scale (GRS). The NRS is sensitive to the short-term changes in pain intensity associated with emergency care. The GRS or picture scales are particularly useful for populations with limited literacy, including children. In one study of patients who have advanced cancer and pain, 81% were able to complete a picture scale, whereas only 75% could complete the visual analog scale. In another study, the authors noted that male patients were uncomfortable with scales depicting severe pain using tears. Picture scales with such depictions might profitably be avoided because they may be biased in the direction of less severe pain in male patients. No matter the specific pain scale used, assessments should be repeated after therapeutic interventions and at the time of ED discharge.

### THE PROBLEM OF EMERGENCY DEPARTMENT OLIGOANALGESIA

Although adequate analgesia in the ED is an important goal of treatment, the underuse of analgesics, termed “oligoanalgesia” by Wilson and Pendleton in 1989, occurs in a significant proportion of ED patients. A variety of factors are felt to give provenance to pain undertreatment (Box 75.1).

Recognized risk factors for ED oligoanalgesia include extremes of age and minority ethnicity. It has been suggested that patients’ expectations for pain treatment and perceptions of pain intensity do not differ by ethnic groups.
when patients are matched for socioeconomic factors. Differences have been noted, however, in the way that patients of different cultural backgrounds express their pain. Differences in the interactions of physicians and patients of a different ethnic group have been described and may affect physician assessment. When affect, actual patient-physician interaction, and cultural expressions of ethnicity are removed from a case presentation, such as with written clinical vignettes, patients with similar pain are similarly treated by physicians. Cultural discordance between the patient and the physician may hinder the ability of patients to convey an understanding of their pain to their physician.

Although there is a general reluctance to accept patient report as the most reliable indicator of pain and disparities between patients’ and physician’s pain intensity ratings may lead to inadequately treated pain, patients themselves may be reluctant to report pain presence and intensity. This may be a result of low expectations of obtaining pain relief, fear of analgesic side effects, and a notion that pain is to be expected as part of the underlying disease or from medical treatments. Some patients have a fear of addiction when prescribed opioids or fear the stigma associated with opioid use.

Although patients may decline opioid analgesics due to concerns about addiction, the emergency department may also be targeted by patients seeking controlled substance misuse or diversion. Unfortunately, prescription opioid abuse is a continuing concern in the U.S. population. The National Survey on Drug Use and Health estimates that among those aged 26 or older, 3.2% reported using pain relievers nonmedically within the past 12 months. It is encouraging that the misuse of pain relievers by youth and young adults appears to be in decline. Among youths aged 12 to 17, nonmedical pain reliever use fell from 3.2% to 2.3% between 2002 and 2011, and among young adults aged 18 to 25, rates have fallen to 3.6% from a high of 5.0% in 2006.

Although pain is far more common than substance abuse, emergency physicians frequently encounter both among patients. Professional discussions of pain in the ED often center on concerns of being duped by patients who fabricate symptoms to obtain opioids, so-called drug-seeking behavior. Complicating this issue, such behaviors may represent an appropriate response by those with untreated chronic pain for whom treatment resources are lacking. In managing pain complaints, emergency physicians are responsible for beneficence and nonmaleficence. They must treat pain and ameliorate suffering while minimizing the extent to which their decisions enable substance abuse by patients and increase the supply of prescription opioids available for abuse by the general public. The increasing functionality of online prescription monitoring programs is a promising development that can aid emergency physicians in differentiating appropriate and problematic requests for opioid analgesics.

**Box 75.1 Factors Underlying Emergency Department Oligoanalgesia**

1. Lack of educational emphasis on pain management
2. Inadequate emergency department (ED) quality improvement systems
3. Lack of ED pain research, particularly among older adult and pediatric populations
4. Emergency providers’ concerns regarding opioid addiction and abuse
5. Fear of opioid adverse effects
6. Racial and ethnic bias

Effective pain management involves both pharmacologic and nonpharmacologic modalities. Simply asking about pain and validating the pain reports has a potent effect on patients’ satisfaction with ED pain management. In one study, patient satisfaction with pain management was predicted more strongly by the perception that ED staff asked about pain than by the actual administration of an analgesic. Other modalities such as reassuring the patient that pain will be addressed, immobilizing and elevating injured extremities, and providing quiet, darkened rooms for patients with migraine headaches are essential aspects of quality pain management.

Pharmacologic therapies should begin as soon as is practical after presentation to the ED. Analgesic protocols allowing early pain treatment can decrease the time to effective treatment and improve patient outcomes. Analgesics may be administered by a variety of routes; however, the majority of medications are administered by the oral or parenteral routes. Oral therapies are most commonly used because they are convenient and inexpensive for patients who can tolerate oral intake. When pain is severe, analgesics must be given immediately and titrated to effect. The intravenous rather than intramuscular (IM) route is indicated in this context. IM injections are painful, they do not allow for titration, absorption is unpredictable, and they result in slow onset of drug action. Unless intravenous access is elusive, there is little to recommend the IM route.

In general, it is inappropriate to delay analgesic use until a diagnosis has been made. In the case of acute abdominal pain, a large number of studies find no deleterious effect of intravenous opioid therapy on our ability to make appropriate diagnoses.

**Specific Treatment Modalities**

A wide variety of analgesics are used in emergency medicine practice. In a 20-site survey of ED analgesic practice, a total of 735 doses of 24 different analgesics were administered to 506 patients receiving analgesics while in the ED. The majority of analgesics administered were opioids (59%), morphine being the most commonly used analgesic (20%), followed by ibuprofen (17%). Analgesics recorded as being administered in the report are listed in Table 75.1.

**Nonopioids**

Commonly available analgesics include opioid and nonopioid agents. When opioids are required for pain treatment, nonopioids should be included to potentiate the opioid analgesic effect and decrease the severity of side effects. Nonopioids include salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen. Unfortunately,
nonopioid agents exhibit an analgesic ceiling effect and cannot be titrated to effect. This limits their usefulness in the setting of severe or fluctuating pain; however, they should be used as an adjunct to opioid therapies unless contraindicated, for the reasons noted earlier.

Acetaminophen is indicated for mild to moderate pain and is often combined with opioid agents. Acetaminophen, unlike NSAIDs, has no antiplatelet activity or anti-inflammatory effect. Although a great deal of attention has been paid to acetaminophen hepatotoxicity, especially in the setting of chronic malnutrition, alcoholism, or liver disease, such effects are uncommon, particularly as compared to NSAID-related gastrointestinal toxicity.

NSAIDs, including salicylates, inhibit prostaglandin synthesis by interfering with cyclooxygenase (COX) enzymes. They cause platelet dysfunction and can precipitate renal failure in patients with renal insufficiency or volume depletion. They increase the risk of gastrointestinal bleeding when taken chronically.

### OPIOIDS

Opioid combination analgesics are commonly used for moderate to severe pain. Although the opioid component in these agents does not exhibit ceiling analgesic effects, the nonopioid component dose must be limited; thus, one cannot titrate these analgesics. The convenience of combination therapy must be balanced against this limitation. Hydrocodone and oxycodone combination agents are associated with less nausea and vomiting and are preferable to codeine combination agents. Also a significant proportion of the population is made up of poor metabolizers of codeine, which must be metabolized to morphine in order to manifest analgesic effects, further limiting its effectiveness.

The tramadol-acetaminophen combination agent is indicated for acute pain; however, experience with this agent in the ED setting is limited. Its mechanism of action is unclear: the tramadol component binds only weakly to opioid receptors and inhibits the reuptake of both norepinephrine and serotonin.

Opioids are the mainstay of ED therapy for moderate to severe pain, and morphine is the standard of comparison for all agents of this class. If contraindicated because of allergy or other sensitivity, hydromorphone or fentanyl may be substituted. These opioids can be rapidly titrated intravenously to control severe pain, allowing institution of an oral regimen. Fentanyl has the advantage of being relatively short acting and is preferred in the setting of multiple trauma, head injury, and potential hemodynamic instability. Intravenous morphine is the standard of treatment for severe pain in the ED. Morphine 0.1 mg/kg bolus has been found to be safe but not usually adequate to effect pain relief. Repeat boluses of 0.05 mg/kg every 5 minutes until pain relief represents a safe incremental strategy.

Meperidine is a problematic opioid for a number of reasons. Many EDs have completely eliminated the use of meperidine because of its metabolism to normeperidine, a toxic metabolite causing central excitation and seizures, as well as its contraindication in patients taking monoamine oxidase inhibitors. It is, however, frequently used. In a review of ED patients treated in the United States for isolated benign headache, meperidine was found to be the most common prescribed treatment, despite national recommendations for the use of nonopioid therapies supported by strong evidence. This likely has more to do with the persistence of medical tradition than with pharmacology. Subtherapeutic doses of intramuscularly administered meperidine have been used to treat a wide variety of acute pain complaints by generations of physicians. The availability of other opioid agents of equal efficacy with fewer contraindications and fewer adverse effects argues against its continued use.

Agonist-antagonist opioids, such as nalbuphine and butorphanol, have mixed effects on opioid receptor subtypes, exhibiting ceiling effects on both analgesia and respiratory depression. Because clinically important respiratory depression is distinctly rare in the setting of acute pain treatment, it is difficult to justify their routine use. One possible exception is for patients with advanced pulmonary disease. In particular, one cannot titrate these drugs to maximal effect because of analgesic ceiling effects. Additionally, these drugs are contraindicated and will induce withdrawal symptoms in patients who are physically dependent on opioids, either because of opioid therapy for chronic pain, methadone maintenance therapy, or active opioid addiction.

### PATIENT-CONTROLLED ANALGESIA

The use of patient-controlled analgesia (PCA) has been described in emergency medicine in adults and children. Although no specific advantage has been found over the titration of opioids, PCAs were found to be at least as effective. In the setting of high demands on nursing resources, PCAs could serve to ensure pain treatment.

ALTERNATIVE DELIVERY ROUTES

Multiple alternative delivery routes for the administration of pain medications have been described. The use of nebulized fentanyl has been described and holds great promise as a route of opioid delivery that can be initiated before an intravenous (IV) needle has been placed. Intranasal fentanyl has also been described and shown to be effective in the ED and the prehospital setting. The promise of nebulized and intranasal pain medications, especially in children who have severe pain but have not had an IV needle placed yet, could be very useful in the ED.

PROCEDURAL SEDATION AND ANALGESIA

Minimal, moderate, and deep sedation have all been described in the ED. Patients often present to the ED in need of painful or complex procedures that require compliance that must be done emergently, and procedural sedation and analgesia (PSA) has adopted a specialized format for procedures in the ED. Unlike most patients who are undergoing sedation in other settings, patients in the ED have unpredictable nothing by mouth (NPO) status, often have concurrent severe systemic disease, and usually are in severe pain before the procedure begins. In addition, unpredictable concurrent events and time or bed constraints in the ED complicate these procedures.

The indications for ED PSA range from pain control for short painful procedures to the need for patient compliance with a complex emergent procedure. Goals for level of sedation during ED PSA range from minimal through moderate and deep sedation, depending on the needs for the procedure. Although it is acknowledged that deep sedation can inadvertently result in patients achieving a level of sedation consistent with anesthesia, this is not typically the goal of ED PSA. Minimal sedation, a drug-induced state during which patients respond appropriately to their developmental age to verbal commands, is generally performed for procedures that require compliance but are not typically painful with the use of local anesthesia. Minimal sedation has been described for lumbar puncture, evidentiary examinations, simple fracture reductions (in combination with local anesthesia), and abscess incision and drainage.

During minimal sedation, cardiovascular and ventilatory functions are usually maintained, although patients should be monitored for inadvertent oversedation to deeper levels with oxygen saturation monitors and close nursing supervision. Agents typical of minimal sedation include fentanyl, midazolam, combinations of the two, and low-dose ketamine.

Moderate sedation is performed on patients who would benefit from either a deeper level of sedation to augment the procedure or from amnesia of the event. Moderate sedation is a drug-induced depression of consciousness during which patients respond appropriately to their developmental age to verbal commands, either alone or with light tactile stimulation. Patients usually have an intact airway and maintain ventilatory function without support. As with minimal sedation, inadvertent oversedation to deeper levels can occur with moderate sedation; appropriate monitoring, including that for oxygen saturation as well as for cardiac and blood pressure, should be done throughout the sedation, and direct observation of the patient’s airway should be maintained throughout the procedure. Agents used for moderate sedation in the ED include propofol, etomidate, ketamine, and the combination of fentanyl and midazolam.

Deep sedation is performed on patients who would benefit from a deeper level of sedation in order to complete the procedure for which they were being sedated. Generally, amnesia of the procedure is similar between moderate and deep sedation, and it is not necessary to sedate patients to a deep level only to obtain amnesia of the procedure. Deep sedation generally is achieved in the ED with the same agents as moderate sedation; the difference is in the intended level of sedation. Monitoring for deep sedation is the same as for moderate with oxygen saturation, cardiac and blood pressure monitoring, and direct observation of the airway. End-tidal carbon dioxide has also been described in ED PSA, but its use over direct observation of the patient’s airway has not been established. Deeply sedated patients can develop respiratory depression but generally maintain a patent airway and adequate ventilation. Patients sedated to this level can progress to a level of sedation consistent with anesthesia, and there is some evidence that this may occur more frequently in patients intended to undergo deep sedation than in those who are to undergo moderate sedation. For this reason, it is usually safer to use moderate than deep sedation in the ED unless the procedure for which the patient was being sedated requires a deeper level of sedation (such as hip reduction).

Patients who progress to an unintended level of sedation consistent with anesthesia are not arousable, even to pain. The ability to independently maintain ventilatory function is usually impaired, and patients often require assistance in maintaining a patent airway. Because patients can quickly progress to this level using the agents typical of moderate and deep sedation, physicians performing moderate and deep sedation must be prepared to provide ventilatory support until the patient has regained consciousness. To decrease the likelihood of aspiration, patients who are undergoing moderate or deep sedation in the ED should be kept NPO. It is difficult to find a consensus on the amount of time a patient should be kept NPO prior to PSA. Many departments use 3 to 6 hours as a minimum. The risk of aspiration must be balanced with the urgency of the procedure, and it is often necessary to perform sedation on patients who have recently eaten when they have an emergent requirement for sedation. In general, the least deep level of sedation possible to complete the procedure should be used in patients who have not been NPO. ED PSA has been described in patients who are medically stable (American Society of Anesthesiologists Physical classes 1 and 2) and in those who are not (classes 3 and 4). PSA for critically ill children has been described using ketamine and in adults using propofol or etomidate. The degree of respiratory depression noted in these patients was similar to that for patients with physical status scores of 1 or 2, but an increased rate of hypotension was seen in physical status 3 and 4 patients who received propofol. It may be that ketamine and etomidate are better suited for the emergent sedation of critically ill patients, but data are not yet sufficient to make a definite recommendation.
Sedated patients are generally monitored by pulse oximetry, which is a sensitive measure of oxygenation. If a patient receives supplemental oxygen before starting PSA, this monitor may not be as sensitive to changes in the patient’s ventilatory status. Preoxygenation is generally recommended for ED PSA; however, there is no evidence that it decreases the incidence of transient hypoxia that has been noted as a complication of PSA. End-tidal carbon dioxide has been recommended as an additional modality for the monitoring of sedated patients. Monitoring expired carbon dioxide during PSA allows for a graphic display of the patient’s ventilatory status that can be a detector of respiratory depression before it becomes clinically apparent. In the event of hypoventilation, the end-tidal CO2 value increases as the respiratory rate decreases. In the event of increasing airway obstruction, the baseline end-tidal CO2 value decreases along with a blunting of the waveform as a result of increased mixing of the nasal expiratory sample with ambient air caused by the turbulence from the obstruction.

Ketamine has been described in adults but predominantly in children for use in ED PSA. It is a dissociative anesthetic that provides 15 to 20 minutes of sedation when given intramuscularly, with a return to baseline mental status in 30 to 60 minutes. It can be given in doses of 1 to 4 mg/kg IM and should be combined with atropine 0.01 mg/kg to prevent hypersalivation. The addition of 0.1 mg/kg of midazolam to ketamine has been described to prevent emergence phenomena, but this has been shown to have unclear use. The 1-mg/kg dose achieves light sedation sufficient for such procedures as lumbar puncture, dressing changes, and simple laceration repair. The doses ranging from 2 to 4 mg/kg result in increasingly deep levels of sedation but have all been shown to generally achieve moderate or deep sedation with a decreasing responsiveness to pain as the dose is increased. Patients sedated with ketamine usually maintain a patent airway and ventilate normally. Laryngospasm has been described with its administration at a fairly rare rate. Patients undergoing PSA with ketamine should be monitored for respiratory depression and possible laryngospasm. Emergence phenomena, described as an unpleasant perceptual experience by patients as they regain consciousness from sedation with ketamine, have been described in adults and children. The use of ketamine IV has also been described for ED PSA. It is generally given at 1 mg/kg IV and has an onset of 1 to 2 minutes, followed by moderate sedation lasting 8 to 12 minutes. The side effects have been described as similar to IM ketamine, and similar precautions should be taken. The combination of ketamine with propofol has also been described, with the theoretical advantage of decreased respiratory depression from propofol alone and decreased vomiting and emergence phenomena over ketamine alone. Several case studies and small trials have shown this combination to be generally safe and efficacious, but data are not sufficient to determine if there are situations in which the combination is superior to propofol for ketamine alone.

The combination of fentanyl and midazolam has been described for minimal, moderate, and deep sedation, and its use for these levels of sedation is not recommended. Dosing for minimal sedation has been described as 0.1 mg/kg IV midazolam followed by 0.5 µg/kg IV fentanyl, with repeated fentanyl boluses every 3 minutes until the patient is adequately sedated. The sedation typically lasts 30 to 60 minutes, with a return to baseline mental status of 45 to 120 minutes. This method of PSA has increasing respiratory depression with increasing levels of sedation, and close respiratory monitoring is required. A sedation regimen similar in duration but without analgesic properties is pentobarbital. It is usually used to sedate children for radiologic procedures. The medication is usually started at 2.5 mg/kg IV, followed by 1.25 mg/kg IV every 5 minutes until sedation is achieved. This is usually used for minimal or moderate sedation, and pulse oximetry is required. The rate of respiratory depression is lower than for other protocols but the sedation is inadequate for painful procedures.

Methohexital has also been described for moderate and deep PSA. It is a very short-acting agent with dense amnestic capabilities. It can be given at 1 mg/kg IV with 0.5 mg/kg repeat boluses every 2 minutes as needed. It has an onset of 30 seconds. The sedation generally lasts 2 to 4 minutes with a return to baseline mental status of 10 to 15 minutes. It has been associated with respiratory depression and a quick progression to deeper levels of sedation than intended, and it can result in oversedation even when carefully titrated. This agent therefore requires close respiratory monitoring throughout the sedation, as with other agents. When compared directly with propofol, it was found to be similarly effective and safe when only a single bolus was given and less safe than propofol when multiple doses were required. It therefore should be used principally for very brief procedures that are expected to last less than 2 to 4 minutes, such as simple fracture and dislocation reductions.

Propofol is well described for ED PSA. It is generally administered as a 1-mg/kg bolus with repeat boluses of 0.5 mg/kg every 3 minutes until the patient is adequately sedated for the procedure. The sedation persists 2 to 5 minutes after a single bolus and longer for patients receiving multiple boluses, with a return to baseline mental status in 10 to 15 minutes. This medication has been associated with rates of clinically apparent respiratory depression from 4% to 7.7% in ED PSA, so close respiratory monitoring is required as with the other agents. It has also been associated with hypotension in critically ill patients and should be used with caution in this group.

Another agent used in ED PSA is etomidate. It is usually given as a single bolus of 0.1 to 0.3 mg/kg, with an onset of sedation in 30 to 60 seconds and sedation lasting 7 to 10 minutes. It is not associated with hypotension and is therefore optimal in patients who are at risk for this condition. It is, however, associated with myoclonic jerking in up to 25% of patients receiving the medication, which can sometimes complicate the procedure for which the patient has been sedated. This makes it slightly suboptimal relative to propofol in healthy patients. Etomidate has been associated with adrenal suppression. This has been noted in studies of single boluses of 0.3 mg/kg, but no significant changes in cortisol levels were found, and the significance of this outcome remains unclear.
KEY POINTS

- Failure to recognize and treat pain may cause unnecessary increases in anxiety and delayed return to function among emergency department patients.
- Barriers to superior emergency department pain management include knowledge deficits among providers and inadequate quality improvement efforts.
- The true prevalence of opioid addiction among emergency department patients is unknown and likely overestimated by emergency physicians and nurses.
- Few specialty-specific treatment guidelines exist to promote best practices for emergency department pain management.
- Emergency providers tend to disbelieve pain reports that do not conform to expectations.

Pain in the critically ill is poorly understood. Only recently has attention and investigation turned toward the issues of pain assessment and treatment in this patient population, and existing literature is scant. The prevalence of poorly treated pain in the critically ill is considerable and greater than commonly believed among health care physicians. This chapter examines some salient issues as well as the modern, pertinent literature detailing barriers to assessing and treating pain in a critical care setting, as well as some strategies for dealing with this challenging clinical dilemma.

PREVALENCE OF PAIN IN THE INTENSIVE CARE UNIT

Patients admitted to the intensive care unit (ICU), although often unable to communicate as a result of the severity of their disease process or the presence of impediments such as artificial airways or endotracheal tubes (ETTs), experience pain and discomfort that often goes unrecognized and untreated. Between 63% and 77% of patients report experiencing pain while in the ICU.1

An observational study in 128 Italian ICUs of 661 postoperative patients found that 36.3% of patients did not receive any analgesia in the first 48 hours of their ICU stay.2 “Pain control” was the reason for the opioid administration in only 54.5% of instances in which an opioid was given. Fentanyl was the most commonly administered opioid. Although fentanyl’s rapidity of onset makes it perhaps desirable in an ICU setting, its use by prolonged infusion may be counterproductive in that its lipophilicity contributes to a prolonged offset of action when weaning or discontinuing this medication.

One study attempted to characterize the experience of a group of critically ill patients at high risk for hospital death.3 Between 55% and 75% of 100 cancer patients reported the experience of pain, discomfort, anxiety, sleep disturbance, or unsatisfied hunger or thirst.

One prospective cohort study of 400 medical ICU patients found that those patients for whom analgesics were prescribed had a higher concomitant incidence of hemodynamic monitoring, greater use of neuromuscular blocking agents, more mechanical ventilation days, and longer ICU and hospital lengths of stay.4 Consistent with these findings, patients who received analgesics also had higher trauma injury severity scores (TISS) and predicted mortality.

BARRIERS TO PAIN ASSESSMENT IN THE INTENSIVE CARE UNIT

Given the potential compromise of patients’ physiologic stability and communication skills secondary to underlying disease processes, the ICU presents a unique environment for the assessment and treatment of pain. This presents unique challenges to clinicians that may not commonly be seen in other arenas of pain control. As mentioned, the presence of impediments to communication such as the presence of an endotracheal tube (ETT) or the severity of underlying critical illness may prevent typical ICU patients from communicating with the nursing or physician staff their level of discomfort (Box 76.1). Indeed, critical care patients have a much higher risk of enduring untreated pain because they often cannot communicate secondary to altered mental status, mechanical ventilation, and sedation.5 A clinician’s observation and subjective rating of ICU patient pain often underestimates that patient’s pain, and whenever possible, ICU patients should rate their own pain.6

A critically ill patient may be obtunded secondary to the underlying disease process or physiologically compromised by a process such as sepsis or shock. The question has been raised as to how much real pain the patient is experiencing, and this question is difficult to answer. Many patients may not remember these experiences, and even if these experiences can be recalled, there are limitations of assessing pain retrospectively.7 A chief challenge in assessing pain in the ICU comes when assessing patients in whom communication may be compromised. Increased vigilance by physicians and nursing staff, as well as the development and use of alternative means of pain assessment, are necessary when patients cannot verbalize pain.

One study examined the assessment and treatment of pain in two surgical ICUs in a university hospital setting.8 After the investigators found poor results in both of these areas, the following action plans of improvement were sequentially implemented: (1) education of the physician and nursing staff regarding the importance of pain and to measure pain with a modified visual analog scale (VAS) that is similar to a numeric rating scale (Fig. 76.1), (2) assurance that these modified VAS scales were readily available at patients’ bedsides, (3) documentation of patients’ pain scores on daily ICU rounds, and (4) creation of an expectation in these ICUs that a pain score greater than 3 is a cause for intervention. Although 42% of nursing interval assessments were not measured on a standard 10-point scale at baseline, after the 5-week period of
implementation of these strategies, pain assessments according to this scale increased to more than 70%. The study also found that patients whose pain scores were less than 3/10 increased from 50% before these interventions were begun to greater than 90% after they were completed.

Additional methods of evaluating pain in patients unable to communicate verbally have been developed from similar techniques in the pediatric arena. This would include the various behavioral pain assessment scales, in which pain scores are recorded by assessing a variety of patients' nonverbal behaviors and sometimes including changes in vital signs. An investigation described earlier found that placing VAS cards at the patients' bedside permits some patients to point at a spot on the scale that corresponds to their pain score.8

Moreover, pain in critically ill and postoperative pediatric patients is essential for their comfort and benefit, and the use of pain protocols in these regards improves patient comfort.10 More compliance and implantation of such protocols is very much needed in the pediatric critical care population. Another study attempted to compare three different pain assessment tools—the Critical-Care Pain Observation Tool (CPOT), the adult Nonverbal Pain Scale (NVPS), and the Faces, Legs, Activity, Cry, and Consolability scale (FLACC)—in nonverbal critically ill patients in a cardiac postanesthesia care unit. These scales were compared immediately before, 1 minute, and 20 minutes after two discomforting events: suctioning and repositioning. Both the CPOT and NVPS were found to be more reliable than the FLACC, which is predominantly used in a pediatric setting.5 After standardized implementation, the CPOT resulted in a more consistent assessment of pain in critically ill patients and fewer analgesic and sedative agents being administered.10

One group11 attempted to validate a behavioral pain scale (Fig. 76.2)12 for use in the ICU environment, noting that no pain scale for patients incapacitated by critical illness had yet been validated. Noting a significant difference between physiologic variables such as heart rate and mean arterial pressure, the observers were able to validate a behavioral pain scale at rest and during painful procedures. The behaviors evaluated in determining a score for pain were facial expression, upper limb movements, and compliance with mechanical ventilation. This scale was also felt to be feasible from a time standpoint, with an average assessment time of 4 minutes.

The difficulty of treating pain in those hospitalized in the ICU has been clearly documented, and there is a defined lack of high-level evidence for clinical decision making in these regards. Frequent need for rapid drug titration can contribute significantly to interpatient variability in response, which is likely more magnified in those who are critically ill. Moreover, there can be significant difficulty in distinguishing adverse drug events from other comorbid medical conditions in ICU patients.13

Highlighting this clinical dilemma of treating pain in ICU patients, the SUPPORT investigators examined more than 4000 ICU patients over 2 years. In the data-gathering phase I portion, family members reported moderate to severe pain at least half the time for 50% of conscious patients who died in the hospital.14 Similar results were found in another study, in which a sample of 24 surgical patients from two different hospitals was interviewed after transfer from the ICU. Sixty-three percent of the patients rated their pain as being moderate to severe in intensity while in the ICU.15

Another study analyzed the adequacy of pain control for 17 trauma patients during the initial aspect of their ICU admission.16 In contrast to 47% of patients rating their pain as severe, 95% of house staff and 81% of nurses reported the patients had received adequate pain control. This is underscored by the fact that 53% of house staff did not ask patients if pain control was satisfactory. The impact of insufficient analgesia was evidenced by the fact that 68% of patients reported that pain affected their ability to cough and 55% had trouble deep breathing. Presumed barriers to adequate pain control were felt to include a disparity in the perception of pain between patients and caregivers, patients refusing to request pain medicine despite the presence of moderate to severe pain, and physician and nurse concerns about patients’ adverse physiologic response to further or increased doses of analgesics. It was noted that 19% of patients reported a fear of addiction to opioids. Misconceptions regarding opioid pharmacology on the part of caregivers have been reported.16 In one report, some members of a nursing staff felt that the use of anxiolytics negated the need for larger doses of opioids.

A critically ill patient’s ability to communicate pain may be impaired by the severity of the injury or the presence of factors that impede communication, such as the presence of endotracheal or positive pressure ventilation. One study attempted to put forth guidelines regarding sedation and analgesia in the critically ill patient nearing death17 (Box 76.2). In doing so, the panel recognized the difficulty of pain assessment in this setting as a result of several factors including communication problems particular to the ICU environment, the severity of critical illness and potential presence of multisystem organ failure, the possibility of a decreased level of consciousness resulting from illness and drugs, and difficulty in the interpretation and reporting of
clinical signs. In the treatment of terminal disease, there are several possibilities for titrating sedation and analgesia: patient request, signs of respiratory distress, and physiologic signs such as tachycardia, hypotension, diaphoresis, facial grimacing, tearing, vocalization, or patient restlessness.

One investigation used a questionnaire to collect data on patients’ stressful experiences associated with being in an ICU and with mechanical ventilation. Of those who remembered the ETT, 68% were significantly bothered by not being able to speak (68%), pain associated with the ETT (56%), and anxiety regarding the ETT (59%). It is not surprising that this study found that those who did not remember the ETT or ICU were on average more severely ill and subject to a longer duration of mechanical ventilation than the group who remembered these experiences. It is quite possible, given the severity of their disease process, that the former group may have been more likely to be chemically paralyzed or heavily sedated.

**Box 76.2 Guidelines for Relief of Pain and Suffering in the Intensive Care Unit**

**Relief of Pain and Suffering**

To relieve pain and suffering at the end of life, both pharmacologic and nonpharmacologic means should be used. Nonpharmacologic interventions include ensuring the presence of family, friends, and pastoral care (if desired) and changing the technological intensive care unit (ICU) environment to a more private and peaceful one.

**Initial Dosage**

Most ICU patients require narcotics and sedatives to ease the pain and suffering associated with their critical illness. The amount of drugs needed varies on an individual basis. As in active disease treatment, palliative care must be individualized.

**Titration of Analgesics and Sedatives**

Once analgesics and sedatives are initiated, they are increased in response to (1) the patient’s request; (2) signs of respiratory distress; (3) physiologic signs—unexplained tachycardia, hypertension, diaphoresis; (4) facial grimacing, tearing, vocalizations with movements, turns or other nursing care; and (5) restlessness.

**Does a Maximum Dose Exist?**

No maximum dose of narcotics or sedatives exists. The goal of palliative care is to provide relief of pain and suffering, and whatever amount of drugs accomplishes this goal is the amount needed for that individual patient.

**Should Analgesics and Sedatives Be Administered in Response to Signs and Symptoms of Pain and Suffering or Before They Begin?**

Support for both approaches exists among intensivists. The treatment of signs and symptoms of pain and suffering is good palliative care. When appropriate doses of narcotics and sedatives are used and the intent of the physician is clear and well documented, pre-emptive dosing in anticipation of pain and suffering is not euthanasia or assisted suicide but good palliative care.

**BENEFITS OF ASSESSING AND TREATING PAIN IN THE INTENSIVE CARE UNIT**

ICU patients who are intubated may be at higher risk for pulmonary complications after surgery. Postoperative pain in these patients results in a pattern of shallow breathing with fewer sigh breaths. Complications of retention of secretion, atelectasis, hypoxemia, and pulmonary infections may be seen among this group. Epidural analgesia, intrapleural analgesia, intravenous patient-controlled analgesia (PCA), and intercostal nerve blockade (the duration of which is based on the duration of the local anesthetic used) are options in this situation. Clinical situations in which placement of thoracic epidural analgesia may be of significant benefit to the patient in the ICU include patients with postthoracotomy pain; these catheters may be left in place to provide coverage of chest tube site pain until the chest tubes are discontinued. The placement of epidural catheters for pain control may aid trauma patients with rib fractures and also may help to facilitate weaning from mechanical ventilation.

PCA in the ICU is useful in an awake and alert patient by allowing the patient to receive on-demand dosing of analgesic agents, either via the epidural or intravenous route. Ballantyne and colleagues published a meta-analysis of randomized, controlled trials to examine postoperative analgesic therapies and their effects on pulmonary outcomes. Epidural opioids tended to decrease the incidence of atelectasis (respiratory rate [RR] = 0.53, 95% cardiac index [CI] = 0.33 to 0.85) and showed a less impressive tendency to decrease the incidence
of pulmonary infections (RR = 0.53, 95% CI = 0.18 to 1.53) and overall pulmonary complications (RR = 0.51, 95% CI = 0.20 to 1.33) when compared with systemically administered opioids. Epidural local anesthetics, compared to systemically administered opioids, were found to decrease the incidence of pulmonary infections (RR = 0.36, 95% CI = 0.21 to 0.65) and overall pulmonary complications (RR = 0.58, 95% CI = 0.42 to 0.80). No clinically or statistically significant differences were found in other measures of pulmonary outcome, including forced expiratory volume in 1 second (FEV₁), forced vital capacity (FVC), and peak expiratory flow rate (PEFR). This meta-analysis sheds light on the value of postoperative epidural analgesia in reducing postoperative pulmonary morbidity and questions the correlation of these spirometry values as predictors of postoperative pulmonary morbidity.

The benefit of controlling perioperative pain to attenuate the perioperative stress response has been debated. This response brings about an increase in sympathetic tone, increased secretion of catecholamines and catabolic hormones such as glucagon and cortisol, and decreased secretion of anabolic hormones such as insulin. It also increases antidiuretic hormone (ADH) and aldosterone secretion, electrolyte abnormalities, and protein catabolism. One theory suggests that opioids diminish the hyperglycemic and epinephrine responses because of efferent nerve blockade to the adrenal medulla yet have no effect on the cortisol response as a result of incomplete afferent nerve block.22

One group attempted to study the quality of the dying process in the ICU by retrospectively interviewing family members of 38 ICU decedents.23 This investigation found that family members perceived that the patients experienced substantial physical symptoms during the last week of life, but they felt that their loved ones’ pain was under satisfactory control less than half the time. A review of the hospital records showed a near universal absence of data regarding pain assessment as well as records of how sedatives and analgesics were titrated to pain and symptom relief. Of the many items measured, the perception of how well the patient’s pain was under control correlated strongly with the quality-of-dying ratings as measured in the study. The authors concluded that end-of-life care efforts in the ICU include management of pain as well as support of dignity, respect, peace, and maximizing patient’s pain control.

Implementing a structured and scheduled approach to pain management in the ICU may also be of significant value, both to the patient and to the medical institution providing care. ICU patients whose pain regimens were titrated based on standardized sedation, analgesia, and delirium scores attained better analgesia, received fewer opiates, and, despite comparable sedation, endured a shorter duration of mechanical ventilation.24 Also, based on a wellness model and the World Health Organization’s multimodal analgesic ladder, pain outcomes after cardiac surgery were improved. Where “as needed” analgesics were previously implemented, scheduled dosing around the clock and prior to procedural pain provided effective pain relief in 95% of 120 patients over a 3-month period, for every ICU staff shift for the first 6 days after cardiac surgery postoperatively. Side effect profiles improved, and median length of stay after surgery decreased. Moreover, implementation of a structured ICU pain protocol at the University of Iowa medical ICU reduced the number of ventilator days required from 10.3 to 8.9, the cost per patient by $10,500, and a savings of nearly $2 million for the hospital over a 26-month period.25

### METHODS OF PAIN CONTROL IN THE INTENSIVE CARE UNIT

This topic is limited to a discussion of methods of pain control (Box 76.3) as pertinent to the ICU setting, given that these issues are discussed in detail in other chapters in this text.

Analgesia may be administered by blocking afferent impulses carried along neural pathways, affecting integration in the central nervous system (which may display plasticity and central sensitization in response to pain), and blocking efferent impulses modulated by the neuroendocrine or sympathetic nervous system.22

Opioids mediate analgesia by binding with both central and peripheral opioid receptors, with the µ and κ receptors most important for analgesia. An “ideal” opioid would have rapid onset, ease of titration, lack of accumulation of the drug or its metabolites, and low cost.26 Morphine has ideal characteristics but may precipitate histamine release and theoretically might cause hypotension in the ICU patient with diminished volume status. In addition, active metabolites such as morphine-3- and morphine-6-glucuronide may accumulate in the presence of renal insufficiency. Meperidine is a poor drug for use in the ICU. It is metabolized to normeperidine, the accumulation of which may lead to delirium and seizures in patients with renal compromise. Opioids are discussed in more detail in Chapter 37.

The Society of Critical Care Medicine put forth practice parameters with regard to the use of opioids in the intensive care unit.27 The authors suggested that morphine is the initial agent of choice and is best started at a loading dose of 0.05 mg/kg administered over 5 to 15 minutes. It was suggested that most adults require 4 to 6 mg/hr after an adequate loading dose. This report also suggested that fentanyl (1 to 2 mcg/kg/hr after one or more loading doses of 1 to 2 mcg/kg) or hydromorphone (initiated at 0.5 mg and titrated by 0.5-mg increments to a general range of 1 to 2 mg every 1 to 2 hours) are acceptable alternatives to morphine. It is important to remember that opioid-tolerant patients often require higher doses of opioid analgesia than their opioid-naïve counterparts.

The use of opioids may lead to hypotension in patients with intravascular volume compromise or those reliant on

---

**Box 76.3 Methods of Pain Control in the Intensive Care Unit**

- Opioids
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Neuraxial (epidural and intrathecal) local anesthetics and opioids
- Peripheral nerve blocks (including sympathetic nerve blocks)
- Pre-emptive strategies before major surgery
- Nonpharmacologic approaches (i.e., hypnosis)
sympathetic tone for end-organ perfusion, which may be a significant issue in the ICU population. The route of administration is important. Subcutaneous and intramuscular injections, never optimal for pain relief in any setting, are not advisable given the uncertain perfusion and absorption seen in many ICU patients.\(^3\)\(^3\) Transdermal fentanyl presents similar issues and is suboptimal for acute pain management given the 12- to 24-hour delay in both onset and offset of analgesia.\(^2\)\(^9\) Patients who are able to cooperate may benefit from the institution of intravenous patient-controlled analgesia (IVPCA). IVPCA possesses an inherent safety mechanism in that the patient stops using the demand feature when pain is controlled and when side effects such as sedation are more prominent. This property of IVPCA helps minimize the chance of opioid overdose and resultant respiratory depression while optimizing the timely delivery of analgesic agent to the patient.\(^3\)\(^0\)

A group of authors examined the effect of thoracic epidural bupivacaine-morphine versus IVPCA morphine after thoracoabdominal esophagectomy.\(^3\)\(^1\) Pain scores at rest and with mobilization were better in the epidural group on postoperative day 1, as were the opioid-mediated side effects such as sedation. It was noted, however, that one third of those in the epidural group had their infusion discontinued earlier than planned because of technical failures such as insufficient analgesia or catheter displacement. Group assignment had no effect on ICU stay, duration of hospitalization, or mortality. Given the ability of epidural analgesia to decrease sympathetic tone, it is not surprising that this study found that the epidural group received larger amounts of colloid and crystalloid intravenously in the first 24 hours.

Intrathecal dosing of opioids may be done perioperatively, before a patient’s transfer to the ICU. Questions have been raised regarding the need for monitoring these patients for delayed respiratory depression, as well as the subsequent timing of analgesics. This issue was examined by a prospective, randomized, double-blind study in postoperative lumbar spinal fusion patients.\(^3\)\(^2\) Patients were randomized to receive intraoperative injection of 0.2 mg (group 1), 0.5 mg (group 2), or 0.4 mg (group 3) of morphine into the subarachnoid space under direct visualization. Pain levels were similar in groups 2 and 3 at zero hours and at 12 hours after surgery, but they were significantly higher in group 1. The patients’ respiratory rates were significantly lower in group 3 than in groups 1 and 2. The PaCO\(_2\) was also higher in group 3. No difference, however, was found in pruritus or nausea among the three groups. Some intensivists have suggested that this would argue for 0.3 mg as an optimal perioperative intrathecal morphine dose. Nonsteroidal anti-inflammatory agents (NSAIDs) should not be discounted as useful adjuncts in some ICU patients. Ketorolac, an intravenous NSAID, has been shown to have opioid-sparing effects and therefore may limit opioid-mediated side effects. This and other nonselective inhibitors of cyclooxygenase (COX) may have adverse effects on gastric mucosal perfusion, platelet aggregation, and renal perfusion in patients with suboptimal intravascular volume status. Therefore, it is recommended that ketorolac be limited to only 5 days’ use and administered with caution in older adults.\(^3\)\(^5\) Newer, highly selective COX-2 inhibitors are not in common use in the ICU setting and may be inappropriate in older adults given the documented increase in adverse cardiac events in this population.\(^3\)\(^4\)

The ICU burn patient population is particularly important to take note of, as pain is often one of their most serious and persistent complaints. As an adjunct approach to their pain management, hypnosis was demonstrated in burn patients to reduce pain intensity and anxiety, improve efficiency of administering opioids, improve wound outcome, decrease costs, and overall improve patient care of burn ICU patients without pharmacologically induced side effects.\(^3\)\(^5\)

Interventional pain procedures also may have a role in the ICU. Thoracic epidural infusion of local anesthetic, with or without the addition of an opioid, may be useful for patients with traumatic rib fractures, who often encounter difficulty weaning from mechanical ventilation secondary to significant chest wall pain.\(^3\)\(^0\) The use of intercostal nerve blocks is debatable given that the relief only lasts as long as the duration of action of the local anesthetic used.

Another potential role for an interventional pain procedure in the ICU is poor distal perfusion in an extremity. Sympathetic blocks may prove useful in such situations.\(^3\)\(^6\) This may be achieved by the direct performance of either a sympathetic ganglion block, such as a stellate ganglion block, or lumbar sympathetic block to improve perfusion in an affected upper or lower extremity, respectively. An indwelling axillary or femoral nerve sheath catheter might also be a means of providing local anesthetic on a continual basis, either with or without superimposed patient-demand dosing.\(^3\)\(^7\)

One study examined a pre-emptive strategy for reducing opioid consumption in elderly patients undergoing cardiac surgery by pretreating surgical candidates with 130 mg of pregabalin prior to surgery and then with 75 mg of pregabalin twice daily for 5 days after surgery in a randomized, double-blind placebo-controlled trial. The group of patients administered pregabalin demonstrated a marked reduction of postoperative opioid consumption, to almost 50%, from the time of extubation to the fifth postoperative day, as compared to those on placebo. Patients treated with pregabalin also experienced reduced incidence of postoperative confusion on the first postoperative day, suggesting an opioid-sparing benefit in this instance. However, time to extubation was 138 minutes shorter in the placebo group. Interestingly, patients on the short-term pregabalin regimen experienced less pain 3 months postoperatively than the placebo group. Therefore, pregabalin appears to have potential short- and long-term benefits for critically ill patients undergoing cardiac surgery, and its use should be further investigated in these regards.\(^3\)\(^8\)

### EPIDURAL INFUSIONS IN THE INTENSIVE CARE UNIT

Epidural infusions may consist of a combination of a local anesthetic and an opioid. This allows the synergy of two mechanisms of action: local anesthetics work by blocking sodium channels on the nerve membrane, and opioids work through opioid receptors in the substantia gelatinosa of the dorsal horn of the spinal cord. This combination also minimizes the potential toxicity or side effects from each agent. The potential for seizures or cardiac toxicity from the local anesthetic or sedation or respiratory depression from the opioid may be attenuated because less of each agent is used when they are used in combination.\(^3\)\(^9\)
Many local anesthetic–opioid combinations include fentanyl. Fentanyl is relatively lipophilic and tends to affect the neuraxis at or near the level of the spinal cord, where it is infused. It will also achieve plasma levels relatively quickly because of its lipophilicity. Morphine, conversely, has relatively hydrophilic properties. It tends to ascend cephalad in the neuraxis, potentially contributing to delayed respiratory depression.

The clinical situation in the ICU may dictate the choice of opioid in the infusion. Thoracic epidural analgesia (TEA) may be beneficial for pain control in post-thoracotomy patients to cover incisional pain as well as pain from chest tube sites, which can be particularly problematic with regard to pain control. Given the restricted use of intravenous fluids associated in many thoracic surgical cases, the patient may arrive in the ICU with a picture of uncontrolled pain in the face of relatively low blood pressure. A dose of local anesthetic given via the epidural catheter may precipitate hypotension as a result of interruption of sympathetic tone and may lead to compromise of end-organ perfusion. Given the desirability of maintaining the epidural catheter for ongoing pain control, one solution to this problem is to provide a continuous epidural infusion of morphine. Excellent neuraxial anesthesia can be given without the hypotension that might ensue from a local anesthetic. There is a possibility of progressing to a local anesthetic–opioid combination as the patient progresses to euvelema.

Attention has been given to the use of epidural analgesia in the ICU in the presence of post-traumatic rib fractures. Epidural analgesia has been compared with IVPCA and found to improve patients’ pain scores. This study reviewed the charts of 64 patients with three or more rib fractures after a motor vehicle accident and had initiation of intravenous (IV) PCA morphine or TEA with bupivacaine and fentanyl within 24 hours of admission. Despite the fact that the patients who received epidural analgesia were older and sustained more rib fractures, their pain scores on a 5-point scale were significantly lower for up to 80 hours from baseline. Another study examined epidural approaches in patients with chronic obstructive pulmonary disease undergoing open surgery for abdominal aortic aneurysm, and it was determined that both epidural anesthesia and postoperative epidural analgesia improved postoperative respiratory function and reduced postoperative pain in comparison with general anesthesia and systemic analgesia.

One review also suggested that TEA may be a cornerstone of a multifaceted strategy for improving (pain) outcomes in lung transplantation. TEA was demonstrated to decrease the duration of mechanical ventilation, as well as ICU length of stay and number of respiratory complications. This is based on a low level of evidence of published studies, however, so further prospective trials are warranted.

A study retrospectively reviewed more than 64,000 patients from the National Trauma Data Bank with one or more rib fractures. The authors found that mortality and pulmonary morbidity increased with the number of rib fractures. It was found that only 2% of all patients with fractured ribs received epidural analgesia. This use was increased in patients who suffered six or more rib fractures. The use of epidural analgesia was associated with a significant decrease in hospital mortality compared to alternative forms of analgesia, leading the authors to conclude that this modality of pain control appears to be underused.

## SEDATION IN THE INTENSIVE CARE UNIT

The main indications for sedation in an ICU setting include patient tolerance for ventilation, tolerance for medical and nursing interventions, and actual patient symptoms, with more systematic assessments of patient pain and sedation level needed to properly administer the ideal level of pharmacologic sedation. Before treating anxiety in the critically ill patient, it is also crucial to identify other underlying disorders that can contribute to this problem. These include hypoxemia, hypoglycemia, hypotension, metabolic disturbances, and drug and alcohol withdrawal. Agitation may lead to harmful sequelae such as breathing against the ventilator, increase in oxygen consumption, and removal of monitoring devices and catheters. No one gold standard exists to quantify sedation, and the Ramsay, Riker, Motor Activity Assessment, and Vancouver scales all have been used for this process (Tables 76.1 to 76.4).

Common sedatives used in the care of the critically ill patient include benzodiazepines such as midazolam and lorazepam, hypnotic agents such as propofol, and centrally acting α2-agents such as dexmedetomidine. Titrating a given sedative to a defined end point has been recommended with subsequent systematic tapering of the dose or, alternatively, daily interruption of sedation with retitration to minimize prolonged sedation.

A report in the *Journal of the American Medical Association (JAMA)* offered a broad view regarding the use of dexmedetomidine in comparison with both midazolam and propofol in mechanically ventilated ICU patients. Two randomized controlled trials demonstrated that dexmedetomidine was noninferior to propofol and midazolam in maintaining target levels of sedation in ICU patients who required prolonged mechanical ventilation. Moreover, dexmedetomidine also appears to reduce the duration of mechanical ventilation as compared to midazolam, and it reduces time to extubation in comparison with both midazolam and propofol. Dexmedetomidine also reduced delirium and improved patient communication with nursing staff as compared to propofol. However, dexmedetomidine use had no effect on length of ICU or hospital stay and also induced higher rates of hypotension and bradycardia as compared with midazolam. Overall, the *JAMA* study

concluded that dexmedetomidine is a viable long-term sedative in the ICU setting that can reduce duration of mechanical ventilation and improve comfort.\(^\text{51}\)

The effect of the specific agent on weaning from mechanical ventilation was examined.\(^\text{52}\) A remifentanil-based regimen (started at 0.1 to 0.15 mcg/kg/minute and titrated in 0.025-mcg/kg/minute increments every 5 to 10 minutes to optimum levels based on clinical judgment), when compared with a midazolam-based regimen (administered by infusion or by boluses and titrated to optimum levels based on clinical judgment), resulted in a decreased duration of mechanical ventilation by more than 2 days. It also reduced, by 1 day, the time from the start of the weaning process to the time of extubation. The authors did not comment on the relative cost of the two agents and whether an overall cost savings was appreciated in the remifentanil-based group.

Implementation of a guided, structured protocol for sedation of mechanically ventilated patients at the Brigham and Women’s Hospital medical intensive care unit was reviewed by retrospective analysis. Adopting a formalized protocol for sedation management in these regards resulted in more goal-directed administration of sedatives, frequency of sedation assessment documentation, and increased percentage of assessments of mechanically ventilated patients at or near the sedation goal. Although compliance with such a protocol improved, this did not result in improved clinical outcomes, highlighting the continued challenges associated with successfully implementing sedation and pain protocols in an intensive care setting.\(^\text{53}\)

### KEY POINTS

1. Pain in the critically ill patient is often difficult to assess due to existing communication barriers.
2. Use of several behavioral scales may be helpful in attempting to quantify pain and discomfort in the critically ill.
3. Despite appropriate focus on what may be life-threatening physiologic abnormalities in the critically ill patient, pain control is not to be ignored as an essential component of care for this population.

### CONCLUSION

Assessment and treatment of pain in the critically ill population are challenging tasks given the frequent lability in patients’ physiologic status and the compromise in their ability to communicate. Intensivists have an array of therapeutic...
options available including NSAIDs, opioids (both by infusion and by IVPCA), and central and peripheral nerve blockades (i.e., sympathetic nerve blocks and continuous epidural analgesia). Although undertreatment of pain in ICU patients is well documented, data suggest that organizational changes, implementation of standardized pain regimens and sedation/analgesia protocols, and appropriate use of pharmacologic therapy may improve pain control in the critically ill patient. Sedation is equally important as analgesia in pain control, and newly studied agents such as dexmedetomidine, with shorter ventilation times and better comfort, offer more promise in overall pain control.

**SUGGESTED READINGS**

A controlled trial to improve care for seriously ill hospitalized patients. The study to understand prognoses and preferences for outcomes and risks of treatments (SUPPORT): the SUPPORT principal investigators. JAMA. 1995;274:1591-1598.

The end stages of chronic, progressive, life-limiting diseases bring a host of difficult symptoms and causes of suffering. There are disease-mediated symptoms, such as pain, dyspnea, fatigue, and loss of mobility, and there are the accompanying emotional states, such as depression, anxiety, and a sense of uselessness. These symptoms and states intertwine and interact in a complex manner, and each one deserves attention.

Of the many symptoms experienced by those at the end of life (EOL), pain is one of the most common and most feared. Pain is often undertreated, even when prevalence rates and syndromes are well understood and the means of relief are within all physicians' capabilities to provide, directly or through consultation. With careful assessment and a comprehensive plan of care that addresses the various aspects of the patient's needs, pain can be controlled in the majority of cases. Awareness and provision of basic and specialized interventions can ensure comfort for all patients through the final stages of a terminal illness. This is equally important in order to prevent prolonged and pathologic grief in surviving loved ones.

All the members of a palliative care team play important roles in comprehensive pain management. The roles of both physicians and nurses begin with assessment and continue throughout the development of a plan of care and its implementation. Rehabilitation specialists, clinical pharmacists, psychologists, social workers, and spiritual counselors also provide important elements in helping patients optimize their quality of life, stay comfortable, heal relationships, complete unfinished business, and find peace as they approach death. To provide optimal pain control, all health care professionals must understand the causes and prevalence of pain at the end of life, the treatments used to provide relief, and the barriers that prevent good management. To champion this position there are now multiple guidelines regarding pain assessment and management during this time. One example is from the American College of Physicians, which also, for the first time in the medical literature, defines the EOL period as "a phase of life when someone is living with an illness that will worsen and eventually cause death. It is not limited to the short period of time when the patient is moribund." This challenges providers to think about EOL pain in a much more upstream fashion as many of these patients will be in this phase of their lives for years.

To illustrate some common scenarios, we present three different fictional, but typical, case studies.

CASE 77.1 Pain Assessment and Care Planning in a Cognitively Intact Patient

Judith is a frail 81-year-old who lives on her own with assistance from a home care nurse and from a daughter, who lives nearby. She was admitted to the hospital with acute respiratory failure resulting from bronchitis. She has advanced chronic obstructive pulmonary disease (COPD), with general fatigue, a poor appetite, and a sleep disorder. She also reports severe, debilitating pain in the midthoracic region from postherpetic neuralgia (PHN). She also struggles with congestive heart failure (CHF), coronary artery disease, and attendant angina pectoris that is usually relieved with nitrates. Judith says that she has been feeling "pretty low" lately and finds herself becoming irritated at small events. She characterizes her pain as "bad as it can be" (Fig. 77.1). After a 2- to 3-day intensive care unit (ICU) stay, she will be ready for discharge. However, her pain from PHN is still not controlled, and her life expectancy is most likely limited because of her ongoing comorbidities. She does not have a written advance directive. The hospital staff discusses the next step.

PREVALENCE OF PAIN AT THE END OF LIFE

Assessing pain in patients approaching the end of life requires a multifactorial evaluation. It is important to acknowledge and address the prevalence, high incidence, and serious adverse consequences of pain in the end-stage conditions that affect patients with advanced medical illness, such as controlled and uncontrolled cancer, heart disease, human immunodeficiency virus (HIV) disease, neurodegenerative diseases (e.g., amyotrophic lateral sclerosis [ALS] and multiple sclerosis), and end-stage renal and respiratory diseases (Box 77.1 and Fig. 77.2). These conditions may also be accompanied by other pain-producing disorders that may require separate treatments, as in the case mentioned.

The prevalence of pain in the terminally ill varies by diagnosis and demographics. Approximately one third of the people who are actively receiving treatment for cancer and two thirds of those with advanced malignant disease experience pain. Almost 75% of patients with advanced cancer who are admitted to the hospital report pain on admission. In a study of cancer patients who were very near the
end of life, pain occurred in 54% and 34% at 4 weeks and 1 week prior to death, respectively. Uncontrolled cancer pain also predicts hospital admissions. In an outpatient cancer center, an evaluation of more than 5000 patient encounters where the pain intensity scores were high (7 to 10 on a scale of 0 to 10) demonstrated that 29% of these patients were hospitalized within 30 days of those visits. In another study of more than 13,000 cancer patients in U.S. nursing homes, an average of 30% of the patients reported daily pain. In those patients, pain varied according to age, sex, race, marital status, physical function, depression, and cognitive status.

In other studies of patients admitted to palliative care units, pain often is the dominant symptom, along with fatigue and dyspnea. Until recently it was widely believed that patients dying from nonmalignant disease did not have high levels of pain. However, it is now known that patients dying from cardiac failure, COPD, end-stage renal disease, and other end-stage diseases suffer similar levels of pain to those found in patients with malignant disease. In fact, comparing advanced cancer patients to those with symptomatic congestive heart failure (CHF), it is now clear that the symptom burden is as great, or greater, in the latter. In a multicenter Veterans Administration (VA) study of the symptoms CHF patients experience, it was noted that over 55% of the them had pain, the majority of which rated their pain as moderate to severe. This was more common than the sensation of dyspnea. People at particular risk for undertreatment include older adults, minorities, and women.

An attempt has been made to characterize the pain experience of those with HIV disease because of the frequency for this disorder to be seen in palliative care settings. More than 56% of patients with HIV disease report pain, with the most common manifestations being headache, abdominal pain, chest pain, and neuropathies. Low CD4+ cell counts and HIV-1 ribonucleic acid (RNA) levels are associated with higher rates of neuropathy. There have been many reports of undertreatment of patients with HIV disease, including those patients with a history of addictive disease.

**ASSESSING PAIN AT THE END OF LIFE**

Assessment of pain, including a thorough history and comprehensive physical examination, guides the choice of diagnostic studies and the development of the pharmacologic and nonpharmacologic treatment plan. The primary source of information in a pain assessment should be a patient’s self-report. Many different pain rating scales are available, ranging from complex multidimensional tools to very simple numeric and picture scales, which can help patients identify pain and then document the efficacy of treatment. Widely used examples of this include the FACES Pain Scale, the McGill Pain Questionnaire, and the Brief Pain Inventory. When using pain scales, be sure to follow the directions for administration carefully.
A pain scale that suits a given patient’s ability to self-report should be part of each patient’s medical record. Health professionals should teach patients and their families to use these scales themselves to help in longitudinal pain assessment and continuity of care. Patients with terminal illnesses should be encouraged to describe their experiences of pain in their own words. However, many patients near the end of life are unable to provide detailed descriptions of their pain character, intensity, or location. Particularly for patients with cognitive impairment, self-assessments may be difficult to interpret. Nevertheless, even in these patients, self-assessments remain the cornerstone of pain management. For these patients, the use of the “pain thermometer” has been validated as a self-report instrument for pain intensity in patients with mild to moderate cognitive impairment.25

**CASE 77.1** Pain Assessment and Care Planning in a Cognitively Intact Patient (continued)

Judith describes her PHN as a “burning, needling pain” near her spine, spreading out across her back on the right, beneath her axilla, and around to her breast. Her pain subsides sometimes, but rarely goes away altogether. Knowing the character and location of her neuropathic pain allows her caregivers to pinpoint adjuvant pain relief. In contrast, Judith’s angina pain is “a deep, heavy ache” in her chest. She notes that it is intermittent and stressful, because she never knows quite when to expect it. By asking her to keep track of when her angina occurs, her caregivers are able to predict more precisely when it may be triggered and advise her accordingly, perhaps reducing both severity and frequency.

A comprehensive evaluation of pain should include an assessment of the pain intensity, character, frequency, onset, duration, and location as well as a detailed history of pain, a physical and neurologic examination, and psychosocial assessment. Diagnostic evaluation that includes tests to determine the cause of pain are important to corroborate clinical impressions of the cause of pain and mechanisms, but diagnostic workup should neither delay empiric treatment nor add excessive burden to the patient, especially when death is imminent. It also is important to take into account common pain- and advanced illness–related comorbidities, such as sleep disturbances and depression, which can affect pain levels, suffering, and functioning.26,27

Terminally ill patients sometimes complain of pain as a way of expressing other forms of suffering, distress, griefing, anxiety, or depression. When this is the case, psychosocial or spiritual evaluation and intervention will be more effective than analgesics. It is well established that attention and emotion influence pain processing and perception, and conversely inadequately managed pain can lead to anxiety and depression.8-10 Therefore, comprehensive assessment is required to determine the optimal plan of care, as specific to pain etiology as possible. Particularly for health care providers unfamiliar with the care of patients near the end of life, involvement of other disciplines (e.g., nursing, social work, chaplaincy) can be very valuable in uncovering other sources of emotional or spiritual suffering that may be confusing the pain assessment.

**DIFFERENTIATING PAIN MECHANISMS AND CHOOSING APPROPRIATE THERAPIES AT THE END OF LIFE**

Patients in the terminal stage of an illness often experience multiple mechanisms of pain simultaneously (e.g., both nociceptive and neuropathic). Nevertheless, it is important to differentiate among different types of pain because the type of treatment and its success are largely dictated by the pain mechanism and its original source.28,29 In some conditions, especially metastatic cancer, pain is often caused by a complex mix of nociceptive and neuropathic factors. Though neuropathic pain afflicts 7% to 8% of the general population,30 its effective recognition and management might be wanting given the lack of exposure in medical education on this topic. An evaluation of 104 U.S. medical schools found only 48 of them include neuropathic pain as a required topic and on average only 0.5 hour is spent teaching about it.31 Evidence-based guidelines are available,30,32 and should be utilized while keeping in mind that an important strategy for treating EOL patients is using one medication that might treat more than one type of pain or multiple symptoms. For example, an opioid might be helpful for neuropathic pain as well as angina. A tricyclic antidepressant can be employed for both postherpetic neuralgia and a sleep disorder. This strategy is supported in the medically frail population.33

**EFFECTS OF UNRELIEVED PAIN ON THE PATIENT AND CAREGIVER**

There is growing evidence that inadequate pain relief might hasten death, not only via the well-recognized morbid effects of increasing physiologic stress, reducing mobility, increasing proclivities toward pneumonia and thromboembolism, and increasing the work of breathing and myocardial oxygen requirements, but also through immune suppression.34 Pain may lead to a spiritual despair and significant decrease in emotional well-being because the individual’s quality of life is impaired.56 It is the professional and ethical responsibility of clinicians to focus on and attend to adequate pain relief for their patients and to properly educate patients and their caregivers about analgesic therapies.35 Palliative care and hospice programs are charged with caring for not just the patient but the family/caregivers as well. Caregiving is a risk factor for mortality.56 This carries not only physical consequences but emotional, economic, and social ones.37 When pain and other distressing symptoms are properly attended and advance directives are completed to guide the caregiver, quality scores for EOL care increase, costs and resource utilization decrease, and caregiver stress is diminished.38-40
Returning to Judith, who has COPD, coronary artery disease, and PHN, it is clear that discussions about care preferences (i.e., advance directives) are optimal before a medical crisis and while there is cognitive capacity for decision making. However, under the current circumstances, a care planning meeting with the attending clinician, consultant clinicians (e.g., palliative care/hospice team), and designated responsible family member is of paramount importance. The team must adequately control her pain before discharge with a follow-up plan in place, or they must transfer her to a skilled facility.

**Pain Assessment and Care Planning in a Cognitively Intact Patient (continued)**

**Case 77.2** Pain Assessment and Care Planning in a Severely Cognitively Impaired Patient

Grace is a 74-year-old in the late stages of Alzheimer’s disease with severe osteoarthritis in her knees and spine. She lives with her married daughter and two grandchildren. Her daughter and a son living nearby provide her essential care, and until recently she has remained active and ambulatory. She is beginning to experience severe pain from her arthritis, manifest by grimacing, crying, and moaning. The current caregivers are not always sure what she is expressing, but they understand that she is in some distress and are eager to help alleviate it. They meet with their family physician to talk about options. Because Grace is in the far-advanced stage of Alzheimer’s disease, the physician refers her to hospice for comprehensive care and support of her family. During her initial evaluation, the family stresses that their primary goal is to make sure that Mom is comfortable. The hospice nurse evaluates Grace and determines that she responds well to a variety of nonpharmacologic interventions. Her family members express a willingness to use a variety of hands-on and nonpharmacologic techniques to help Grace live her last days relatively free of pain and suffering. Meanwhile, she is started on a regimen of around-the-clock acetaminophen (1000 mg three times daily) with the option for more potent pharmacologic therapies left open.

**NONPHARMACOLOGIC APPROACHES TO PAIN MANAGEMENT IN PALLIATIVE CARE**

An important aspect of any management strategy is the use of nonpharmacologic treatments. Various nonpharmacologic approaches to pain are effective in alleviating pain for patients with advanced illness. These include physical interventions, such as positioning and active or passive mobilization (therapeutic exercise); techniques, such as transcutaneous electrical nerve stimulation (TENS), massage, and heat or cold; and complementary and alternative medicine techniques, music, and relaxation or imagery exercises. Table 77.1 offers a list of some of the most common nonpharmacologic interventions.

The type of intervention, or combination of interventions, depends on the source and severity of pain as well as the physical condition and receptivity of the patient. In an investigation of the prevalence of complementary and alternative medicine use in an end-of-life population, Tilden and colleagues, through a series of phone interviews with family caregivers of recently deceased patients, found that 53.7% of the deceased used some kind of complementary therapy, were more likely to be younger with college degrees and higher household incomes, and were more likely to have used one or more life-sustaining treatments. Symptom relief was the most frequent reason given for complementary and alternative medicine use. A study by Weiner and Ernst that reviewed common complementary and alternative treatment modalities for the treatment of persistent musculoskeletal pain found that the use of these modalities is increasing in older adults. The study authors concluded that rigorous clinical trials examining efficacy are still needed before definitive recommendations regarding the application of these modalities can be made.

Aside from their objective efficacy, a medical sociologic study by Garnett on the use of complementary therapies by palliative care nurses sees these therapies as an “emotional inoculation” that builds resiliency and an important bond between patient and caregiver. Nonpharmacologic interventions often comfort the patient while involving and empowering family and other caregivers. The necessity of feeling effective for caregivers should not be overlooked—it can have a direct effect on the experience of the patient as well as the emotional survival of the family caregiver in particular. A study by Keefe and colleagues on the self-efficacy of family caregivers of cancer patients found that caregivers who rated their self-efficacy as high reported much lower levels of caregiver strain as well as lower negative mood and higher positive mood. Caregiver self-efficacy in managing the patient’s pain was related to the patient’s physical well-being. When the caregiver reported high self-efficacy, the patient reported having more energy, feeling less ill, and spending less time in bed.
Functional rehabilitation and physical therapy techniques in appropriately selected patients can add to quality of life even in the face of limited life expectancy. In the case presented, Grace typifies patients who respond well to nonpharmacologic pain interventions. A study by Montagnini and colleagues,\textsuperscript{46} assessing the use of physical therapy in a hospital-based palliative care setting, found that a significant proportion demonstrated improvement in function after 2 weeks. The study authors found that patients with a diagnosis of dementia were most likely to show improvement in functional status and concluded that physical therapy assessment and use were uncommon in the studied group, but when implemented, 56\% of the patients benefited.

                              | persistent low electrical nerve stimulation back pain.                       |
| **Acupuncture**              | Popular complementary therapy for patients with cancer and other end-stage pain:  
                              | • Many patients with cancer use acupuncture when symptoms persist with conventional  
                              | treatments, or as a complement to their ongoing treatments.  
                              | • Several researchers have found acupuncture to be an effective antidepressant.  
                              | • Studies show that acupuncture has a significant positive effect on chronic  
                              | obstructive pulmonary disease (COPD), dyspnea associated with end-stage  
                              | cancer, and asthma.                                                   |
| **Cognitive interventions**   | Some common cognitive interventions:  
                              | • Psychological tools and strategies for the purposes of self-regulating emotions  
                              | • Distraction from noxious sensations and thoughts  
                              | • Methods for reducing negative attitudes  
                              | • Involving patients in cognitive self-care may improve mood and increase coping  
                              | behaviors                                                             |
| **Music therapy**            | Music effectively reduces anxiety and improves mood for:  
                              | • Medical and surgical patients  
                              | • Patients in intensive care units  
                              | • Patients undergoing procedures  
                              | • Children as well as adults  
                              | • Low-cost intervention  
                              | • Often reduces chronic pain  
                              | • Music improves the quality of life, enhancing a sense of comfort and relaxation  
                              | • Music to caregivers may be a cost-effective and enjoyable strategy for improving  
                              | empathy, compassion, and relationship-centered care without interfering with technical  
                              | aspects of care                                                      |

**MASSAGE**

Research suggests that patients with cancer, particularly in the palliative care setting, are increasingly using aromatherapy and massage. There is good evidence that these therapies may reduce anxiety for short periods. A study by Soden and colleagues\textsuperscript{47} was designed to compare the effects of 4-week courses of aromatherapy with massage and massage alone on physical and psychological symptoms in patients with advanced cancer. The study authors were unable to demonstrate any significant long-term benefits of aromatherapy or massage in terms of improving pain control, anxiety, or quality of life, but sleep scores improved significantly in both groups, and there were statistically significant reductions in depression scores in the massage group, suggesting that patients with high levels of psychological distress respond best to these therapies. When massage has been evaluated for impact in treating osteoarthritis of the knee, it has been found to lower pain scores and improve functionality.\textsuperscript{38} In this 8-week study with 125 participants receiving either usual care or weekly massage regimens, it was reported that there is an increasing effect with greater total time of massage until a plateau was reached at 60 minutes per week.

**ACUPUNCTURE AND TRANSCUTANEOUS NERVE STIMULATION (TENS)**

These modalities may be effective in selected patients based on meta-analyses of the literature and findings of National
Institutes of Health (NIH) consensus panels. When looked at for osteoarthritis of the knee, TENS has been found to require further study based on a Cochrane review. Patients with the following characteristics appear to benefit most from acupuncture: a diagnosis of osteoarthritis, living in a multi-person household, being female, and failing other therapies. For percutaneous procedures, appropriate cautions, skilled certified practitioners, and fastidious aseptic techniques are required to protect patients and staff from untoward adverse outcomes. Similarly, for therapies involving electrical stimulation, awareness of implanted devices (pumps, stimulators, implantable cardioverter defibrillators, or pacemakers) and precautions to prevent malfunction must be taken.

COGNITIVE INTERVENTIONS

Simple psychological interventions can have a significant impact on pain. As an example, Paqueta and colleagues explored the idea that everyday emotion regulation through self-supporting maintenance or change in positive and negative emotions can help reduce pain intensity in the hospitalized older adult. Emotion regulation was found to be prospectively related to pain intensity for both overall emotion and anxiety-specific regulation. The study authors suggested that promoting emotion regulation as a self-management strategy could contribute to cost-effective pain management in general or targeted older adult populations.

MUSIC THERAPY

There is growing interest in the therapeutic use of music. The difficulties inherent in the medical treatment of this population make the use of music, as a noninvasive therapeutic modality, attractive. Five studies with a total of 175 participants in a Cochrane review suggested a benefit for patients near the EOL, though the results were subject to participants in a Cochrane review suggested a benefit for acupuncture: a diagnosis of osteoarthritis, living in a multi-person household, being female, and failing other therapies. For percutaneous procedures, appropriate cautions, skilled certified practitioners, and fastidious aseptic techniques are required to protect patients and staff from untoward adverse outcomes. Similarly, for therapies involving electrical stimulation, awareness of implanted devices (pumps, stimulators, implantable cardioverter defibrillators, or pacemakers) and precautions to prevent malfunction must be taken.

CHOOSEING THE BEST APPROACH

Although pain at the EOL is often thought to come from cancer or HIV, discomfort from osteoarthritis needs much more attention. An observational study of more than 4700 older adult decedents found the prevalence of pain in the last month of life to be 60% in those with arthritis and 26% in those without (P < 0.001). A combination of treatments is usually most effective when using nonpharmacologic approaches to pain management. When cognition is compromised, constant vigilance for the presence of pain by monitoring behavior and nonverbal cues that deviate from a patient’s baseline is advised. If the presence of pain is unclear, it might be warranted to attempt analgesic intervention. Similar to pharmacotherapy, multimodal approaches offer the potential benefit of additive and synergistic effects. Because nonpharmacologic therapies need to be tailored to individual likes, dislikes, and effectiveness, knowledge of the various modalities, management of expectations, open-mindedness, and a “trial-and-error” approach should be embraced.

CASE 77.2 Pain Assessment and Care Planning in a Severely Cognitively Impaired Patient (continued)

The hospice nurse was able to offer Grace’s family a variety of hands-on and alternative modalities that could be used in addition to pharmacologic interventions to successfully comfort the patient. The nurse found that simple stretches and strengthening and mobilization exercises were effective for reducing the stiffness that was associated with Grace’s musculoskeletal disease. This helped to relax the patient and prevent the usual anxiety that is associated with getting her out of bed in the morning and daily personal care, such as bathing and toileting. A simple TENS unit appeared to ease the patient’s knee pain. The nurse was also able to guide the family in some interventions that reduced Grace’s anxiety and increased the family’s sense of involvement and effectiveness. They found that songs from her youth brought Grace a great deal of pleasure, and her son, a fan of the music, enjoyed spending listening time with her. Physical contact often calmed Grace, and the nurse trained Grace’s granddaughter in simple massage techniques. These interventions seemed to be effective and helped the family to feel that they were contributing to Grace’s care and well-being.

CASE 77.3 Complex Symptom Management in the Home Setting

Ben is a 79-year-old with metastatic colon cancer who has just returned to his home in an assisted-living facility postoperatively after a bowel resection. He sees a geriatric nurse practitioner, in collaboration with a family physician, for ongoing primary care. It has become clear that there are widespread metastases, and his oncologist agrees that the current goal of care is comfort only. Ben is still ambulatory and in the early stages of his terminal illness. No further chemotherapy or radiation therapies are indicated, but the patient reports progressive abdominal pain, and symptoms suggestive of intermittent bowel obstruction have developed. Ben refuses further hospitalization and surgery, and prefers noninterventional therapies, if at all possible. A consulting pharmacist and medical director from the local hospice are asked to come in and help the nurse practitioner choose the best pharmacotherapy for pain and bowel-related signs and symptoms, including types of drugs, route of drug administration, and the best way to minimize possible side effects. The explicit goals of care are a comfortable, dignified death, crisis prevention, and self-determined life closure (no prolongation of dying by medical intervention).

PAIN MANAGEMENT AND PALLIATIVE CARE FOR CANCER PATIENTS

Cancer, arguably more than any other disease process, has been the model from which the evidence base has sprung for aggressive attention to pain control and palliation of the whole person and for their families. It is also a driving force
for quality improvement measures. Pain is the most frequent complaint for cancer patients presenting to the emergency department.\textsuperscript{58} Compared to cancer patients who die in a hospital, those who die at home have higher quality of life scores and their bereaved family members are at less risk for developing psychiatric illness.\textsuperscript{59} Because of data such as these, the cancer community has developed evidence-based recommendations on pain management.\textsuperscript{60} It is also now recommended that all cancer patients have access to palliative care services so that patient-centered care is seamlessly integrated into standard oncology practice.\textsuperscript{61}

**DRUGS FOR PAIN RELIEF IN PALLIATIVE CARE**

Pharmacologic therapies for pain include nonopioids, opioids, adjuvant analgesics, disease-modifying therapies, and (in some cases) interventional techniques. Intractable pain and symptoms that are not responsive to basic therapeutic techniques, although not common, must be treated appropriately and aggressively.\textsuperscript{1} In some highly selective cases, palliative sedation may be warranted.\textsuperscript{62} A sound understanding of pharmacotherapy for pain treatment allows the palliative care/hospice team to create a comprehensive plan of care as well as recognize and assess medication-related adverse effects, understand drug-drug and drug-disease interactions, and educate patients and caregivers regarding appropriate medication usage. Recognition of the limits of usual therapies and the ability to muster expert assistance are important skills. This will ensure a comfortable process of dying for the well-being of the patient and for the sake of those in attendance.

Genetic factors, pathologic processes, concurrent medication, and aging all influence drug response and disposition. However, there are also a variety of nonmedical factors that influence responses to drug treatment in patients with far-advanced disease, including the social, environmental, and psychological milieu as well as the general vulnerability of this population. Understanding the clinical pharmacology of the drugs in question is essential for professional caregivers.\textsuperscript{63} Commonly, there is a need to use drugs for non-U.S. Food and Drug Administration (FDA)–approved indications or routes of administration, simply because randomized controlled clinical trials have not been performed, because (usually) of financial constraints. Rational polypharmacy (combining drugs with different mechanisms of action to produce additive or synergistic effects and minimize adverse effects) is often necessary, but there is a high potential for drug interactions, so close monitoring is required.

The principles of effective symptom control are always paramount: diagnose the underlying cause of each symptom and tailor the treatment to individual circumstances and clinical context. Keep in mind that normal pharmacokinetics and pharmacodynamics may be considerably altered by end-stage disease states. For example, in patients with chronic liver disease or hepatic metastases, drugs may bypass hepatic metabolism altogether, increasing bioavailability. Similarly, renal clearance is almost always diminished during the dying process, leading to the accumulation of drug metabolites, some of which (e.g., those of morphine) may be toxic.\textsuperscript{6,63}

**COMMUNICATING WITH PATIENTS, FAMILIES, AND OTHER HEALTH CARE PROFESSIONALS**

Communicating clearly about pharmacologic pain control with patients, families, and other members of the palliative care/hospice team is essential to providing effective pain management. It is important to be specific about the types of drugs that are available, how they are likely to affect the patient, how they are to be administered, and how they may interact with existing medications. Despite the importance of pain management at the end of life, there are often substantial roadblocks to overcome in getting patients the treatment that they need. Professional health care workers may have unsubstantiated but strong beliefs about analgesic use, especially opioid use, that lead to underprescribing.\textsuperscript{14,64}

Several surveys show that physicians, nurses, and pharmacists express concerns about addiction, tolerance, and side effects of morphine and related compounds.\textsuperscript{65} These fears are pervasive among patients and family members as well. Studies have suggested that these fears lead to undermedication and increased pain intensity.\textsuperscript{66} Concerns about being a “good” patient or belief in the inevitability of cancer pain lead patients to hesitate in reporting pain. In these studies, less educated and older patients were most likely to express these beliefs.

Often a physician or other providers may be reluctant to offer the patient direct and objective information on his or her health, especially toward the end of life, seeking to “soften the blow” by keeping the details vague. Most patients, however, prefer complete information about their condition.\textsuperscript{67,68} However, patients may wish to defer decision making to the physician or family members.\textsuperscript{69,70} Physicians have a professional duty to determine patients’ medical wishes. As a purely practical matter, by default or situational necessity, this responsibility may fall to the nurse or nurse practitioner. It is important to know that there are helpful tools, such as simple card sorting, that can be used to facilitate this exchange; for example, the five-card Control Preference Scale uses cards to portray different roles in treatment decision making with a statement and a picture.\textsuperscript{71}

**DISPELLING COMMON MYTHS ABOUT PAIN MANAGEMENT**

Understanding the barriers that are faced when treating pain can lead professionals to better educate and counsel patients and their families.\textsuperscript{45} Patients should be asked whether they are concerned about addiction and tolerance (often described as becoming “used to” or “immune” to the drug).\textsuperscript{72} At the end of life, patients may need to rely on family members or other support persons to dispense medications. Studies suggest that patients’ pain experiences and family members’ perceptions about them do not correlate well, leading to inadequate provision of analgesia.\textsuperscript{73,74} The interdisciplinary palliative care/hospice team is essential in the communication effort, with nurses, social workers, chaplains, physicians, volunteers, and others providing support in exploring the meaning of pain and barriers to pain relief. Education, counseling, reframing, and spiritual support are imperative.
Providers can also be concerned about precipitating death with the use of medications such as opioids or benzodiazepines that are used aggressively during the EOL phase or when someone is actively dying (aberrant respirations, hypotension, diminished cognition, low urine output). It has been established that patients have legal and ethical rights to symptom management during this time. Furthermore, and importantly, there is no evidence to suggest that administration of these medications will hasten death. Indeed the opposite has been observed with patients living longer periods of time when symptom-driven medications are delivered compared to those without the medications. The reason for this is unsettled but physiologic-based theories have been published. The provider has a duty to address the ethical, legal, and physiologic rationale for medications with patients and caregivers in this situation.

### OVERVIEW OF NONOPIOID AND OPIOID THERAPY IN ADVANCED DISEASE

This section provides a brief overview of commonly used pharmacologic agents available in the United States for the treatment of persistent pain associated with advanced disease. Pain-relieving drugs can be categorized as nonopioid analgesics, opioid analgesics, and adjuvant analgesics. Detailed knowledge of these classes of agents is necessary to provide quality palliative care, and although a comprehensive review is beyond the scope of this chapter, links to more detailed lists of all drugs used for pain control throughout the world can be found in Table 77.2. Of note, newer formulations or delivery systems are coming on to the market regularly. They may have a place in the EOL medication repertoire in the future. For now it is important to recognize that currently none of the new or renovated analgesic agents have been shown to be superior to the medications described in this chapter in the EOL population.

There are several possible methods of approaching pharmacologic pain management for patients with advanced diseases. Patients may require several different medications to deal with a variety of pain syndromes and disease-related discomfort. For expedient and thorough treatment, it is often wise to adopt a stepwise approach to the use of pain medications. The World Health Organization (WHO) has developed a simple three-step model for managing cancer pain that can be applied to many different situations. It has been modified over time to adapt to the evolving fields of pain and palliative medicine (Fig. 77.3). This revised approach recommends that mild pain (1 to 3 on a numeric analog scale) should be treated with nonopioid pain relievers, such as aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs), with or without adjuvant therapy. Higher pain intensities indicate the use of nonopioid analgesics along with opiate derivatives, such as hydrocodone, oxycodone, or tramadol. If pain is not relieved, then titration of opioids, such as morphine, hydromorphone, and fentanyl, in combination with nonopioid analgesics and adjuvants, is indicated. Refractory pain syndromes often require more invasive techniques, such as spinal opioids, nerve block, or neurostimulation.

### NONOPIOID ANALGESICS

#### ACETAMINOPHEN

Acetaminophen has been determined to be one of the safest analgesics for long-term use in the management of mild pain or as a supplement in the management of more intense pain syndromes. It is especially useful in the management of nonspecific musculoskeletal pain or pain associated with osteoarthritis, but it should be considered an adjunct to any chronic pain regimen. It is often forgotten or overlooked when severe pain is being treated in terminally ill patients, but it can be quite effective as a “coanalgesic.” It is important to take into account acetaminophen’s limited anti-inflammatory effect and its hepatic effects. Reduced doses or avoidance of acetaminophen is recommended for patients with renal insufficiency or liver failure, particularly individuals with significant alcohol use. In 2011, one of the manufacturers of acetaminophen announced that the historic 4 grams per day limit placed on it was voluntarily reduced to a lower maximum dose of 3 grams per day for all patients. How this new limit should impact hepatic dysfunction, if at all, is to be determined.

#### NSAIDs

NSAIDs reduce the biosynthesis of prostaglandins by inhibiting cyclooxygenase (COX) and the cascade of inflammatory events that cause, amplify, or maintain nociception. NSAIDs also appear to directly affect the peripheral and central nervous systems. COX has been identified in spinal

**Figure 77.3** Modification of WHO 3-Step Ladder. NSAIDs, nonsteroidal anti-inflammatory drugs. (From Fine PG. The evolving and important role of anesthesiology in palliative care. Anesth Analg. 2005;100:183-188.)
cord neurons and may play a role in the development of neuropathic pain, but these agents do not appear to be useful in the treatment of neuropathic pain. The “classic” NSAIDs (e.g., aspirin or ibuprofen) are relatively nonselective in their inhibitory effects on the enzymes that convert arachidonic acid to prostaglandins, so gastrointestinal ulceration, renal dysfunction, and impaired platelet aggregation are common. The COX-2 selective NSAIDs rofecoxib and valdecoxib have been taken off the market, and because of potential problems and concerns with gastrointestinal bleeding and thrombosis, celecoxib should be used with caution in high-risk palliative care patients for protracted periods.

NSAIDs are useful in treating many pain conditions mediated by inflammation, including those caused by cancer. These agents cause minimal nausea, constipation, sedation, or effects on mental function, although there is evidence that their use can impair short-term memory in older patients. These agents may be very useful for moderate to severe pain control, either alone or as an adjunct to opioid analgesic therapy. Adding NSAIDs to an opioid regimen may allow a reduced opioid dose when sedation, obtundation, confusion, dizziness, or other central nervous system effects of opioid analgesic therapy alone become problematic. Extended-release formulations are likely to increase compliance and adherence. As with acetaminophen, decreased renal function and liver failure are relative contraindications for NSAID use. Platelet dysfunction or other potential bleeding disorders also contraindicate use of the nonselective NSAIDs because of their inhibitory effects on platelet aggregation, a clear advantage of the coxib class of NSAIDs. If NSAIDs are effective but there is need for prolonged use or there is a history of gastrointestinal complications, proton pump inhibitors can be given to lower the risk of gastrointestinal bleeding. For more information on NSAIDs, see Chapter 41.

OPIOID ANALGESICS

Opioid analgesics are the most useful agents for the treatment of pain associated with advanced disease, including neuropathic pain. There are few, if any, indications for the mixed agonist-antagonist agents, especially in older patients at end of life. The pure antagonists are used to treat acute overdose and, in selected cases, to prevent opioid-induced bowel dysfunction. The opioids used most commonly in palliative care are morphine, hydromorphone, fentanyl, oxycodone, and methadone.

The only absolute contraindication to the use of an opioid is a history of a hypersensitivity reaction (e.g., rash, wheezing, and edema). Allergic reactions are almost exclusively limited to the morphine derivatives, and the prevalence of true allergic reactions to synthetic opioids is much lower. There is significant inter- and intra-individual variation in clinical responses to the various opioids, so dose titration is the best approach to initial management. Idiosyncratic responses may require trials of different agents in order to determine the most effective drug and route of delivery for any given patient. Table 77.3 lists more specific suggestions regarding optimal selection of opioids in end-of-life care, and Table 77.4 lists the commonly used opioids.

Opioid analgesics may accumulate toxic metabolites over time, especially when drug clearance and elimination decrease as disease progresses and organ function deteriorates. Use of meperidine is specifically discouraged for repeated dosing over time because of its neurotoxic metabolite, normeperidine. In the United States, propoxyphene has been taken off the market because of the active metabolite norpropoxyphene, its weak analgesic efficacy, and the significant acetaminophen dose found in some formulations. The mixed agonist-antagonist agents— typified by butorphanol, nalbuphine, and pentazocine—are not recommended for the treatment of pain in patients with advanced disease. They have limited efficacy, and their use may cause an acute abstinence syndrome in patients using pure agonist opioids. For further information on opioids and chronic opioid therapy, see Chapters 37 and 38.

MORPHINE, THE PROTOTYPE OPIOID RECEPTOR

Morphine, the prototype agonist, is considered the gold standard of opioid analgesics and is used as a measure for dose equivalence. Although some patients cannot tolerate morphine because of pruritus, headache, dysphoria, or other adverse effects, common initial dosing effects, such as sedation and nausea, often resolve within a few days. It is best to anticipate these adverse effects, especially constipation, nausea, and sedation, and prevent or treat appropriately (see the following discussion). Morphine-3-glucuronide, a metabolite of morphine, may contribute to myoclonus, seizures, and hyperalgesia, particularly when patients cannot clear the metabolite as a result of renal impairment. Side effects and metabolite effects can be differentiated over time. Side effects generally occur soon after the drug is absorbed, whereas metabolite effects are generally delayed by several days. Morphine’s bitter taste may be prohibitive, especially if “immediate-release” tablets are left in the mouth to dissolve. In this case, several options are available. One available type of long-acting morphine comes in a capsule that can be opened, releasing small pellets that can be mixed in applesauce or other soft food. Oral morphine solution can be swallowed, or small volumes (0.5 to 1 mL) of a concentrated solution (e.g., 20 mg/mL) can be placed in the mouth of patients whose voluntary swallowing capabilities are significantly limited.

FENTANYL

Fentanyl is a lipophilic opioid that can be administered several ways including parenterally, spinally, transdermally, and transmucosally. Because of its potency, dosing is usually conducted in micrograms. It should be noted that on July 15, 2005, the FDA issued a public health advisory to alert health care professionals, patients, and their caregivers of reports of death and other serious side effects from overdoses of fentanyl in patients using transdermal fentanyl for pain control. Careful fentanyl dosing is particularly important in older patients; a study of transdermal fentanyl postoperative patients found that absorption was significantly delayed in men 64 to 82 years of age compared with men 25 to 38 years of age.

In consideration of these cautions, transdermal fentanyl, often called the fentanyl patch, is particularly useful when patients cannot swallow, do not remember to take medications, or experience adverse effects from other opioids. Opioid-naive patients should begin with titrated immediate-release opioids to establish the needed 24-hour dose of...

Oxycodone is a synthetic opioid available in a long-acting formulation (OxyContin), as well as immediate-release tablets (alone or with acetaminophen) and liquid. It is approximately as lipid-soluble as morphine but has better oral absorption. Side effects appear to be similar to those experienced with morphine, but one study comparing the two formulations in patients with advanced cancer found that oxycodone was less likely to cause nausea and vomiting.

Methadone has several characteristics that make it useful in the management of severe, chronic pain. Methadone has a half-life of 24 to 36 hours with a much longer terminal half-life, allowing for prolonged dosing intervals. However, the analgesic half-life of methadone is often much shorter. Methadone is an N-methyl-D-aspartate (NMDA) receptor antagonist, which may be of particular benefit in neuropathic pain.

Methadone is much less costly than comparable doses of proprietary continuous-release formulations, making it potentially more available for patients without sufficient financial resources for more expensive drugs.

Despite these advantages, much is unknown about the appropriate dosing ratio between methadone and morphine,

*Dose provides analgesia equivalent to 10 mg of morphine given by IM route. These ratios are useful guides when switching drugs or routes of administration. In clinical practice, the potency of the IM route is considered to be identical to the IV and subcutaneous routes.

†When switching from one opioid to another, incomplete cross-tolerance requires a reduction in the dose of the new drug by 25% to 50% to prevent excessive opioid effects. Provision of “rescue” medication during the conversion period (a few days) prevents breakthrough pain that may result from relative underdosing. When switching to methadone from another drug, the reduction in the equianalgesic dose should be greater, usually 75% to 90%.

‡Extensive survey data suggest that the relative potency ratio of IM to PO morphine, which has been shown to be 1:6 in an acute dosing study, is 1:2 to 1:3 with chronic dosing.

FDA, U.S. Food and Drug Administration; IM, intramuscular; IV, intravenous; NA, not applicable or no data available; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, per mouth; PR, per rectum. Originally published in Fine PG, Portenoy RK. A Clinical Guide to Opioid Analgesia. Minneapolis: McGraw-Hill Healthcare Information; 2004.
as well as the safest and most effective time course for conversion from another opioid to methadone. Current data suggest that the dose ratio increases as the previous dose of oral opioid equivalents increases, and although the long half-life is an advantage, it also increases the potential for drug accumulation prior to achieving steady-state blood levels. There may be a risk of oversedation and respiratory depression after 2 to 5 days of treatment with methadone. Close monitoring of these potentially adverse or even life-threatening effects is required. Data suggest that methadone can lead to life-threatening QT interval prolongation. As a result, patients not in hospice programs, and even selected hospice patients, should have interval QT screening before and during methadone treatment.

Patients currently receiving methadone as part of a maintenance program for addictive disease often develop cross-tolerance to opioids and require higher doses than opioid-naïve patients. Prescribing methadone for addictive disease requires a special license in the United States, so prescriptions for methadone to manage pain in palliative care should specify “for pain.”

HYDROMORPHONE

Hydromorphone is a synthetic opioid that can be a useful alternative to morphine in patients at end of life. It is available in oral tablets, liquids, suppositories, and parenteral formulations, but the only long-acting U.S. formulation was recalled by the FDA because of interactions with alcohol that could lead to excessively rapid drug release. As a synthetic opioid, hydromorphone can be useful if there is inadequate pain control or when patients experience true allergic responses to morphine or intolerable side effects occur. The metabolite hydromorphone-3-glucuronide may lead to the same opioid neurotoxicity seen with morphine metabolites: myoclonus, hyperalgesia, and seizures. This is particularly likely in patients with renal dysfunction.

ROUTES FOR ADMINISTERING OPIOIDS

The oral route is generally preferred when patients are capable and enteral absorption is not problematic. In the palliative care setting, alternative routes of administration must be available for patients who can no longer swallow or when other dynamics preclude the oral route. These include transdermal, transmucosal, rectal, vaginal, topical, epidural, and intrathecal. In a study of cancer patients at 4 weeks, 1 week, and 24 hours before death, more than half of the patients required more than one route of opioid administration. As patients approached death and oral use diminished, the use of intermittent subcutaneous injections and intravenous or subcutaneous infusions increased. Therefore, in caring for patients near the end of life, it is essential to identify alternatives to oral administration that can be used if necessary.

Enteral feeding tubes can be used to access the gut when patients can no longer swallow. The rectum, stoma, or vagina can be used to deliver medication, although fecal contents, mucosal dryness, thrombocytopenia, or painful lesions may preclude the use of these routes. For morphine, commercially prepared suppositories, compounded suppositories, or micro-enemas can be used to deliver the drug directly to the rectum or stoma. Sustained-release morphine tablets have been used rectally, with resultant delayed time to peak plasma level and approximately 90% of the bioavailability achieved by oral administration.

Because the vagina has no sphincter, a tampon covered with a condom or an inflated urinary catheter balloon may be used to prevent early discharge of the drug. Although useful, the rectal or vaginal routes may be unacceptable to many patients and their caregivers, especially when the patient is obtunded or unable to assist.

Parenteral administration in palliative care is usually limited to subcutaneous and intravenous delivery because repeated intramuscular opioid delivery is excessively noxious. The intravenous route provides rapid drug delivery but requires vascular access that may not be easily obtained or maintained in a home or long-term care setting. In the absence of intravenous access, it must be remembered that subcutaneous boluses, although effective, have a slower onset and lower peak effect when compared with intravenous boluses. Subcutaneous infusions as much as 10 mL/hour are usually absorbed, although most patients tolerate 2 to 3 mL/hour with the least difficulty.

Intraspinal routes, including epidural or intrathecal delivery, may allow administration of drugs, such as opioids, local anesthetics, and α-adrenergic agonists. A randomized controlled trial demonstrated benefit for cancer patients experiencing pain. However, the equipment used to deliver these medications is complex, requiring specialized knowledge for health care professionals and potentially greater caregiver burden. Risk of infection and other complications along with up-front and maintenance costs are significant concerns when contemplating high-technology procedures. Selection should be based on greater than 6 months’ life expectancy for implanted programmable pumps, and adequate organizational infrastructure to manage these devices should be in place.

ADJUVANT THERAPIES

The term adjuvant analgesics is often used synonymously with coanalgesics, pain-modifying drugs, and similar descriptors. A wide variety of nonopioid medications from several pharmacologic classes have been demonstrated to reduce pain caused by various pathologic conditions (e.g., tricyclic antidepressants) or modify the ongoing disease process in a way that specifically reduces pain (e.g., bisphosphonates). Under most circumstances these drugs are indicated for the treatment of severe neuropathic pain or bone pain, and opioid analogesics are used concurrently to provide adequate pain relief. Typical adjuvants include tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressants, anticonvulsants, corticosteroids, and other disease-modifying drugs, such as bisphosphonates for metastatic bone pain. See Table 77.5 for a listing of current adjuvant therapies for neuropathic pain. For more information on adjuvant analgesics, see Chapters 39 and 40.

ANTIDEPRESSANTS

The analgesic effect of tricyclic antidepressants appears to be related to inhibition of norepinephrine and serotonin reuptake, making these neurotransmitters more available within
central nervous system pain inhibitory pathways. There are many significant, controlled clinical trials for several pain conditions, and guidelines list tricyclic antidepressants as one of the first-line therapies for neuropathic pain.\textsuperscript{30,123,124} The significant side effects, especially in older patients, require careful titration and monitoring in palliative care populations, but their sleep-enhancing and mood-elevating effects may be beneficial enough to outweigh their disadvantages.\textsuperscript{125} The newer mixed SNRIs—selective serotonin reuptake inhibitors (SSRIs), such as venlafaxine and duloxetine—may offer some of the advantages of tricyclic antidepressants without the anticholinergic side effects.\textsuperscript{126} See Chapter 39 for a more complete discussion of antidepressants.

</table>

**ANTICONVULSANTS**

The older anticonvulsants, such as carbamazepine and clonazepam, putatively relieve pain by blocking sodium channels.\textsuperscript{125} These compounds are very useful in the treatment of certain types of neuropathic pain, especially pain with episodic, lancinating qualities such as trigeminal neuralgia. Gabapentin seems to have several different mechanisms of action, although calcium ion channel blockade is thought to be its main pain-inhibiting mechanism.\textsuperscript{127} The analgesic doses of gabapentin reported to be effective in a typical and common neuropathic pain condition, painful diabetic neuropathy, ranged from 900 mg/day to...
Corticosteroids

Corticosteroids are particularly useful for neuropathic, visceral, and bone pain syndromes in patients with far advanced disease, including plexopathies and pain associated with stretching of the liver capsule as a result of metastases. Dexamethasone produces the least amount of mineralocorticoid effect, making it the least toxic choice. Dexamethasone is available in oral, intravenous, subcutaneous, and epidural formulations. The standard dose is 16 to 24 mg/day and can be administered once daily due to the long half-life of this drug, but divided doses are usually used to mitigate high-dose toxic effects, such as psychosis and severe blood sugar abnormalities in diabetic patients. Doses as high as 100 mg may be given with severe pain crises, similar to the doses used in acute neurologic emergencies. Intravenous bolus doses should be administered over several minutes to reduce untoward reactions, such as burning sensations.

Local Anesthetics

Local anesthetics are useful for relieving neuropathic pain. They can be given orally, topically, intravenously, subcutaneously, or spinally. Mexiletine has been reported to be useful when anticonvulsants and other adjuvant therapies have failed. Doses start at 150 mg/day and increase to levels as high as 900 mg/day in divided doses. Pretreatment electrocardiogram evaluation is recommended to evaluate for conduction blocks that can be exacerbated by oral local anesthetics. Local anesthetic gels and patches have been used to prevent the pain that is associated with needled stick and other minor procedures. Both gel and patch (lidocaine 5% patch) versions of lidocaine have been shown to reduce the pain of PHN. Intravenous lidocaine at 1 to 5 mg/kg (maximum, 500 mg) administered over 1 hour, followed by a continuous infusion of 1 to 2 mg/kg/hour, has been reported to reduce patients’ intractable neuropathic pain in inpatient palliative care and home hospice settings. Epidural or intrathecal lidocaine or bupivacaine delivered with an opioid can reduce neuropathic pain.

Bisphosphonates

Bisphosphonates inhibit osteoclast-mediated bone resorption and alleviate pain related to metastatic bone disease and multiple myeloma, reduce the incidence of pathologic fractures, and are used to treat tumor-related hypercalcemia. In patients with breast cancer and multiple myeloma, zoledronic acid has demonstrated improved safety and efficacy compared with pamidronate. Similarly, there appears to be more sustained pain relief with zoledronic acid compared with other bisphosphonates in patients with metastatic prostate cancer. Clinical trials in patients with lung and renal cell carcinoma have also shown therapeutic benefit from regular infusions of zoledronic acid.

Chemotherapy and Radiation Therapy

Palliative chemotherapy is the use of antitumor therapy to relieve the symptoms that are associated with malignancy. Patient goals, performance status, sensitivity of the tumor, and potential toxicities must be considered. Examples of symptoms that may improve with chemotherapy include relief of chest wall pain from reduced tumor ulceration through the use of hormonal therapy in breast cancer. Some newer agents, such as docetaxel, reduce pain and improve quality of life in hormone-refractory prostate cancer, and topotecan and epidermal growth factor receptor inhibitors accomplish similar results for patients with lung cancers.

Radiation therapy is also a highly useful adjunct to control pain from bone metastasis and pressure-inducing and ulcerative malignancies. Single-fraction and hypofractionated regimens are proving to be effective in very sick patients and those with limited life expectancy in whom the opportunity costs of multiple treatment sessions are untenable. These therapies are often underused in hospice or palliative care, and they should be considered for any patient with a life expectancy of more than a few weeks.

Other Options

Medications typically seen in the setting of the operating room or the intensive care unit can have a role in severe or refractory pain that range from neuropathic pain from chemotherapeutics to opioid-induced hyperalgesia. Examples are ketamine and dexmedetomidine. Ketamine is a potent NMDA-receptor channel blocker available for administration intravenously, subcutaneously, orally in solution, sublingually, and via nasal passages. It has been evaluated for both pain and mood disorders. In these relatively small trials or case series as well as the authors’ experience, it can be extremely useful in select situations. Dexmedetomidine is an alpha-2 adrenergic agonist. The mechanism of action is similar to that of clonidine but it is significantly more alpha specific. The benefit of this drug is that it can produce sedation and analgesia but does not cause respiratory depression. Reports have emerged in using this for refractory pains.

Palliative sedation is a procedure in which medications are used to lower the level of consciousness to limit the awareness of suffering that a patient finds intolerable and intractable. Though it has met resistance in the past, it has been through the scrutiny of both ethicists and judges and has been determined to be an acceptable practice for properly selected patients. A prospective study has demonstrated that patients undergoing palliative sedation experience no life-shortening effect. The procedure should not be done without experience or guidance. The National Hospice and Palliative Care Organization released a position paper on the topic.
Emerging nonpharmacologic therapies should also be watched with interest. One involves use of the MC5-A Calmarare device, also known as Scrambler therapy. This novel machine provides electrocutaneous nerve stimulation for neuromodulation. This attempt to provide cutaneous nerves with “nonpain” information, thus blocking the effect of pain information. The small studies show promise. One of them found that chronic neuropathic pain was more effectively controlled with Scrambler therapy than guideline-based management.154,155

**BEGINNING THERAPY, ADDING OR CHANGING DRUGS, AND BREAKTHROUGH PAIN**

Application of practical and mechanism-based approaches, coupled with context-appropriate follow-up, will optimize drug and other palliative therapies. The “best first choice” and subsequent timing of opioid rotation will depend on patient-specific medical, psychological, and social considerations and a sound knowledge of opioid pharmacotherapy. If adverse effects exceed the analgesic benefit of the drug, conversion to an equianalgesic dose of a different opioid is recommended. Because cross-tolerance is incomplete, it is important to reduce the calculated dose by one third to one half and titrate upward based on the patient’s pain intensity scores.5

Titrating and combining drugs that may provide additive or synergistic effects should proceed along rational lines, based on the pharmacokinetics and monitored pharmacodynamics of the drugs. Frail patients and those with pain crises may require observation in a monitored setting in order to provide safe and effective relief within an acceptable time frame.

Transitory flares of pain, or breakthrough pain, can be expected both at rest and during movement. If breakthrough pain lasts longer than a few minutes, rescue doses of the patient’s current analgesics may provide relief.156 In patients without parenteral access, oral transmucosal fentanyl may be useful for rapid episodic pain relief or during a brief but painful dressing change. Frail older adults or severely debilitated patients should start with the 200-mcg dose and efficacy should be monitored, advancing to higher-dose units as needed.157 Clinicians must be aware that unlike other breakthrough pain drugs, the around-the-clock dose of opioid does not predict the effective dose of oral transmucosal fentanyl. Some pain relief can usually be expected in about 5 to 10 minutes after administration. Patients should use oral transmucosal fentanyl citrate over a period of 15 minutes because more active sucking will result in more swallowing and less transmucosal absorption.

Because misunderstandings lead to undertreatment, all clinicians involved in the care of patients with advanced illness and pain must be able to differentiate and clearly explain to patients and their families the clinical conditions of tolerance, physical dependence, and the rarity of addiction related to opioid use at end of life. It also is critically important to be aware that there is no established relationship between titration of opioid analgesics to affect pain relief and timing of death in palliative care or hospice settings.158,159

**MINIMIZING AND MANAGING ADVERSE EFFECTS**

Drugs for pain can cause a variety of adverse effects for patients in palliative care. The normal side effects associated with pain-relief medications are often exacerbated by changes in metabolism caused by end-stage disease, polypharmacy associated with advanced age, and other factors. Following are some of the more common adverse effects and an overview of possible approaches to preventing or alleviating them.

**CONSTIPATION**

Patients in palliative care frequently experience constipation, in part because of opioid therapy.66 Always begin a prophylactic bowel regimen when commencing opioid analgesic therapy. Avoid bulking agents such as psyllium because these tend to increase desiccation time in the large bowel, and debilitated patients can rarely take in sufficient fluid to facilitate the action of bulking agents. Instead, starting with cost-effective and palatable products, such as senna tea and fruit or senna plus docusate sodium (Colace) for patients with a history of “sluggish” bowel function, is advised. If this is ineffective at creating regular laxation, then prescription therapies are indicated (e.g., bisacodyl, senna derivatives, propylene glycol).65 Tables listing recommended regimens are readily available in clinical guidelines and texts. When traditional regimens have failed to bring about the desired effect, using a peripherally acting mu opioid receptor antagonist such as methylnaltrexone can be useful. This new drug class is a targeted therapy for opioid-induced constipation, and because it does not enter the central nervous system there are no symptoms of opioid withdrawal or increased pain. These have been studied in patients with advanced illness.160,161

**SEDATION**

Excessive sedation may occur with the initial doses of opioids. If sedation persists after 24 to 48 hours and other correctable causes have been identified and treated, psycho- stimulants may be beneficial. These include dextroamphetamine 2.5 to 5 mg by mouth every morning and midday or methylphenidate 5 to 10 mg by mouth every morning and 2.5 to 5 mg midday (although higher doses are frequently used, and use later in the day may be required for wakefulness throughout the evening hours, if desired).5 Adjust both the dose and timing to prevent nocturnal insomnia, and monitor for undesirable psychotomimetic effects (such as agitation, hallucinations, and irritability). Once-daily dosing of modafinil, a newer agent approved to manage narcolepsy, has been reported to relieve opioid-induced sedation.162

**RESPIRATORY DEPRESSION**

Respiratory depression is rarely a clinically significant problem for opioid-tolerant patients who are in pain.63 When respiratory depression occurs in a patient with advanced
disease, the cause is usually multifactorial.\(^{163,164}\) When depressed consciousness occurs along with a respiratory rate less than 8/minute or hypoxemia (\(O_2\) saturation less than 90\%) associated with opioid use, slow, cautious titration of naloxone can be instituted (0.4 mg [one ampule, 400 mcg, diluted in 10 mL injectable saline = 0.4 mcg/mL]) every 3 to 5 minutes while providing respiratory support and supplemental oxygen. This should be done according to the patient’s goals or in conjunction with their surrogate decision maker. Excessive administration may cause abrupt opioid reversal with pain and autonomic crisis.

**NAUSEA AND VOMITING**

Nausea is common and vomiting is an occasional adverse effect associated with opioids as a result of activation of the chemoreceptor trigger zone in the medulla, vestibular sensitivity, and delayed gastric emptying, but habituation occurs in most cases within several days.\(^5\) Assess for other treatable causes. In severe cases or when nausea and vomiting are not self-limited, pharmacotherapy is indicated. Usually, low doses of an \(H_1\) blocker (e.g., diphenhydramine) are all that is required while the patient habituates to this unpleasant side effect. If there is no relief within a few days, metoclopramide or a different opioid is recommended; also consider transdermal rather than enteral therapy.\(^{28,63}\)

**MYOCLONUS**

Myoclonic jerking can occur with high-dose opioid therapy. If myoclonus develops, switch to an alternate opioid, especially if using morphine. Evidence suggests that this symptom is associated with metabolite accumulation, particularly in the face of renal dysfunction.\(^5\) A lower relative dose of the substituted drug may be possible because of incomplete cross-tolerance. Clonazepam 0.5 to 1 mg by mouth every 6 to 8 hours, to be increased as needed and tolerated, may be useful in treating myoclonus in patients who are still alert, able to communicate, and take oral preparations.\(^{165}\) Lorazepam can be given sublingually if the patient is unable to swallow. Otherwise, parenteral administration of diazepam is indicated if symptoms are distressing. Grand mal seizures associated with high-dose parenteral opioid infusions have been reported and may be caused by preservatives in the solution.\(^{166}\) Preservative-free solutions should be used when administering high-dose infusions.

**PRURITUS**

Pruritus can occur with most opioids, although it appears to be most common with morphine. Fentanyl and oxymorphone may be less likely to cause histamine release. Most antipruritus therapies cause sedation, so the patient must see this as an acceptable trade-off. Antihistamines (such as diphenhydramine) are the most common first-line approach to this opioid-induced symptom. Ondansetron and paroxetine have been reported to be effective in relieving opioid-induced pruritus, but no randomized controlled studies exist.\(^{167,168}\)

---

**CASE 77.3 Complex Symptom Management in the Home Setting (continued)**

After examination and consultation, it was determined that Ben could continue to reside in the assisted-living facility, attended to by home-based hospice staff. Treatment proceeded with subcutaneous administration of octreotide and hydromorphone to relieve bowel symptoms and provide analgesia on an as-needed basis. In this way the unpleasantness of nasogastric suctioning, nausea, and vomiting was avoided, and he was able to die in a manner consistent with his preferences.

**CONCLUSION**

Effective pain management in advanced medical illness and at the end of life is a critical component of quality medical care to ensure dignified, safe, and comfortable dying. To quote Sir William Osler, the “father of modern medicine,” “The study of morbid anatomy combined with careful clinical observations has taught us to recognize our limitations and to accept the fact that a disease itself may be incurable and that the best we can do is to relieve symptoms and make the patient comfortable.”

Principles to help improve this important domain of clinical care can be summarized with the following key points regarding pharmacotherapy for the relief of pain in far-advanced illness.

**KEY POINTS**

- Ensure that communications about goals of care and treatment plans among professional caregiving staff and the patient and family members are clear and understood in order to optimize outcomes and minimize potential conflicts.
- Determine the etiology of pain and the social and prognostic circumstances that will affect the pain experience and pain therapy.
- Focus on discernible clinical end points:
  - Pain reduction
  - Functional capacities
  - Mood
  - Sleep
  - Relationships
  - Pleasure in living
- Match the mechanism of pain with the class of drug whenever possible; initiate therapy and adjust dose according to therapeutic response, side effects, and known pharmacokinetics of the drug.
  - Anticipate and monitor for adverse effects.
  - Prevent side effects.
  - Actively treat side effects.
KEY POINTS—cont’d

- Acetaminophen should be the first consideration in the treatment of mild to moderate pain of musculoskeletal origin.
- Use adjunctive drug therapies, especially for neuropathic pain.
- Opioid analgesic drugs are often necessary to relieve moderate to severe pain, and long-acting or sustained-release analgesic preparations should be used for continuous pain.
- Breakthrough pain should be identified and treated by the use of fast-onset, short-acting preparations.
- Last, and perhaps most important, know your limits. When a patient is not responding to therapy, be prepared to consult with someone who has more training, expertise, and experience.

REFERENCES

Pain management in the home is a family experience, as every aspect of care provided to the patient affects the family system as a whole. Successful pain management at home depends on a patient and family who understand and are invested in the pain management regimen and express confidence in implementing the plan as prescribed. This includes understanding the difference between around-the-clock and prn dosing; knowing when to use “rescue” doses; being able to identify and report changes in the pain site, character, and severity; as well as having the ability to recognize and report adverse side effects from the analgesic prescribed and to manage the technical aspects of the pain treatment plan.

Pain associated with cancer must be viewed within a cluster of symptoms that need to be monitored and managed by the family. Pain changes, its assessment and management, are made more complex by the presence of other symptoms, the likelihood that increased pain may be associated with disease progression, and the component of suffering frequently experienced by family caregivers. Various family dynamics also can change the pain experience.

Because of the complexity of cancer pain management, the patient and family can rarely manage pain in the home setting on their own. Rather, they need guidance and support from the oncology team. Effective communication among the primary physician, advanced practice nurse, home care, nurse and family, as well as ready access to the point person among these professionals, is essential for the success of the home care plan. A system of ongoing monitoring and support for the patient and family needs to be in place to ensure the effectiveness of pain relief measures and early identification of caregiver burden and unmet needs. Careful discharge planning followed by regular assessment and reassessment can facilitate effective pain management and support for the patient at home as well as minimize pain “emergencies.”

Chronic pain associated with cancer is an extremely stressful situation for both patient and family. Surveys indicate that pain is experienced by 30% to 60% of cancer patients during active therapy and in more than two thirds of those with advanced disease. In addition, symptom clusters and multiple symptoms tend to be the norm, not the exception, in advanced cancer patients with pain. These patients spend minimal time in the hospital and most of the time in their homes. The experience of chronic pain, therefore, is mainly a home experience, one that involves not only pain but also multiple other symptoms, and one that involves not only the patient but also the patient’s family and friends. Unrelieved pain is incapacitating and undermines quality of life; it interferes with physical functioning and social interaction and is strongly associated with heightened psychological distress. Uncontrolled severe pain, or episodes of excruciating pain in this setting, can lead to a desire for hastened death.

The literature is replete with discussions about the prevalence of pain, its undertreatment, and barriers to adequate pain management. Less attention had been given to factors affecting pain management in the home, although a growing literature explores issues particular to this topic. These issues include knowledge and attitudes about cancer pain and its management among patient and family members, stress in family caregivers and community nurses, management of the technical aspects of pain in the home, and communication. Recognition of the “responsibility without adequate training or power” phenomenon that nurses commonly experience in the home care setting has been an impetus for the development of training programs for home care nurses in pain management. Many families experience the same phenomenon. Family caregivers are expected to play a primary role in cancer pain relief across all stages of the disease and yet are frequently given little or no training on how to do so. Structured pain education programs have been shown to result in positive outcomes for patients and their family caregivers.

Understanding the factors that influence adequacy of pain management in the home has become increasingly important in the face of the current trend toward shorter inpatient hospital stays, earlier hospital discharges, and the expectation that extremely sick patients will be managed at home. This trend is likely to continue in light of health care reform and new systems of care such as the medical home. Family members, with community nursing support, are on the front line of home pain management.
BARRIERS TO PAIN MANAGEMENT IN THE HOME

Generally speaking, the home environment offers substantial benefits to the individual with cancer and pain, but home care also can result in intense burdens for family caregivers resulting in compromised care. Home care is best viewed as a family experience with the recognition that every aspect of care provided to the patient will affect family caregivers. At the same time, barriers have been described that hinder pain management in the home, including patient and family fears of addiction, failure to report pain, and limited access to care.

The intense demands on family caregiving at home, especially in the provision of 24-hour physical care, is well described. Less attention has been placed on the emotional burden to the family of assuming responsibility for the patient’s well-being in the home. In addition, little has been written about the care of cancer patients with pain who are discharged home to a high-risk, drug-abuse environment. Encompassing a relatively small group of individuals, their needs can be great. However, with careful planning and close monitoring, safe pain management at home can be achieved for most people with cancer.

An early small descriptive study (trial of 10), which investigated the experience of managing pain at home from the perspectives of the patient, the primary family caregiver, and the home-care nurse, encapsulated many of the important areas that affect pain management in the home. Areas of decision making and conflict mainly centered around the use of medications. Patients were preoccupied with decisions about which pain medication to take and how much. Negative side effects and meaning in regard to these medications contributed to conflicts in patients’ minds about whether they were doing the “right thing” in taking the pain medication.

Nearly all the patients assumed that their pain would increase with impending death. Patients’ decisions about how to live with the pain included considerations about the impact of their actions and words on family members and health care professionals. Sometimes these factors led the patient to deny the pain. Similarly, the decisions and conflicts that arose most frequently for family caregivers were related to pain medication, making decisions about which pill to give, and when to give the medication. Exacerbating these decisions were concerns related to overdosing, adverse side effects, and addiction. Sometimes the family member admitted to withholding information from the patient or the nurse in an attempt to benefit the patient in some way. For example, depending on the decision-making process of the family member, more or less medication might be given. Other studies conducted on knowledge and beliefs about pain management in cancer patients and their families found that although patients and families share similar beliefs about pain, family members tend to have a higher degree of emotional distress associated with observing pain in their loved ones.

PAIN MEDICATION ADMINISTRATION AND ADHERENCE IN THE HOME

For family caregivers of cancer patients, effective medication management involves a complex set of activities, which include filling the prescription, safely storing the pain medication, organizing and dispensing medication as needed or on a fixed dosing schedule, monitoring effectiveness and adverse events, and communicating about those symptoms with the oncology team.

Nonadherence, defined as the inability of patients to take medications as prescribed, is a major concern in pain management. Nonadherence is usually multifactorial and may lead to undertreatment or even potentially dangerous medication errors. Caregivers’ lack of experience with opioids, fears of addiction, and fears about managing pain medications in the home setting can lead to under-reporting of pain and undermedication. This was the case in a study involving 89 days of oncology inpatients and their primary caregivers. In this study, patient-caregiver ratings of pain were non-congruent, with patients reporting higher pain and poorer performance status levels. The authors concluded that patients were reluctant to report their pain to family members for fear of causing them distress. As a consequence, 45% of family caregivers underestimated their loved ones’ pain, whereas 55% overestimated it. In another study involving caregivers of patients with advanced cancer, caregiver distress led to hypervigilance by caregivers, exaggeration of the patient’s pain experience by caregivers, and over-reporting of the patient’s pain experience. These studies suggest that caregivers’ burden and distress can influence symptom management in patients.

THE ROLE OF CAREGIVERS IN THE ASSESSMENT OF PAIN

Effective pain management is dependent on an accurate assessment. When the patient is being cared for at home, the physician frequently relies on second- or third-hand information supplied by the patient, family, or home care nurse on the severity of the pain, adequacy of relief, presence of side effects, and associated toxicity. Correct interpretation of the patient’s and caregiver’s report of pain is essential. According to Elliot and colleagues and suggested by the preceding studies, three dimensions constitute a patient’s pain experience: cognitive factors (including attitudes, beliefs, and knowledge), sensory or physical input, and affective or emotional experience. Elliot and coworkers found that although patients and families reported parallel perceptions of the patient’s cancer pain, family members consistently assessed the patient’s level of pain somewhat higher than the patient. This suggested to them the effect of observing rather than experiencing the pain. In addition, Ward and colleagues reported that patients with increased concerns were less likely to use analgesics adequately. These studies, as well as others, document that family caregivers are often as affected by pain as the patient, and sometimes more so.

There are important implications here for evaluating the efficacy of a pain management strategy, if the assessment is largely dependent on a family member’s report. The report of poorly controlled pain may indicate the family member’s distress as well as that of the patient. Areas of family distress include fatigue, lack of knowledge about pain management, concern about addiction, concern about harming the patient, and an
An overwhelming feeling of responsibility to the patient and distress must be addressed if pain is to be adequately managed. There is a close relationship between the two.

In a comprehensive review of 129 quantitative research studies on family caregivers and palliative care in the home setting, family caregivers reported providing extensive help to dying relatives in the areas of medication and symptom management. Other studies have reported an inverse relationship between the health and function of the cancer patient and the amount of caregiver burden with caregiver strain, depression, and anxiety reaching its peak as the patient enters the terminal phase.

In another comprehensive review of more than 100 qualitative studies on family caregiving at home at the end of life, the general consensus across studies was that caregivers reported a lack of preparation, knowledge, and skills in symptom, pain, and medication management, especially with the technical aspects of medication administration. Recommendations included teaching family caregivers about the practical aspects of care at the end of life and making sure caregivers were routinely provided with general information about the nature and course of the patient’s disease. Yet caregiving is not uniform and the needs of caregivers of cancer patients are neither identical nor static. Caregiver burden and comfort with home pain management regimens must be assessed and reassessed over time.

A national survey of 1677 family caregivers, including caregivers of cancer patients, documented the complexity of medical management in the home setting. More than 90% of caregivers ordered, picked up, and paid for the patient’s medication. Caregivers dispensed pills, prepared pillboxes, or gave medication in the form of injections, inhalers, eye and eardrops, and infusion pumps. Although caregivers found medication-related tasks to be inconvenient, repetitive, and time consuming, fewer than half had received counseling or training in the area of medication management.

The difficulties that patients and family caregivers commonly encounter when trying to put a pain management regimen into place at home are summarized in Box 78.1. They illustrate that patients and family caregivers need ongoing support and help with problem solving in order to optimize their pain management regimen. Most caregivers rely on nurses for information related to medications.

In addition to the numerous and sometimes overwhelming responsibilities related to the pharmacologic management of pain in the home, patients and family caregivers use many nondrug strategies for pain relief. Although some of these techniques are taught in the hospital setting, they are seldom reinforced by the medical team once the patient is discharged home. Nondrug interventions include both physical and cognitive approaches. Physical approaches include interventions such as heat, cold, and massage. Cognitive strategies include a variety of relaxation techniques, imagery, meditation, and prayer. These nondrug strategies, especially those that are a “fit” with the patient’s values and belief system, can be enormously helpful in not only enhancing pain relief but also in helping the individual to regain a sense of control.

Hospitalization and discharge episodes are notorious for interrupting the pain regimens of cancer patients as a new treatment team is involved or as new medications are added or withdrawn in light of new medical conditions or side effects. Common to all groups, however, is the need for basic education on cancer pain management with the individualized home pain management regimen clearly written out in a language that the patient and family can understand; a pain management plan that is financially feasible for the patient; verification that prescribed analgesics are available in the community; confirmation that the patient and family are secure with the discharge and follow-up plans; and assurance that the patient is not discharged (if at all possible) within 24 hours of a change in opioid drug or route of administration (Box 78.2).

To facilitate discharge planning for patients with cancer-related pain and ease the transition from hospital to home, it is useful to classify patients into different groups, depending on specific needs and risk factors (Table 78.1). This is important because discharge-planning needs and home care needs are specific to each group.

Group 1 comprises patients who have stable pain, and are, for example, using an oral, transmucosal, rectal, or transdermal route of opioid administration. These patients may or may not be pursuing a course of curative or life-prolonging therapy. The patient is usually followed on an outpatient basis with ongoing prescriptions written by the primary physician or nurse practitioner. The patient is instructed to contact the primary physician or nurse practitioner for any change in the quality, severity, or site of the pain and the

occurrence of adverse side effects. Prior to the patient’s discharge home, it is important that the community pharmacy be contacted to make sure that it has the necessary opioid in stock or is willing to obtain it. It is good practice for the physician or pain management nurse to initiate contact with the patient within the first week of discharge to confirm that pain is adequately controlled and that the patient and family feel confident with the pain management approach. This initial telephone contact also confirms that pain management is a priority and the patient’s pain will continue to be monitored closely with resources readily available even though care is now on an ambulatory basis. The cost of medication on an outpatient basis can be a significant barrier for patients without a prescription plan. The ability of a patient to both pay for and obtain the outpatient analgesic prescription must be established prior to discharge home. Often the patient does not volunteer this information unless specifically asked for it. The social worker can be very helpful in this area. Several pharmaceutical companies have specific patient “hardship” programs. A social worker can again be very helpful in evaluating a patient’s eligibility for these programs and accessing these resources.

If a patient’s pain escalates once at home, it is crucial to explore with the patient or family caregiver whether the pain medication is being taken as prescribed. It is not unusual that a pain management regimen is not adhered to once an individual goes home, for the variety of reasons described earlier. The reasons for nonadherence need to be discussed in an open and frank manner. Tailoring a pain management regimen that fits in with the patient’s and family caregiver’s values, goals, and capabilities is essential if symptoms are to be controlled at home.

Group 2 consists of patients who require a parenteral route of drug administration to control their pain. Although the majority of patients do well on the oral or transdermal route of opioid administration, some will require ongoing administration through a parenteral route. The most common indications for a parenteral infusion in the cancer population are bowel obstruction or malabsorption, severe stomatitis, intractable nausea and vomiting, and dysphagia. A parenteral opioid infusion also is considered for patients with rapidly escalating and unstable pain or those with frequent and severe episodes of breakthrough pain. In these situations, the use of patient-controlled analgesia in combination with the continuous parenteral infusion helps ensure more effective pain relief. Finally, an opioid parenteral infusion may be considered if the oral route produces severe gastrointestinal side effects. Similar to the patients in group 1, these patients may or may not be pursuing a

course of curative or life-prolonging therapy. They are not imminently dying and do not meet hospice criteria for long-term follow-up. Discharge planning is more complex than for those in group 1 and requires a team approach, with good communication between the hospital and the community. In some institutions, a specific discharge planner, usually a nurse, plays an important role in organizing the home care plan once the needs have been identified by the team. The discharge planner facilitates referral to home care agencies (e.g., a home infusion company) and is able to identify insurance constraints or availability of drug constraints so that alternative avenues may be sought to provide the patient and family with the care that they need.

It is rarely feasible to maintain peripheral intravenous access for continuous infusion in the home. Continuous infusions are usually only considered in patients who have an indwelling central venous port or other long-term central venous device. Placement of one of these devices is occasionally necessary prior to the patient’s discharge home in order to accommodate a large volume of fluid—for example, in the case of a fentanyl infusion. In most cases, however, a continuous subcutaneous infusion can accomplish the goals of therapy without the need for intravenous access.

The degree of support that is needed to maintain a parenteral infusion at home varies widely, depending on the patient and family characteristics. Specific educational issues need to be addressed with all patients and caregivers. These include knowledge of drug effects and side effects; the use of rescue doses; operation of the infusion device, specifically turning the pump on and off and changing the battery; and knowledge of how to change the cassette or infusion bag. A minority of patients/families never achieve a comfort level in changing the infusion cassette or bag. In those instances, the infusion home care nurse will usually make the necessary changes. It is mandatory that all patients and their families who are receiving a parenteral infusion at home have a 24-hour resource person available to them to troubleshoot the system (Box 78.3). The most common error encountered in a continuous infusion at home using a computerized pump is incorrect programming—for example, failure to reprogram the pump when the concentration of the opioid in the cassette or bag is changed. This leads to an inadvertent overdosing or underdosing of the patient. Such errors can be largely circumvented through the use of a flowchart kept in the patient’s home. Errors will be picked up rapidly if the patient is being adequately monitored. The first sign of an incorrectly programmed pump might be increasing pain or the occurrence of side effects such as increasing sedation or nausea and vomiting.

The cost of a parenteral opioid home infusion may be high. It includes rental of the pump, involvement of a home infusion agency including pharmacy overheads, delivery of the premixed medication to the home, and availability of home infusion nurses on a 24-hour basis. However, the cost of poorly controlled pain is even higher in both human terms and from the need to rehospitalize the patient for uncontrolled pain. Medicare, Medicaid, and most private insurances cover the cost of home infusion pain management, as long as there is a clearly documented indication for such an approach. For Medicare and Medicaid patients, if an opioid other than morphine is being used, a letter is usually needed to explain why the alternative opioid has been chosen. The specific insurance requirements regarding drug specificity must be clarified prior to the patient’s discharge.

Group 3 includes patients who are imminently dying and want to go home. Patients in this group may or may not require a parenteral route of drug administration to control their pain. Systems are in place, however, to manage even the most complex patients at home if the family is strongly committed to this end. Various models are in place to facilitate good pain control. Regardless of which model is selected as the optimal mechanism for the delivery of home pain management at the end of life, the common theme for all models is one of an interdisciplinary team approach to care, with the patient and family at the center of such care.

Family caregivers play a major role in home-based palliative care and hospice programs. Generally speaking, higher symptom burden for patients is associated with higher caregiver burden, but most cancer patients opt for care at home during this end stage of life. Anxiety related to ineffective symptom control and fear of administering medication are frequently reported by caregivers across many palliative home care studies, suggesting that education, skill building, and ongoing support for caregivers are essential components of home cancer care and pain management.

Hospice care, the most widely available model of home care for the dying, focuses on optimizing quality of life in those not seeking, and unlikely to benefit from, life-sustaining treatment. Hospice programs are run by both profit and not-for-profit organizations and have become part of the standard of care offered to patients nearing the end of life. Eligibility requirements for enrollment in a hospice program include a life expectancy of 6 months or less. A major advantage for patients and families followed in a hospice home care program is regular home visits by the hospice nurse and 24-hour emergency support from skilled hospice nurses with backup from the hospice medical staff. In addition, the cost of all medication related to the terminal illness is included in the hospice benefit without additional charge to the patient. Because of the variety of hospice models, levels of sophistication, and depth of services offered, the needs of the patient and the services offered through the program should be evaluated before referral. For example, although

5. Evaluate other drugs being used.
most hospice programs have changed their policy toward the use of technology in end-of-life care, in contrast to an earlier “no high-tech” approach, severe restrictions on the financial reimbursement for programs may limit their ability to deliver care to patients requiring the parenteral route of opioid infusion to manage their pain. The physician who refers the dying patient to hospice care can remain as actively involved in the patient’s ongoing pain management as he or she chooses to be. In some instances, the referring physician remains the patient’s primary physician and works with the hospice team in titrating the opioids to ensure comfort. In other instances, the referring physician asks the hospice physician to assume that role.

Group 4 consists of patients with chronic cancer-related pain who are going home to an environment where it is suspected that drug diversion may occur. The patients themselves or their families may or may not have a history of illicit drug use. In general, patients with a history of drug abuse are at risk for having their pain undertreated.82,83 Three subgroups of patients can be identified: (1) patients who are actively using street drugs, (2) patients who are in methadone maintenance programs, and (3) patients who have not used illicit drugs for many years.82

Patients in the first subgroup strain the resources of even the most sophisticated home management pain team and require strict monitoring during opioid therapy. It must be recognized that these patients, like any other patients, may experience severe pain associated with their cancer but will probably require larger doses of opioids to control the pain because of the development of tolerance. One physician or advanced practice nurse should be identified as the point person to adjust analgesics and write all prescriptions, and one nurse should be identified as the person to organize and coordinate the patient’s plan of care.84 If the patient is on an oral drug regimen, it may be necessary to give only a 1-week supply of the opioid at a time. Giving a larger amount at one time invariably results in the patient “running out of the drug” regardless of the amount given. Psychiatric symptoms and comorbidities such as anxiety, depression, and bipolar disorders are frequently seen in this population and need to be addressed.82,84 A team approach is essential in the care of these patients. If the patient is in a methadone maintenance program, it is important that the program is contacted for assistance in planning the patient’s overall care.

For some patients being discharged home into a drug-abuse or chaotic environment, the use of an oral route of opioid administration is not feasible because of constant drug loss. Occasionally these patients are placed on a parenteral route of opioid administration to ensure adequate pain control and safety, maintain tighter control on the amount of drug used, and minimize the risk of drug diversion. In these situations, no extra opioid cassettes or infusion bags are left in the home and neither the patient nor family is taught how to change the infusion cassette. The home infusion nurse performs bag or cassette changes. In addition, in some situations, cassettes and not bags are used for the infusion, as there is less risk of “siphoning off” the medication. Personal experience using this approach with several patients has been extraordinarily successful. The patient’s pain has been controlled and unaccounted for drug usage kept to a minimum. Patients also appear to appreciate the considerable amount of attention they receive. It is, however, time intensive and requires close coordination and communication among the prescribing physician or advanced practice nurse, the home infusion pharmacist, and the home infusion nurse.

Group 5 includes patients with cancer and pain who are unable to be cared for at home and are to be discharged to an extended-care facility. These facilities are rarely able to accommodate a patient whose pain requires a parenteral route of opioid administration. These patients are frequently elderly, debilitated, and receiving polypharmacy for chronic medical conditions. They are at high risk for inadequate pain assessment and consequent undermedication for pain.85 In addition, the elderly and debilitated patient’s therapeutic margin may be narrow, and the patient may be at increased risk for developing troublesome side effects including sedation and confusion.86 Close monitoring is required, with careful dose titration and adjustment based on ongoing assessment. This requires training, skill, and an institutional system in place that screens for the presence of pain and adequacy of relief on a regularly scheduled basis. Until recently, the staff in long-term care facilities had little training in pain management and end-of-life care. This training is still limited, although the Joint Commission on Accreditation of Healthcare Organizations standards has made such training mandatory.87

In the current situation, it is essential that verbal communication be established between the physician/advanced practice nurse or pain management nurse from the discharging institution and the physician and nursing supervisor from the extended-care facility. This communication should take place prior to the patient’s discharge to the facility. The two teams can then work together to ensure adequate pain relief for the patient. Some long-term care facilities have established contracts with community hospice programs and have developed palliative care approaches to the care of their residents. As this is still not the norm, the selection of a long-term care facility for someone with cancer and pain must be done with great care.

Group 6 is made up of cancer survivors with chronic pain related to their cancer treatment. With advances in cancer therapy, increasing numbers of patients are being cured of their cancer or living with cancer as a chronic disease. A proportion of this population will develop a pain syndrome and neuropathies as a consequence of the cancer itself or its treatment. Sometimes these conditions resolve over time but irreversible damage to tissue and nerves may have occurred and the pain syndrome becomes chronic.88

Neuropathic pain syndromes associated with neurotoxic chemotherapies, surgery such as a mastectomy or thoracotomy, lymph node dissections, and radiation therapy have long been recognized as chronic pain syndromes in cancer survivors. Pain associated with osteoporosis and vertebral fractures, a direct effect of treatment in breast and prostate cancer, or long-term steroid use in brain tumor patients, has more recently been recognized as a significant problem for cancer survivors. Alerting cancer survivors to the possibility that pain can persist following cancer treatment increases the likelihood that such ongoing pain will be reported and addressed.23 Overall, pain in cancer survivors is probably under-reported and undertreated. Concerns about addiction may be raised for clinicians as well as the patients or their families.
Group 7 consists of older adults with pain. Pain assessment and management at home presents unique challenges in this group. Older patients frequently under-report their pain. They may have concurrent medical illnesses as well as a variety of painful musculoskeletal disorders unrelated to cancer or its treatment. In addition, older individuals have a higher incidence of cognitive impairment, hearing and visual deficits, and medication side effects than those in younger age groups. This complicates pain management.

Because older adults may have hearing and visual deficits and take longer to process information than younger patients, enough time must be built into the system to allow for effective communication. Speech should be clear and unhurried, words and questions should be rephrased to be sure that they are understood, and the patient should be allowed plenty of time to ask and respond to questions. These same principles apply for the medically frail or terminally ill and are outlined in Box 78.4.

### Box 78.4  Home Care Challenges When Managing Pain in Older Adults or the Medically Frail

1. Multiple concurrent medical problems
2. Multiple symptoms
3. Multiple medications and forgetting which to use for which symptom
4. Cognitive impairment including poor memory (confused by instructions, forget what they have been told)
5. Sensory loss including vision and hearing (cannot hear instructions or read them)
6. Under-report pain (fear of hospitalization, taking medications, and being a “complainer”)
7. Fearful of using opioids (side effects, addiction)
8. Feelings of being overwhelmed, powerless, demoralized, and hopeless when given information they cannot understand
9. Depression
10. Partner may be an older adult and infirm too
11. Money worries

In preparing patients with chronic pain and their family members to go home, the focus should be on security, clarification of the pain management plan, and communication. It is essential that the patient and family are given specific, detailed, written instructions, in layman’s language, of the pain management approach to be used, both pharmacologic and nonpharmacologic. The principle underpinning the pain management approach, that analgesics should be used to prevent pain rather than having to be “earned” through experiencing severe pain, is underscored. This principle encompasses addressing the concerns surrounding the prevalence of addiction when opioids are used to manage pain and the clinical significance of tolerance (e.g., that the opioids may no longer be effective if they are used early on in a disease process). In addition, safety issues surrounding opioids in the home need to be reviewed. These include that the opioids be kept in a safe place out of the reach of children; that unused opioids be flushed down the toilet or returned to the prescribing institution for disposal; that if parenteral opioids are used, a syringe and needle disposal kit be obtained; and that needles and syringes, however well wrapped, should not be disposed of in household garbage containers.

### COMMUNICATION: THE CORNERSTONE OF GOOD PAIN MANAGEMENT IN THE HOME

The patient and family must have no ambiguity as to whom to call on a 24-hour basis if pain is not well controlled or if the patient experiences troublesome side effects. Tools of communication are reinforced, which include keeping a daily diary to record pain level (using a numeric estimate [e.g., a 0-10 scale] or a categorical scale [e.g., none, slight, moderate, severe]), medication taken, other pain-relieving strategies used, extent and duration of pain relief, activity level, and interference with quality of life. Keeping a pain diary has been found to heighten patient and caregiver awareness of the pattern of pain, guide pain management behaviors, enhance a sense of control, and facilitate communication. To ensure that the pain management plan instituted in the hospital can be maintained at home, a series of steps can be taken. First, if home care nursing has been instituted, the home care nurse should be contacted to discuss the pain management plan. Second, the community pharmacy should be contacted to ensure that it has the prescribed opioids in stock, or if not, is willing to obtain the medication. In addition, it should be established specifically when the drugs will be available in the home pharmacy so that the patient is not left uncovered. In the event that the local pharmacy neither has nor can obtain the prescribed opioid, an alternative source for the patient must be located prior to discharge from the hospital. Third, the physician or nurse practitioner who will be responsible for writing the opioid prescriptions and titrating the drug must be clearly identified. Fourth, the family should be instructed to establish a routine where the amount of medication remaining is checked on a scheduled basis so that the medication does
not “run out” (the Friday night and holiday syndrome). Some families find it helpful to keep a 1-week supply of the medication to the side, and when they need to go into that supply, it reminds them to call their prescribing clinician for a new prescription. These simple steps can help ease the transition from hospital to home for the patient with chronic pain and the family.\(^48\) Factors that place cancer patients at risk for poorly controlled pain in the home are reflected in Box 78.5.

### COMMUNICATION TOOLS FOR MONITORING PATIENTS WITH PAIN AT HOME

The use of the telephone is an important aspect of monitoring and managing pain on an outpatient basis.\(^{93,94}\) In addition, it makes expert resources available to communities where this might not otherwise be the case. Continuity of care also can be fostered through 24-hour telephone availability of a pain management expert (usually an advanced practice nurse) to the patients, their families, and community professionals. Telemonitoring has been widely used in a variety of chronic diseases. For the cancer patient with chronic pain, a telemonitoring system may be a useful tool to reinforce patient and family teaching around medication use and nonpharmacologic approaches to pain control. The system is reasonably inexpensive and can be used through a television or computer screen. As computers have become more commonplace in the home, the use of websites, e-mail, and computer programs to reinforce patient and family teaching and to document changes in the management approach is becoming more commonplace.

### SUMMARY

Although the basic principles of pain management are the same whether the patient is being cared for in an acute care setting, at home, or in a long-term care facility, there is a major shift in responsibility for day-to-day pain management when the patient is to be cared for at home. What was primarily the responsibility of the nurse/physician team in the inpatient setting becomes the responsibility of the patient and family. Pain management in the home becomes a family experience, as every aspect of care provided to the patient affects the family system as a whole.

Successful pain management at home depends on an informed and confident patient and family with collaboration and effective communication among the physician or advanced practice nurse, home care nurse, and patient and family. Most important, a system of ongoing monitoring and support for the patient and family must be in place to ensure the effectiveness of pain relief measures and early identification of undue stress on the part of the family. Careful discharge planning helps facilitate appropriate pain management and support for the patient at home and for the family caregivers.

### KEY POINTS

- There is a major shift in responsibility for day-to-day pain management when a patient is to be cared for at home.
- What was primarily the responsibility of the nurse/physician team becomes the responsibility of the patient and family.
- Pain management in the home is a family experience.
KEY POINTS—cont’d

• When the patient is seriously ill, frail, or an older adult, assessment and management of pain become more complex. Multiple symptoms and polypharmacy become the norm.
• A family is expected to keep track of and administer multiple medications frequently with minimal training, which may lead to an overwhelmed family, nonadherence to a pain management plan, and poorly controlled pain.
• Comprehensive patient and family assessment helps identify factors that make the patient at risk for having poorly controlled pain in the home setting.
• Tailoring a pain management regimen that fits the patient’s and family caregiver’s values, goals, and capabilities is important if pain control is to be maintained in the home.
• Family and patient education in pain and symptom management as well as ongoing support from competent pain practitioners are essential.
• Clear, straightforward communication, both verbal and in writing, is a critical component of this education and support.
• Continuity of care can be fostered through the 24-hour telephone availability of a pain management expert to the patients, their families, and community professionals.

REFERENCES

Several federal agencies have acknowledged and set goals toward eliminating racial and ethnic disparities in health (and health care) and promoting health equity.\(^1\) The literature discussing health and health care inequities based on social determinants (e.g., age, race, gender, class) has mostly failed to address the quality of pain care or the impact that pain has on overall health and well-being.\(^4\) However, the health and health care disparity literature has often focused on diseases frequently associated with pain, such as cardiovascular disease, cancer, diabetes, osteoarthritis, and obesity.\(^4,10,11\) Unfortunately, pain has been viewed as a symptom and not a disease, even when it persists and has long-term physical (e.g., disability) and emotional (e.g., depression) health implications. In fact, a report of the Institute of Medicine (IOM), Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care, devoted only a few pages to analgesic care for acute and cancer pain, although pain has important and unique health considerations and socioeconomic implications.\(^12,13\) The lack of attention to pain in general and to disparate pain care in particular is also missing from other well-publicized public health agendas designed to improve the nation’s colloquial health-related quality of life.\(^14\) Fortunately, the IOM’s recent report Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research acknowledges pain’s unique implications, as well as disparate care, while including important policy recommendations.\(^15\)

Race, gender, and age-related health disparities impair public health and are national problems.\(^6,16,18\) An emerging literature has begun to highlight differences in pain perception, as well as disparities in pain care, in racial and ethnic minorities for all types of pain and across all settings.\(^19,20\) Consistent with the social justice literature, in which pain relief is acknowledged to be a fundamental human rights issue, this chapter provides a platform to discuss the impact of pain, pain assessment, and management as a unique and significant public health problem.\(^51,25\)

**IMPACT OF PAIN ON OVERALL HEALTH AND WELL-BEING**

Pain is defined by the International Association for the Study of Pain (IASP) as an unpleasant sensory and emotional experience associated with actual or potential tissue damage.\(^27\) Pain can further be defined by its cause or duration in terms of acute pain (i.e., pain that is short-lived, usually lasting less than 3 months), cancer-related pain (i.e., pain caused by cancer or its treatment), chronic benign or nonmalignant pain (i.e., pain persisting for longer than 6 months that is not due to cancer), or some combination (e.g., cancer-related chronic pain).\(^10,27\) Aging and increased survival from cancer, diabetes, and trauma have yielded an increase in pain complaints.\(^28\) Regardless of the etiology, pain diminishes overall physical, social, and emotional health.\(^29,30\)

The IOM estimates that more than 100 million Americans live with chronic pain.\(^15\) The increasing prevalence of pain has significant socioeconomic and health ramifications for the individual and progressively impairs collective health in the United States.\(^13,31,33\) The third largest global health problem, pain causes significant psychological, physical, and social perturbations that result in needless suffering and subsequent disability.\(^12,24,32,34-37\) Yet pain is a neglected topic in medicine that leads to concomitant depression, anxiety, post-traumatic stress disorder (PTSD), sleep disturbance, fatigue, and decreased overall physical functioning.\(^28,33,38,39\) Living with pain may also cause an individual to withdraw from societal roles, thereby leading to impaired family, community, and career relationships, and diminish health and quality of life.\(^29,34,40-43\) With these facts in mind, the World Health Organization (WHO) joined the IASP and the European Federation of IASP Chapters to host the first Global Day Against Pain in 2004 to document the tremendous disease burden associated with acute, chronic, and cancer-related pain.\(^44\) The literature suggests that racial and ethnic minorities are disproportionately affected by pain.

**THE COST OF PAIN**

Currently, pain complaints are the most frequent cause of disability in the United States and lead to more than 700 million lost workdays. The second leading cause of all U.S. physician visits, pain complaints account for more than $500 billion in annual health care expenditures.\(^45-47\) Americans also spend an additional $40 billion per year on chronic
pain. Older adults use more health care resources (e.g., prescription pain medications, procedures) than younger adults do. The prevalence of chronic pain will increase as the U.S. population ages, especially among baby boomers (i.e., those born between 1946 and 1964). Nearly 50% of older Americans live with pain, and racial and ethnic minorities are at increased risk for suboptimal care regardless of age and type of pain. By 2030 there will be an estimated 71.5 million people older than 65 years and 137 million individuals of racial and ethnic minorities in the United States. More specifically, by 2030 the number of hip and knee replacements is expected to grow by 154% (572,000 procedures) and by 673% (5.48 million procedures), respectively. Without improvements in the quality and availability of care, pain will have devastating socioeconomic and health ramifications for an increasingly aging society. Unfortunately, the medical advantages yielding increased longevity for most white Americans have not been uniformly applied to all Americans. For example, racial and ethnic minorities experience many chronic illnesses (e.g., diabetes, cancer) associated with aging and report pain at an earlier age than whites do.

Both positive and negative life experiences have an impact on health and pain. Chronic pain often coexists with other medical conditions associated with aging (e.g., sleep problems, arthritis, Parkinson’s disease, and depression), thereby further impairing health. The literature focusing on the intersection between race, gender, and aging has primarily dealt with younger adults and white women; the findings from these studies are not readily generalizable to large and growing population groups such as older racial and ethnic minority women. A key concept common to large and growing population groups such as older racial and ethnic minorities is increased longevity for most white Americans have not been uniformly applied to all Americans. For example, racial and ethnic minorities experience many chronic illnesses (e.g., diabetes, cancer) associated with aging and report pain at an earlier age than whites do.

Despite scientific advances and the ability to alleviate suffering, pain and health disparities remain critical public health issues. However, the science of health disparities with respect to pain is in its infancy. In 1998 the National Institutes of Health (NIH) held a symposium on pain in older (29% of whom consisted of racial and ethnic minorities and 59% were women). By 2030, 20% of the U.S. population will be 65 years or older (50% of the total projected to be members of racial and ethnic minorities and >60% of the total to be women). The 2008 NIH exploratory workshop on pain in the elderly acknowledged the importance of social determinants, but data on race, ethnicity, and gender differences were not provided. New knowledge aimed at clarifying the health domains affected and potential racial and ethnic differences at the individual and group level is essential for health care planning. Consistent with the health disparity literature, older adults, racial and ethnic minorities, women, and impoverished individuals (especially low-income racial and ethnic minority women) may be particularly vulnerable to chronic pain’s negative sequelae, but few prospective and longitudinal studies have examined pain’s impact on vulnerable and underserved populations.

In a retrospective study of 7000 black and white Americans with chronic pain seen at a tertiary care pain center, important differences were found in health based on race and ethnicity. Overall, African Americans reported significantly more comorbid conditions, higher pain scores, increased pain severity, more suffering, and less pain control than did white Americans across the age continuum. Black Americans also reported increased physical disability in activities of daily living as a result of pain (e.g., sexual activity, self-care, occupation, family life) and more problems with falling and staying asleep. The mental health of black Americans living with chronic pain was also more negatively affected than that of whites living with chronic pain. Although both black and white Americans met the criteria for clinical depression, black Americans (regardless of age and gender) were significantly more depressed and reported more symptoms consistent with PTSD and anxiety across the age continuum regardless of gender. It is unclear whether these findings reflect undertreatment, over-reporting of differences in pain sensitivity, or some combination of both. Racial and ethnic minorities are frequently more reluctant than white Americans to seek treatment of mental health disorders, and such disorders are often poorly addressed, misdiagnosed, and inadequately treated when they do seek care. Nonetheless, it is well documented that most individuals with depression go without treatment. Thus, it follows that pain and its negative sequelae are more likely to decrease the overall health and well-being of racial and ethnic minorities than that of white Americans.

**HEALTH DISPARITIES AND PAIN**

An individual’s response to pain is influenced by complex interactions between biologic, physiologic, emotional, social, and cultural factors. Differences in pain learning, culturally imposed factors, pain care attitudes and beliefs, comorbid conditions, coping styles, and social roles (i.e., career, community, and family responsibilities) may work cooperatively and competitively to influence the pain experience. These differences may predispose some toward multiple actions that maximize rather than minimize threats...
to bodily integrity and thereby amplify or exacerbate chronic pain. People with similar disease activity report differences in pain intensity and its impact. Experimental models have shown wide variability in response to a painful stimulus. Race, ethnicity, gender, disease, age, culture, socioeconomic status (SES), past experiences, response bias, and the experimental setting influence pain measurement, coping, health, and the pain response. However, the clinical relevance of experimentally induced pain and how sociodemographic factors influence clinical pain syndromes remain unknown.

Folkman and colleagues described coping as “a person’s cognitive and behavioral efforts to manage the internal and external demands of the person-environment transaction appraised as taxing or exceeding their resources.” Maladaptive coping styles (e.g., catastrophizing, repression) and poor adjustment (e.g., poor information seeking, passivity) influence the response to pain. Passive coping and catastrophizing are detrimental to successfully coping with a pain problem. Social support also has a significant role in coping with many chronic conditions and plays an important role in pain management. Well-validated models support the role of pain-related fear and postulate behavioral responses (e.g., confrontation, avoidance) that ultimately determine outcome. Most models propose that people in pain become enmeshed in a downward spiral of increased fear, avoidance, anxiety, depression, disability, and pain. When there is no pain-related fear and rapid confrontation, an adaptive response yielding recovery and better functioning occurs. Unfortunately, most coping illness models were tested on primarily homogeneous white and younger adult populations and did not consider social roles. Thus, these models are not generalizable to growing populations, which is a critical limitation in an aging and diversifying society.

Differences in coping have been identified. Several studies have revealed that blacks with chronic pain report more suffering from the pain than do whites regardless of age or gender. Blacks tend to use religious coping (e.g., church participation), wishful thinking, and social support systems when dealing with stress more than whites do. They often describe stoicism and believe that pain is inevitable but fear reporting their pain because family and friends may not understand. Associations between John Henryism (i.e., actively coping with stressors by working increasingly harder against potentially insurmountable obstacles) and higher blood pressure, hypertension, and bodily pain were described in a general population of older blacks. In view of the high prevalence of hypertension in racial and ethnic minorities, further investigations are necessary to see whether John Henryism is actually detrimental or helpful to racial and ethnic minorities with chronic pain. Green and associates showed that blacks with chronic pain tend to believe more so than whites that race and ethnicity affect the health care and pain care that they receive. Black patients also tend to believe that good patients avoid talking about pain and that pain medications cannot really control pain.

SES also influences pain. Living in a resource-poor neighborhood was found to affect older blacks more than older whites, thus confirming that neighborhood resources contribute to the negative consequences of chronic pain. A study comparing younger black and white Americans reported that increasing neighborhood resources is associated with decreased negative chronic pain outcomes. In other studies, racial and ethnic minorities, low-income individuals, and older adults were found to face structural barriers to obtaining prescription analgesics in their local pharmacies even when their pain was assessed and treated. Comorbid diseases commonly associated with pain (e.g., cancer) also influence health and well-being more frequently in blacks than in whites. Differences in coping styles, health status, health service access and use, social roles, sociodemographic characteristics, and stressors may also predispose some individuals to an adaptive or ineffective response to pain. Thus, race, ethnicity, SES, neighborhood resources, and comorbid conditions are important considerations when examining the impact of pain on health and health care.
PATIENT VARIABILITY

Intra-race variability in pain complaints has been observed. Younger blacks reported higher pain intensity and depression than older blacks did.89 When comparing health status and pain treatment perceptions in older adults, blacks were significantly younger; reported more bodily pain, poorer health, and more problems with social functioning; and had greater role limitations because of emotional problems than white Americans did.89,92 After controlling for age, marital status, education, and pain duration in younger women with chronic pain, black women were found to have greater pain intensity, depression, disability, and PTSD symptoms than did white women.182 Another study identified three clusters of patients with chronic pain within age, race, and gender groups: (1) chronic pain syndrome, (2) good pain control, and (3) disability with a mild pain syndrome.130 Blacks and younger adults were more likely to have chronic pain syndrome.130 Blacks with “chronic pain syndrome” or disability with mild pain syndrome reported higher disability than did their counterparts.130 Older patients and women in the good pain control group reported lower levels of pain and depression, whereas those with “disability with mild pain syndrome” had lower pain and depression.182 Thus, the response to chronic pain varies according to race, gender, and age.130

Race and ethnicity influence pain management–seeking behavior, but the mechanisms remain unclear. What is clear is that the pain complaints of racial and ethnic minorities, older adults, impoverished people, and women are often not treated the same as the pain complaints of white men, who receive better-quality care.103,183,184 Patient behavior, how patients communicate (e.g., language barriers), physician-patient communication, and stereotyping can complicate assessment.185-191 Communication differences increase the likelihood of pain complaints being discounted. In addition, most measures used to assess pain lacked cultural and linguistic sensitivity and were not validated in racially and ethnically diverse populations, thus contributing to the persistence of disturbing racial and ethnic disparities in health and pain care.192-196

CLINICIAN VARIABILITY IN PAIN MANAGEMENT DECISION MAKING

Although pain complaints are very common, they are often poorly managed. Patients report that their pain complaints are frequently unheard and undertreated by physicians.115,167,169 In addition, clinicians report that they are not knowledgeable or satisfied with the pain care that they provide.35,57,160 Given these considerations, it is surprising that pain education remains a neglected topic in most medical, nursing, dental, and pharmacy school curricula, a shortcoming that further contributes to poor pain care.123,197-201 A study of practicing Michigan physicians revealed that nearly 30% reported that they had not received any medical school, residency, or continuing medical education specifically directed at managing pain.57 Thus, physicians and other health care providers are ill equipped to assess and treat pain. Consequently, it is not surprising that most clinicians express low satisfaction, confidence, and goals when treating pain while also prescribing better treatment (e.g., referral to specialist) for men than for women, even when women had similar or more pain than men did.55-57,89,202 In addition, health care system factors, trust, legal factors, and health care provider decision making influence pain assessment regardless of guidelines designed to ensure adequate pain care.

The worker’s compensation literature also provides evidence of disparate pain care.153,205 Blacks were twice as likely to be disabled 6 months following an occupational back injury, and blacks without legal representation received less treatment and lower disability ratings than did whites without legal representation.204,205 Overall, Tait and Chibnall found that race and SES disparities are present in the worker’s compensation system, with black men receiving less compensation than white men for similar injuries.203

The quality of physician-prescribed pain care also varies with respect to race, ethnicity, and gender for similar pain problems.19,93,185,206-209 In a retrospective study of emergency care, a twofold difference in receiving analgesics based on
The cancer pain literature shows health care and cancer care disparities, with blacks suffering more severe cancer-related pain, inaccurate pain assessment, and inadequate pain treatment in comparison to whites. The cancer survivor literature reveals similar results, with women having higher rates of pain and blacks suffering greater interference. Multiple factors influence the disparities in cancer care: (1) environmental variables (e.g., segregation, exposure to toxins), (2) patient sociodemographic factors and differences in pain sensitivity (e.g., health behavior, beliefs, attitudes, and coping strategies), (3) health care provider factors (e.g., pain knowledge and education, cultural competence, language barriers, stereotypes, and bias), and (4) health care system variables (e.g., health insurance, access to care). It follows that these factors may play a significant role in disparities in pain care.

Racial and ethnic minority cancer patients were prescribed less potent analgesics and were significantly undertreated with respect to the WHO recommendations for managing cancer pain. Those treated at university centers or centers primarily caring for racial and ethnic minorities were more likely to receive inadequate analgesia than were whites treated elsewhere and in the community. Other studies have shown that physicians underestimate pain severity in Hispanic and black patients.

For instance, Bernabei and coworkers showed that black nursing home residents were less likely to have their pain assessed; if their pain was assessed, they still received less pain medication than white residents did. Although 40% of blacks with cancer pain reported daily pain, 25% received no analgesics whatsoever. Green and colleagues recently revealed shortcomings in assessing and treating breakthrough pain (pain flares interrupting well-controlled baseline pain) in advanced cancer, with women and racial and ethnic minorities reporting increased pain and worse health.

Green and associates showed that chronic pain was poorly assessed and treated, with blacks and women being adversely affected. Suboptimal pain care in all clinical settings combined with clinician variability in pain management decision making complicates pain therapy in racial and ethnic minorities and women. A Michigan study revealed that 20% of cancer survivors experienced cancer-related chronic pain, with women and blacks disproportionately affected. Green and Ndoo-Brumblay also showed that blacks used less complementary and alternative medicine techniques (including acupuncture) and significantly less manipulation, biofeedback, or relaxation training than did whites for chronic pain. Thus, poor pain assessment, inadequate pain treatment, and decreased ability to obtain pain medications (even when prescribed) complicate appropriate and quality pain management of racial and ethnic minority persons, thereby impairing their overall health and well-being. In general, these studies illustrate that racial and ethnic minorities and low-income people experience more disease burden, receive less pain relief, and are less likely than whites to be adequately assessed for all types of pain and in all settings.

Racial and ethnic minorities face additional barriers to adequate pain management. In two pharmacy studies, those located in minority neighborhoods were less likely to carry opioid analgesics than were those in nonminority neighborhoods. After accounting for zip code median income and stratifying by income, Green and coworkers found structural barriers for racial and ethnic minorities, low-income whites, and older adults, who experienced increased difficulty getting their opioid analgesic prescriptions filled in their local pharmacies across Michigan. Surprisingly, low-income whites had better access to opioid analgesics than did high-income racial and ethnic minorities. Thus, clinician perceptions and goals may lead to the undertreatment of pain (especially in racial and ethnic minorities).

**CRITICAL QUESTIONS AND NEW DIRECTIONS**

The potential implications of poorly treated pain are devastating for the individual, and the cost to society is staggering. Pain profoundly affects morbidity, mortality, quality of life, and health care expenditures. Therefore, ensuring optimal pain management is critically important from a public health perspective. Both patient and physician variability in attitudes and beliefs contributes to suboptimal pain care (with racial and ethnic minorities, low-income people, older adults, and women receiving lower-quality pain care). Pain’s impact and prevalence will increase as Americans live longer and have a profound effect on morbidity and health care expenditures. Assessment remains the cornerstone of quality pain care.

Despite chronic pain’s individual and socioeconomic impact, documented benefits in optimizing pain care, therapeutic advances currently available to treat chronic pain, and guidelines for managing pain, physicians and other health care providers are ill equipped to assess and treat chronic pain. There are also important questions regarding estimates of the amount of pain (severity) and its correlates (physical, emotional, and social burden) in different groups, the extent of poorly assessed and treated pain, planning for the amount of health care required, improving pain care delivery, and differences and variability in quality and the way that health services are provided based on social determinants.

There is evidence that all types of pain have unique health implications in racial and ethnic minorities that are often unrecognized or overlooked. No longitudinal and prospective studies have examined the long-term effects of pain on overall health and well-being in an ethnically diverse population. In addition to race and ethnicity, other social determinants may make certain racial and ethnic minorities more vulnerable to pain. Thus, racial and ethnic minority individuals who are elderly, impoverished, or women are extremely vulnerable to the distressing effects of pain. Culturally and linguistically appropriate interventions must be developed to ensure quality pain assessment and management so that racial and ethnic disparities in pain care can be eliminated. The role of clinician and patient-provider variability in pain management decision making, as well as health insurance, health care system, and regulatory factors, must be examined. By improving pain care for the most underserved and

---

*56,57,89,116,119,121,123,144,229-232*
vulnerable populations in our society, it will be improved for all. In a climate of increasing patient safety concerns, inadequate pain assessment and treatment must be viewed as a quality-of-care issue. Beyond being a quality issue, inequitable pain care based on sociodemographic characteristics is fundamentally a social justice issue. There is a critical need for increased awareness, advocacy, and health care and pain care policy to rectify these ills. Also needed are physician, health care provider, and health system leadership and interventions that ensure (1) access to quality and equitable patient-centered primary care and multidisciplinary pain care that is culturally and linguistically sensitive; (2) the ability to optimize pain assessment and the comorbid conditions often associated with pain by increasing pain education for both patients and clinicians; (3) comprehensive and multidisciplinary approaches, evidence-based guidelines, and research and policy initiatives; and (4) establishment of mechanisms to ensure access to the resources needed to prevent and manage pain at the neighborhood level.

KEY POINTS

- More than 100 million Americans live with chronic pain, and racial and ethnic minorities and women are disproportionately affected.
- Both positive and negative life experiences have an impact on pain and contribute to differences in the pain experience in racial and ethnic minorities, women, older adults, and impoverished persons.
- By 2030, 20% of the U.S. population will be 65 years or older (50% of the total projected to be members of racial and ethnic minorities and >60% of the total to be women).
- Racial and ethnic minorities have decreased access to pain care, are at risk for suboptimal pain assessment and management, and have adverse health outcomes.
- Race and ethnicity, socioeconomic status, gender, and age also influence the quality of pain care, use of health services, clinician decision making, and health outcomes.
- Both patient intra- and inter-race variability and clinician variability contribute to disparities in health and pain care.

REFERENCES

It is traditionally held that the first comparative clinical trial was performed in 1747 by Dr. James Lind (1716-1794) of the British Royal Navy to identify a treatment for scurvy. Lind evenly assigned 12 scurvy-afflicted sailors aboard the HMS Salisbury to receive cider, vitriol (a weak acid), vinegar, seawater, oranges and lemons, or nutmeg paste. After 6 days, only the two sailors who had received oranges and lemons (and thus adequate amounts of vitamin C) had sufficiently recovered to return to duty. Two centuries later, the advent of the pharmaceutical industry and the evolution of methodological concepts led to the first controlled clinical trial in which patients were randomly assigned to different treatments. Performed in 1947-1948, it observed the effects of streptomycin on pulmonary tuberculosis to be significantly better than those of a placebo.2

EVIDENCE-BASED MEDICINE

In contrast, common acceptance of the merit of individual medical or surgical practice—the proverbial “in my experience” (N of one), “in case after case, I have seen” (N of two), and “in my series” (N of three)—evidence-based medicine (EBM) acknowledges that simple intuition, unsystematic clinical experience, and a pathophysiologic rationale are inadequate bases for clinical decision making.3 EBM stresses the critical examination of evidence from clinical research. EBM likewise offers a formal set of steps to complement medical training and “common sense” for clinicians to effectively interpret the results of clinical research (“how to read a paper”) and apply them in their practice (Box 80.1). Last, EBM places a lower value on expert authority than the traditional medical paradigm.4

Many systems for grading the level or quality of evidence and the strength of recommendations have been created. Unfortunately, guideline developers around the world are inconsistent in how they rate quality of evidence and grade strength of recommendations—resulting in confusion among guideline users.5 Although the Grading of Recommendations Assessment, Development and Evaluation (GRADE) Working Group is not without limitations,6 it defines and clearly delineates all of the major domains that affect the reliability of research evidence, including the quantity, quality, consistency, and types of studies of the published evidence, resulting in one of three grades of evidence (high, moderate, or low). GRADE also assigns a rating for strength of evidence of strong or weak, based on the estimate of net benefit relative to harms and other factors, including the quality of evidence, importance of patient preferences and values, as well as costs and burdens. Each recommendation is thus assigned one of six possible grades, based on the strength of the recommendation and the quality of evidence (Table 80.1). Many groups—including the Cochrane Collaboration, the American College of Physicians (ACP), the American College of Chest Physicians (ACCP), the U.S. Agency for Healthcare Research and Quality (AHRQ), the UK National Institute for Health and Clinical Excellence (NICE), and the World Health Organization (WHO)—have adopted GRADE.

Since the term was coined about 30 years ago,2 evidence-based medicine (EBM) has progressed from a novel concept to a buzzword to a mantra.7 Along these lines, it has been observed: “Clinical decisions should, as far as possible, be evidence based. So runs the current clinical dogma. We are urged to lump all the relevant randomised controlled trials into one giant meta-analysis and come out with a combined odds ratio for all decisions.”8 EBM is thus often misconstrued as being only about randomized clinical trials, when it has actually evolved, along with the efforts of GRADE, specifically to take into account evidence from observational studies.

THE SPECTRUM OF OUTCOMES RESEARCH

The appraisal of a new or existing treatment modality—including for pain management—involves three steps (Fig. 80.1).9-11 First, the efficacy, or whether a treatment achieves its intended clinical benefits (“Can it work?”), is demonstrated under “optimal” circumstances in highly controlled settings with carefully selected patients, typically in a randomized controlled trial. Subsequently, the effectiveness, or whether these benefits are also seen under more ordinary or “naturalistic” circumstances, is assessed (“Does it work?”), often by way of an analytic cohort study, though randomized controlled trials can also be designed to evaluate effectiveness. The efficiency or cost-effectiveness (the health status improvement realized for a given amount of resources expended) is sometimes determined via a health care economic evaluation (“Is it worth it?”). An economic evaluation can also provide crucial insight into the value of providing a health care intervention to a specific population.12

Importantly, in order for an intervention to be cost-effective, it must first be shown to be effective. For example, routine imaging for low back pain in the absence of red flags
is associated with no benefit in pain or function compared to usual care without routine imaging. Therefore, even though lumbar x-rays are relatively inexpensive, routine imaging with them cannot be cost-effective. On the other hand, interventions associated with relatively high upfront costs can still be cost-effective if the clinical benefits are substantial or the upfront costs are offset by decreased downstream costs. For example, some studies suggest that spinal cord stimulators for failed back surgery syndrome may be a cost-effective treatment compared to medical management, though others suggest that the high upfront costs may not be offset by lower costs of subsequent care.

EXPERIMENTAL VERSUS OBSERVATIONAL STUDY DESIGNS

Many clinician scientists (not to mention journal editors and reviewers) have viewed the randomized controlled trial as the de facto gold standard of clinical trial design for evaluating the efficacy and safety of a treatment or intervention. However, although a well-conducted randomized trial is generally more valid than other study designs for providing valid (true) results, there are a number of other study designs, which may on a situational basis be more appropriate to apply in conducting human research. For example, for evaluating harms, it may be unethical to randomize patients, or for rare or long-term harms, adequately powered randomized trials may not be feasible.

The array of quantitative study designs are classified as experimental or observational, with observational studies being further divided into descriptive and analytic categories (Fig. 80.2). Observational studies can complement findings from often smaller-scale randomized controlled trials by assessing treatment effectiveness in patients in more realistic day-to-day clinical practice. However, it is important to note that a randomized trial is not necessarily an efficacy study, nor is an observational study necessarily an effectiveness study. Rather, the methods used to ensure that a study evaluates more representative populations, interventions, and comparisons; evaluates patient-centered outcomes; and is conducted in settings typically encountered in clinical practice are what determine whether a study is an efficacy or effectiveness study.

RANDOMIZED CONTROLLED TRIAL

In contrast to observational studies, in which the allocation of interventions is outside of the control of the researchers, clinical trials are a type of experimental study in which the interventions are allocated by the researchers. A controlled

RCTs, randomized controlled trials.
A randomized controlled trial (RCT) on the other hand, is a type of controlled clinical trial predicated on participants being assigned to the possible exposures or interventions purely by the play of chance (“flip of a coin”). When successfully implemented, random allocation produces two or more treatment groups that are free of selection and confounding bias—by both known and unknown factors. When those involved in an RCT are blinded (masked) as to the intervention each participant receives, treatment and assessment bias are also reduced. Thus, when properly designed and performed, an RCT has internal validity: it accurately and reliably measures what it is intended to measure—that is, the relative benefits and harms of two or more interventions. When sample sizes are determined based on an appropriate power analysis, an RCT can efficiently detect small to moderate group outcome differences with the minimum sample size, which exposes the least number of study subjects to the risks of treatment and nontreatment.

A cluster randomized trial (CRT) is a trial in which individuals are randomized in groups—the group as a whole is randomized and not the individual. Physicians, group practices, health plans, or even geographic regions (counties or states) can be defined as clusters. In a CRT, all individuals within a given cluster are assigned to the same study arm. The methodology of cluster randomized trials has been widely discussed. In evaluating a therapy, unlike a standard RCT, a CRT typically focuses on effectiveness by evaluating outcomes under conditions of actual use. A CRT is often done when individual randomization is not feasible. For example, if a clinician is implementing a new low back pain evaluation and treatment study protocol, it would be difficult to randomize some patients in a clinic to one protocol and other patients to another protocol, because there is too much shared knowledge of the different protocols and overlap in clinic personnel. The CRT can also offer considerable cost and time efficiencies when implemented by a health insurance plan that has extensive existing information about its members and their treatments and outcomes, along with an existing research infrastructure. However, compared with individually randomized trials, cluster randomized trials are more complex to design, require more participants to...
obtain equivalent statistical power, and require more complex analysis (e.g., adjustment for the intracluster correlation coefficient of the cluster randomization).\textsuperscript{42-44} A CRT is also typically not blinded. Thus, not surprisingly, the use of this trial design has been fraught with challenges, undermining the validity of some published findings.\textsuperscript{43,45}

For example, a cluster randomized clinical trial investigated the effect of an evidence-based psychosocial educational program (PSEP) on low back pain (LBP) beliefs for 3792 soldiers completing military training.\textsuperscript{46} The military training environment requires living in close quarters with other members of the military unit (company), thus making individual randomization unfeasible. A cluster randomization strategy was thus used for assigning entire companies of soldiers to receive or not receive the PSEP. This meant that for a given company, every soldier who consented to the study received either the PSEP or no education (the control group). The primary outcome measure was the back beliefs questionnaire (BBQ), which assesses the inevitable consequences of and ability to cope with LBP. Compared to baseline, at 12 weeks follow-up, soldiers who received the PSEP had an improvement in their BBQ scores ($P < 0.0001$). Unfortunately, the cluster correlation coefficient was not reported. In addition, it was not possible to blind soldiers to the educational intervention received, though analyses suggested that differences in attrition across groups had little effect on the conclusions.

**CROSS-SECTIONAL STUDY**

A cross-sectional study determines the prevalence (i.e., the existing presence) of a disease at a given point or period in time. If its sample is randomly chosen, such a frequency survey provides a valid snapshot of the characteristics of the source population. It thus can provide an estimate of the magnitude of a problem and thus the significance and rationale for further investigation. A cross-sectional study cannot assess possible causality between a predictor variable (e.g., gender and socioeconomic status) and an outcome variable (e.g., pain intensity). Although a cross-sectional study also cannot assess the comparative outcomes (benefits and risks) of an intervention, the findings of a cross-sectional study can generate hypotheses for further studies.\textsuperscript{26,30,47,48}

For instance, a cross-sectional study was conducted in a nationally representative sample of 27,035 United States (U.S.) adults to estimate the point prevalence of chronic pain and to describe sociodemographic and other characteristics of chronic pain.\textsuperscript{49} The results of this cross-sectional, Internet-based survey revealed a considerable burden of chronic pain among U.S. adults. Although experienced by 31\% of overall respondents, chronic pain was more common with lower socioeconomic status and in females than males. Primary chronic pain was most commonly attributed to lower back pain, followed by osteoarthritis pain.\textsuperscript{49}

**CASE-CONTROL STUDY**

A case-control study is aimed at determining the relationship between a single outcome (disease) and one or more previous possible contributing factors (exposures). Case-control studies look or work backward, starting with the identified outcome or disease (exposures $\rightarrow$ disease). Case-control studies are retrospective, relying on existing data or recall of exposures, and therefore are generally less time consuming and less costly to perform than studies using a prospective design. This study design is particularly suited to outcomes that are rare or have a protracted onset. Cases are subjects with the outcome of interest, whereas controls are subjects without the outcome of interest. It is crucial that the controls be drawn from the same source population (study base) as the cases, such that the controls are comparable to the cases in all important respects except for the outcome of interest.\textsuperscript{30} Controls thus must also be chosen independent of their exposure status. Primary validity threats with a case-control study include selection bias (noncomparable controls without the disease) and recall bias (differential recollection about exposure among cases with the disease). Overmatching can also occur if the cases and controls are matched on a variable that is also associated with the exposure of interest. If one thus matches on a factor that is both affected by exposure and a cause of disease, this will obscure a disease association.\textsuperscript{51} There is no denominator in a case-control study, so an event rate, relative risk, or risk ratio cannot be calculated. Instead an odds ratio (the ratio of the odds of exposure in the cases and the odds of exposure in the controls) is conventionally generated as the measure of association between the exposure and the disease in a case-control study. When the outcomes occur at an infrequent rate, the odds ratio should approximate the relative risk.\textsuperscript{26,30,52}

The potential adverse effect of various nonsteroidal anti-inflammatory drugs (NSAIDs) on patient outcome, in particular acute myocardial infarction (AMI), has been a major clinical concern, with a number of published observational studies.\textsuperscript{53,54} For example, a case-control study was performed to assess the relative risk of AMI among users of celecoxib and rofecoxib in Medicare beneficiaries 65 years of age or older.\textsuperscript{55} Each of the 10,895 identified cases of AMI was matched to four controls on the basis of age, gender, and the month of index date. Current use of rofecoxib was associated with an elevated relative risk of AMI when compared with celecoxib, with an odds ratio (OR) of 1.24 (95\% confidence interval [CI]: 1.05 to 1.46; $P = 0.011$). Dosages of rofecoxib of greater than 25 mg were associated with a higher risk (OR of 1.70; 95\% CI, 1.07 to 2.71; $P = 0.026$) than dosages of 25 mg or less (OR of 1.21; 95\% CI, 1.01 to 1.44; $P = 0.036$). Interestingly, the risk of AMI with rofecoxib was elevated in the first 90 days of use but not thereafter.\textsuperscript{55} Of note, because this study used state-level administrative claims data on all beneficiaries over a 3-year period and applied a broad set of inclusion criteria, recall bias and selection bias were minimized. However, as addressed by its authors, there may have been misclassification of end point of AMI in the Medicare data set, though such misclassification tends to bias toward the null. As with all retrospective observational studies, the results may have been biased by confounding factors not observable or incompletely assessed in the Medicare data set.\textsuperscript{55}

**COHORT STUDY**

A cohort study is aimed at determining the relationship between a single contributing factor (exposure) and one or more possible outcomes (diseases). Cohort studies look or work forward, starting with the identified exposure
samples from the same study base.62 If all data are collected case-control study: that cases and controls represent random makes it easier to satisfy the fundamental assumption of the (new event) rate, relative risk, and relative risk ratio.26-30,58 The cohort study allows for direct estimation of an incidence rare outcomes (diseases) and those with a protracted onset. and costly than other observational studies, especially for stroke.59 During the longitudinal follow-up of 35,056 ran-
determine whether self-reported chronic headache predicts
1.76 (1.26-2.47) at 1-year and 5-year follow-up. No significant
\[1.14 (95\% CI: 1.00 to 1.30, P = 0.05)\]

An illustrative observational cohort study was undertaken to determine whether self-reported chronic headache predicts stroke.59 During the longitudinal follow-up of 35,056 randomly selected Finnish men and women, aged 25 to 64 years at baseline, a total 2167 incident (new) stroke events were recorded. After adjusting for age, smoking, serum cholesterol level, systolic blood pressure, diabetes, and body mass index, among men, the headache-associated hazard ratios (95\% confidence intervals) for stroke were 3.92 (2.01-7.66) and 1.76 (1.26-2.47) at 1-year and 5-year follow-up. No significant association was observed between headache and the risk of stroke among women.60 However, the observed gender-associated difference in stroke risk may have been due to a higher prevalence and a more heterogeneous etiology of headache in women (with their more common migraine and muscular tension headache) compared with men (with their more common vascular or of other intracranial origin). This likely reduced the sensitivity of detecting an association between headache and the risk of stroke among women.59

NESTED CASE-CONTROL STUDY

A nested case-control study is a case-control study in which the cases and controls are selected from members of an existing longitudinal cohort.60 The members of the base cohort are followed for a certain period of time until the specific outcome or end point occurs.28,61 The nested case-control design differs from the non-nested case-control design in that patients are selected from a well-defined cohort, for which data on all members can be obtained.62 This design makes it easier to satisfy the fundamental assumption of the case-control study: that cases and controls represent random samples from the same study base.62 If all data are collected prospectively before the outcome occurs, a nested case-control study is also unlikely to be impacted by recall bias.27

As noted earlier, the association between patient NSAID use and cardiac complications has been the focus of a number of published observational studies.53,54 In another example, data from a large health maintenance organization were used to assemble a cohort of all patients age 18 to 84 years treated with an NSAID over a 3-year period, within which a nested case-control study was performed.59 Each of 8143 identified cases of serious coronary heart disease (acute myocardial infarction and sudden cardiac death) was matched with four controls from the study base based on age, sex, and health plan region. The adjusted odds ratio for rofecoxib (all doses) versus celecoxib was 1.59 (95\% CI: 1.10 to 2.32, \(P = 0.015\)), and for naproxen versus remote NSAID use, the adjusted odds ratio was 1.14 (95\% CI: 1.00 to 1.30, \(P = 0.05\)).63

HEALTH CARE ECONOMIC EVALUATION

Health care economic evaluation has matured considerably since the 1980s. However, despite its widespread promotion to this audience, many physicians and researchers remain reluctant to apply economic evaluation methods in their clinical decision making and clinical trials—including for chronic pain treatment modalities.64,65 Much of this reluctance has been attributed to physicians and their innate propensity to think more in terms of clinical effectiveness and advocacy at the individual patient level rather than about cost-effectiveness at the population or policy level.15,66

Furthermore, as witnessed by the intense United States health care reform debate, there is a strong unwillingness among Americans and hence their elected officials to consider whether an intervention may be cost-effective—often because of fears of government-mandated rationing of care and geriatric discrimination. A provision of the American Recovery and Reinvestment Act (ARRA) of 2009 created and funded the Patient-Centered Outcomes Research Institute (PCORI) to undertake rigorous comparative effectiveness research. The Patient Protection and Affordable Care Act (PPACA) of 2010 in turn specifically prohibited PCORI from undertaking any comparative cost-effective analyses using cost per quality-adjusted life year (QALY) as a common metric.67,68 Nevertheless, given the aging U.S. population, the associated increasing health care utilization but decreasing active workforce, and the unsustainably growing percentage of the United States gross domestic product (GDP) devoted to health care, there is a clear and imminent need for valid health care economic evaluation data to establish health care funding priorities—including for chronic pain treatment modalities.15,70

Efforts to provide optimal care, while controlling unnecessary or wasteful health care expenditures, should focus on delivering “high-value, cost-conscious health care.”71 Whether an intervention provides such high value depends on assessing whether its health benefits justify its costs. There are three key concepts for understanding how to assess the value of health care interventions. First, assessing the benefits, harms, and costs of an intervention is essential to understand whether it provides good value. Second,
assessing the cost of an intervention should include not only the cost of the intervention itself but also any downstream costs that occur because the intervention was performed. Third, the incremental cost-effectiveness ratio estimates the additional cost required to obtain additional health benefits and provides a key measure of the value of a health care intervention. In the United States, most decision makers conclude that interventions that cost less than $50,000 to $60,000 per quality-adjusted life year (QALY) gained is highly cost-effective.71 The point at which an intervention is not cost-effective varies, though many decision makers would consider up to US$100,000 per QALY gained as reasonably cost-effective.

Full health care economic evaluation techniques conventionally include cost-minimization analysis, cost-benefit analysis, cost-effectiveness analysis, and cost-utility analysis.65,72-75 A cost-utility analysis is a cost-effectiveness analysis that measures outcomes using quality-adjusted life years or another similar measure. Such full economic evaluations require that two or more therapeutic interventions be compared in relation to both costs and effects.72,76 The six fundamental steps in undertaking a full economic evaluation include (1) identifying the perspective of the study, (2) identifying the alternatives that will be compared, (3) identifying the relevant costs and effects, (4) determining how to collect the cost and effect data, (5) determining how to perform calculation for cost and effects data, and (6) determining the manner in which to depict the results, draw comparisons, and make conclusions.72,76,77

With proper planning, a health care economic evaluation can be validly performed and reported alongside a clinical randomized controlled trial.15,78-82 However, given the logistical challenges of such a joint study,83 researchers often combine previously published cost and clinical outcome data to create a decision-analysis model.15,84 The validity of such studies depends on how well the model reflects the key clinical issues and on the reliability of the parameters used to estimate costs, outcomes, and utilities. Sensitivity analyses are therefore critical for understanding how conclusions might change depending on variability or uncertainty in key parameters.

Given its high prevalence and high associated direct and indirect medical costs, the cost-effective management of migraine headache has received considerable attention.85 For example, applying decision-analysis modeling demonstrated greater cost-effectiveness of rizatriptan and sumatriptan compared to a combination of ergotamine tartrate plus caffeine in the abortive treatment of an acute migraine attack. The net annual cost savings associated with use of rizatriptan and sumatriptan was US$622.98 per patient, with an incremental QALY of 0.001, meaning that the two triptans dominated ergotamine bolus caffeine (lower costs plus greater utility). The findings were not sensitive to changes in key variables such as efficacy, utility, drug costs, hospitalization cost, and patient preference over alternative therapies.86 In a comparison of five treatments for acute migraine prophylaxis (amitriptyline 75 mg/day, topiramate 100 and 200 mg/day, timolol 20 mg/day, divalproex sodium 1000 mg/day, or propranolol 160 mg/day), a Markov decision-analysis model, with Monte Carlo simulation, indicated that among these preventive medications, probabilistic sensitivity analysis suggested that when the societal willingness to pay is less than US$18,000 per QALY gained, amitriptyline is the most likely cost-effective option.87

### Standards for Reporting Study Design and Findings

In 1858, Pasteur introduced the methods section of the scientific report, creating what is now known as the IMRAD format (introduction, materials and methods, results, and discussion).88,89 Not surprisingly, in the interim heady 150 years, as investigators have applied these various basic study designs, there has been wide variability in their application as well as the content and organization of their published reports. In response, standards for reporting of study design and findings have been promulgated—several of which are applicable to acute and chronic pain management (Table 80.2).

*The main CONSORT Statement is based on the “standard” two-group parallel design. However, there are several types of randomized trials, some of which have different designs (e.g., cluster, noninferiority and equivalence, or pragmatic trials), interventions (e.g., herbal medicinal, nonpharmacologic, or acupuncture), and data (e.g., harms), for which specific CONSORT extensions exist.
The EQUATOR (enhancing the quality of and transparency of health research) network has been created to monitor and propagate the proper use of these guidelines90 and thus "to improve the quality of scientific publications by promoting transparent and accurate reporting of health research."91 Furthermore, an increasing number of major (high-impact) clinical and health care journals require or recommend adherence to the applicable set of such guidelines for submitted manuscripts.

**STANDARDIZATION OF PAIN-RELATED OUTCOME MEASURES**

Regardless of the study design used, pain-related research should assess and report outcomes that are valid, reproducible, and clinically meaningful to patients. Unfortunately, even though measures such as joint range of motion, dynamometer measures of muscle strength, or imaging evidence of successful spinal fusion are often seen as objective, pain is an inherently subjective outcome and correlates only modestly with such measures. Fortunately, research shows that pain can be measured in a valid and reproducible fashion, using measures such as numeric rating or visual analog scales. However, although pain may reflect a patient’s subjective experience, it is insufficient by itself, as self-reported pain often does not correlate well with actual ability to function. Therefore, it is important for studies of pain to go beyond self-reports of pain and to also routinely examine outcomes that measure patients’ behavior and function in their daily lives.

Since its inception in 2002, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) has enlisted a broad array of experts in its efforts to improve the design, execution, and interpretation of clinical trials of treatments for pain.101 IMMPACT has developed a series of consensus reviews and recommendations regarding trials for chronic pain in adults, trials for acute pain in adults, and trials for pediatric acute and chronic pain.102-106 IMMPACT recommends that trials routinely measure outcomes in multiple core domains—including pain, physical functioning, emotional functioning, global improvement, satisfaction with treatment, and adverse events—and includes a list of suggested measurement tools for each of these domains.

**DISTINGUISHING BETWEEN STATISTICAL AND CLINICAL SIGNIFICANCE**

A key concept when interpreting the results of clinical research is that statistically significant results are not always clinically meaningful.110 For example, with a large enough sample size, a study may report a difference in pain scores between the treatment and no treatment groups of an average of 3 points on a 0 to 100 scale, with a $P$ value of 0.01. Although such a difference is statistically significant, the clinical significance is very small or trivial. Another challenge in interpreting results of studies that report mean or differences in outcomes related to pain or function is that such data do not indicate whether they reflect a situation in which some patients generally experienced a small, similar average result.

The minimal clinically important difference (MCID) is defined as the smallest change in an outcome that a patient would perceive as clinically meaningful.112 The IMMPACT group proposed defining the MCID as a 30% or greater improvement in self-reported pain and function. The IMMPACT group also recommended that studies report the proportion of patients in each group who meet the MCID threshold. Based on the absolute difference between groups in the proportion of patients who experienced the MCID, the number needed to treat to achieve one clinically meaningful outcome can be calculated (100/[the percentage of individuals with the MCID in group A minus the percentage of individuals with the MCID in group B]).113 Therefore, in a study in which 40% of patients in group A experience the MCID for pain relief compared with 20% in group B, the number needed to treat would be 100/20 or 5. By contrast, a study in which 40% of patients in group A experience the MCID compared with 37% in group B, the number needed to treat would be 100/3 or 33.

The effect size is a way of assessing results across studies that report similar outcomes (e.g., pain relief) using different measures (e.g., 0 to 4 verbal rating scale, 0 to 10 numerical rating scale, and 0 to 100 visual analogue scale). The effect size (also called the Z score) is a unit-less measure that standardizes results across studies by dividing the difference in the mean scores between groups by the standard deviation. Each point in the effect size is equivalent to a difference in one standard deviation. Although clinical interpretation of effect sizes can vary depending on the outcome being measured, the population assessed, the sample sizes of the studies, and other factors, a general rule of thumb is that an effect size of 0.2 to 0.5 indicates a small effect, >0.5 to 0.8 a moderate effect, and >0.8 a large effect.

**ASSESSING AND ADDRESSING BIAS AND CONFOUNDING IN CLINICAL RESEARCH**

Bias refers to any systematic process, effect, or error in the design or conduct of a study that favors one outcome over others.115 Therefore, studies at greater risk of bias are more likely to be misleading. Important types of bias include (1) selection bias resulting in differences between groups other than the intervention of interest; (2) performance bias due to effects of knowledge of patient assignment to different therapies; (3) attrition bias due to differences between those persons who do versus those who do not complete a study; (4) detection bias resulting in differential interpretation of outcomes based on knowledge of assigned interventions; (5) reporting bias from the selective presentation results, typically those that are more favorable or statistically significant; and (6) publication bias resulting from the preferential publication of studies reporting positive findings.

Methods to reduce the risk of bias in randomized trials include (1) use of adequate randomization and allocation concealment to prevent selection bias; (2) assessment of similarity of groups at baseline to detect important imbalances and failure of randomization to control for known confounders; (3) blinding of patients, caregivers, and research staff to avoid performance and detection bias; (4) low loss
to follow-up and use of intention-to-treat analysis to avoid attrition bias; and (5) full reporting of prespecified primary and secondary outcomes to avoid reporting bias. Given a randomized trial with a large enough sample and successful implementation of randomization, the problem of selection bias is largely eliminated because all confounders—including those that are unmeasured or unknown—are equally distributed among groups. Successful blinding of patients and research staff should largely eliminate performance and detection bias.116

As noted earlier, observational studies by their nature are susceptible to selection bias and confounding by indication, and they cannot blind patients and treating clinicians to the interventions received. Confounding refers to a situation in which the association between an intervention (I) and an outcome (O) is distorted by another factor (C).117 This occurs when I is associated with C, and C is also an independent risk factor for O. For example, patients with back pain may have poorer outcomes when prescribed opioids compared with persons not prescribed opioids. However, if back pain is also associated with psychological comorbidities and psychological comorbidities are independently associated with poorer outcomes, a study that does not address this confounder would provide misleading results about the effects of opioid use on back pain. To address this during the assembly of the cohort, a study could match patients on key confounders such as psychological comorbidities or restrict enrollment to patients without psychological comorbidities. After a cohort has been assembled, a study could evaluate baseline differences among groups in psychological comorbidities to assess the likely impact of this confounder, and it could perform statistical adjustment through regression or other methods (e.g., propensity score matching) to control for its effects or stratification to evaluate how effects vary in defined subgroups.

When considering multiple studies at the level of a body of evidence, it is also important to consider the possibility of publication and related biases due to the selective publication of studies.118 Steps to address publication bias include efforts to locate unpublished studies, and performance of graphical or statistical tests to determine whether publication bias may be present and its potential magnitude.

Different types of evidence studies vary in their susceptibility to bias. Therefore, when evaluating the validity of a study, it is important to consider any design-specific methodological shortcomings, as well as its place on the study design hierarchy. For example, a well-conducted randomized controlled trial will generally be less susceptible to bias than a well-conducted cohort study.

External validity (generalizability or applicability) is separate from risk of bias but also critical for interpreting research evidence. Studies may be at low risk of bias and therefore valid (i.e., give true results), but only apply to very specific situations. It is therefore always important to consider whether the study evaluates effectiveness—or the extent to which a treatment works on average patients in everyday settings—as compared to efficacy—the extent to which a treatment works in highly selected patients in tightly controlled settings.32

### KEY POINTS

- Evidence-based medicine offers a formal set of steps for clinicians to follow in order to effectively interpret the results of clinical research ("how to read a paper") and to apply them in their practice.
- The Grading of Recommendations Assessment, Development and Evaluation (GRADE) system is widely used to grade the quality of published evidence and strength of recommendations.
- A randomized controlled trial is a type of controlled clinical trial predicated on participants being assigned to the possible exposures or interventions purely by the play of chance.
- A cluster randomized trial is a trial in which individuals are randomized in groups—the group as a whole is randomized, and not the individual.
- A case-control study determines the relationship between a single outcome (disease) and one or more previous possible contributing factors (exposures).
- A cohort study determines the relationship between a single contributing factor (exposure) and one or more possible outcomes (diseases).
- A nested case-control study is a case-control study in which the cases and controls are selected from members of an existing longitudinal cohort.
- Efforts to provide optimal care, while controlling unnecessary or wasteful health care expenditures, focus on delivering high-value, cost-conscious health care, which can be determined using health care economic evaluation techniques.
- A key concept when interpreting the results of clinical research is that statistically significant results are not always clinically meaningful (minimal clinically important difference [MCID]).
- Bias refers to any systematic process, effect, or error in the design or conduct of a study that favors one outcome over others, whereas confounding refers to a situation in which the association between an intervention and an outcome is distorted by another factor.

REFERENCES

2. Hart PG. A change in scientific approach: from alternation to randomised allocation in clinical trials in the 1940s. BMJ. (Clinical research ed.) 1999;319:572-573.

Medical experimentation has a long history. Biblical references suggest that as early as the sixth century BCE, King Nebuchadnezzar tested nourishment as an outcome of variation in diet in his subjects. Although scattered reports of other rudimentary experimentation have been documented, most historical accounts indicate that Dr. James Lind inaugurated modern-day clinical research through the first controlled clinical trial in the mid-1700s. Lind, a physician stationed on a British naval vessel, compared the administration of citrus fruit with other therapies for the treatment of patients with scurvy. Using hypothesis generation and testing, he found a cure for the once mysterious disease of scurvy. Dr. Lind set the stage for a rich history in human subject research that has since evolved in sophistication, influence, and magnitude.

Although the scope of clinical research has changed in sophistication and complexity over the centuries, what has not changed are the basic tenets—to understand the causes, evolution, and effects of human disease and to improve our ability to prevent, diagnose, and treat it. However, this privilege of investigation requires professional responsibility to protect the subjects. This assertion underlies the field of research ethics and is the focus of this chapter.

The underlying principles of research ethics are the same as the generally accepted medical ethics. Professional morality is often considered to be based on four overarching principles that form the framework for the ethics that guide us in our practice—respect for autonomy, nonmaleficence, beneficence, and justice. These principles are germane to research ethics.

**Respect for autonomy.** Respect for autonomy addresses the respect for decision making by autonomous persons. It prioritizes a person’s right to hold views, make choices, and take actions based on personal values and beliefs. It is the core of the informed consent and informed refusal discussions that are central to research ethics. The principle of respect for autonomy becomes particularly relevant in vulnerable patients with potentially diminished autonomy, such as those with chronic pain, who may clutch at any opportunity for relief.

**Nonmaleficence.** Nonmaleficence is the moral norm of *primum non nocere.* “above all do no harm.” Pertinent to this principle are considerations of the acceptable risk incurred by doing research and balancing these risks with the prospect of benefit.

**Beneficence.** Beneficence describes actions that promote the welfare of a person, patient, or subject. It tangles with respect for autonomy when patient preferences are at odds with physician judgment. In research ethics, beneficence encompasses the scientific and social value and integrity of the research, as well as any potential benefits to the subject when balanced with the risks.

**Justice.** Justice describes fair, equitable, and appropriate treatment in light of what is due persons. It demands stalwart vigilance to avoid the exploitation of socioeconomically and medically disadvantaged individuals, and it requires systems to ensure that all have a fair opportunity to receive the benefits. Flagrant exploitation in the past has led us to the current guidelines and controversies. From this infrastructure we will build an understanding of research ethics as an application of these principles in general and as it is relevant to research involving pain medicine.

**RESEARCH ETHICS**

**HISTORY OF RESEARCH ETHICS**

 Advances in research ethics have primarily been instigated by the exploitation of human subjects. Even though some evidence suggests that ethical issues in human experimentation had been recognized and addressed as early as the late 1800s, the 1947 Nuremberg Code is commonly cited as the first document to govern the conduct of human research. This code arose from the war trials of Nazi physicians accused of conducting “murderous and torturous human experiments” on prisoners in concentration camps in the name of medical science. The Nuremberg Code was the first to formally outline standards for the ethical conduct of research on humans. It declared that voluntary consent is “absolutely essential,” subjects should be protected from “unnecessary physical and mental suffering and injury,” subjects may withdraw at any time from the experiment, researchers should stop the experiment if continuation is likely to be harmful to the subject, and the experiment has a legitimate likelihood of bearing fruit.

The period following World War II was marked by a time of increased medical research activity and the development of new methods. To further define the requirements for human experimentation, the World Medical Association published the “Declaration of Helsinki.” First adopted in 1964 at the meeting of the World Medical Association in Helsinki, Finland, the document has undergone
multiple, often contentious revisions, most recently in 2008, to address evolving issues in human experimentation.\textsuperscript{10} The document builds on and reinforces many of the principles in the Nuremberg Code but excludes 2 of the 12 items in an effort to address perceived deficiencies in the Nuremberg Code. The requirement for voluntary consent of subjects was replaced by a statement that allows guardians to consent for research in subjects who are “legally incompetent, physically or mentally incapable of giving consent or is a legally incompetent minor.”\textsuperscript{3} In doing so, the Declaration of Helsinki became the first document to address experimentation in children and others with limited decisional capacity. The other substantive changes included indications for cessation of research by the investigator, notification of subjects that they may withdraw at any time, and the distinction between therapeutic and nontherapeutic research.\textsuperscript{3,11}

The Declaration of Helsinki did not halt all questionable research activities in the United States.\textsuperscript{8} In 1966, Dr. Henry K. Beecher, a former anesthetist in chief at the Massachusetts General Hospital, published a landmark paper in the New England Journal of Medicine in which he exposed multiple instances of contemporaneous research that were in direct violation of what was declared at Helsinki. Beecher documented studies that withheld known effective treatment, administered known harmful therapy, and exploited incompetent patients and children. In the face of soaring research funding, Beecher placed a necessary and influential pause on the process to re-examine the ethics of the field and remind investigators, the field of medicine, and society about our moral responsibilities to research subjects. He also suggested that journal editors were responsible to reject manuscripts of unethical research in the hope that “failure to obtain publication would discourage unethical experimentation.”\textsuperscript{12}

In 1972, the Tuskegee Study of Untreated Syphilis became the impetus for the next page in the history of research ethics. The U.S. Public Health Service conducted the Tuskegee study from 1932 through 1972. The study withheld effective therapy for syphilis from hundreds of African American men to observe the progression of syphilis, presumably for the sake of medical research.\textsuperscript{13} In response to the horror generated by the discovery and exposure of this study, the U.S. Congress enacted the National Research Act in 1974. This act created the National Commission for the Protection of Clinical Subjects of Biomedical andBehavioral Research to oversee human experimentation in the United States. In 1979, the commission drafted the Belmont Report.\textsuperscript{5} The Belmont Report describes the basic ethical principles underlying the conduct of research—respect for persons, beneficence, and justice—and it applies them to research conduct by addressing the specific issues of informed consent, risk-benefit assessment, and selection of research subjects.\textsuperscript{5} In addition to establishing the commission, the National Research Act led to the Common Rule in 1991, a set of federal regulations necessitating oversight of government-funded research in the United States. Elements of the policy center on the presence and procedures of institutional review boards (IRBs) and general requirements for informed consent. Subsequent revisions of the regulations addressed vulnerable research subjects, including children.\textsuperscript{8,14,15}

Even though there is widespread support for the basic ethical principles addressed in these documents, their practical use is continuously debated and refined. Some researchers think that the regulations are necessary to operationalize these principles, whereas others see them as an excessive obstacle to research.\textsuperscript{16} The dilemma between promoting scientific advancement and protecting subjects is real and complex; staying on the narrow road that protects both interests requires thoughtful calibration and imaginative solutions.

**ETHICS OF RESEARCH ON HUMAN SUBJECTS**

Applying ethical principles in performing research requires dedication to adherence. Emanuel and colleagues proposed seven requirements for ethical research that comprehensively define and guide evaluations of clinical studies on humans. These requirements provide an inclusive and detailed framework that should ensure performance of ethical research (Box 81.1).\textsuperscript{17}

The requirement for social or scientific value requires that to justify potential risks and use of resources, the research should add knowledge to the field, regardless of whether it leads directly to changes in patient care.\textsuperscript{17} This requires avoiding unnecessary or needlessly repetitive research.\textsuperscript{18} Researchers are obligated to publish their research to benefit society.\textsuperscript{17,19} In pain research, value may include “immediate value,” which may immediately improve health, or “potential value,” which comes from the knowledge of better understanding the science of pain.\textsuperscript{20}

Scientific validity requires the research to have adequate methodologic rigor to potentially produce meaningful results regardless of the value of the proposed research. The scientific value of an idea alone does not ensure its validity.\textsuperscript{17}

Clinical equipoise is a requirement for interventional research validity and, accordingly, becomes a requirement for ethical research. It describes a state of uncertainty about the superiority of the prospective intervention over existing interventions and must be present for an interventional study to be considered ethical.\textsuperscript{21,22} Although clinical equipoise is the accepted basis for many clinical trials, its practical utility has not been without controversy.\textsuperscript{23} Because this stipulation has the potential to present a significant obstacle to initiating clinical trial research, distinctions have been made between individual versus community equipoise by delineating whether the uncertainty must lie with the individual investigator or within the expert medical community.\textsuperscript{21,23}

The requirement for scientific validity is also based on the idea that risks cannot be incurred nor resources used without a functional study design. In pain research, adequate study design may dictate the inclusion of a placebo arm, as often required by the Food and Drug Administration (FDA), a somewhat controversial topic addressed below.

Independent review of research by outside parties is conducted in an attempt to mitigate potential conflicts of interest and address inadequately designed research. In concept, it entails review of all research activity, including project proposal and design, data collection, ongoing monitoring of the research, and final analysis of the results. In practice, it is performed by funding agencies, IRBs, and safety-monitoring boards. Independent review bodies should specifically consider these seven requirements when analyzing the research being reviewed. Independent review is notably concerned about taking advantage of vulnerable patients such as those in chronic pain. Review processes are also pivotal in addressing conflicts of interest. The requirement for respect for potential and enrolled subjects seeks to ensure privacy and confidentiality, allow subjects to freely withdraw from research, inform subjects of the results of the study, and maintain the welfare of subjects. Though seemingly simple operationally, the complexity of this requirement lies in including all the principles and many of the requirements mentioned. In short, it demands placing the research subject as the primary center while still conducting useful research. With reference to pain research, it is worth highlighting the idea of opportunity for withdrawal. People with pain may have unique barriers to accepting their freedom to withdraw from a study because of concerns about obtaining appropriate and effective alternative treatments once they have withdrawn.

Fair subject selection specifies that subject selection and opportunities for participation be based on the goals of the research rather than unrelated factors such as privilege or vulnerability and that those bearing potential risks by participating be able to experience the benefits. An example of research that would violate fair subject selection is testing a new medication primarily on a socioeconomically disadvantaged population for a disease that equally or primarily affects a more advantaged group. This may occur because academic centers are often centered in socioeconomically disadvantaged areas. An example of a different concern is not offering research participation to women when the disease and intervention being studied equally pertain to women. In this case, exclusion of women, perhaps for practical research reasons, may result in subsequent therapeutic recommendations that may not be applicable to the excluded group.

The converse of the requirement for equal opportunity inclusion is exploiting vulnerable populations for research that will not benefit that population or will not result in generalizable knowledge. Nazi experimentation were one such example. Another relevant study is the Willowbrook Hepatitis Study. At the Willowbrook State School for disabled children in Staten Island, New York, numerous disabled children were deliberately infected with infectious hepatitis to study the disease, as well as to test the effects of potential therapies, thus raising concern for exploitation.

For research to be justified, there must be a favorable risk-benefit ratio. Because much of the goal of research is to test untested interventions, the risks and benefits associated with such interventions will in part be unknown or uncertain. To justify research, however, potential risks must be minimized, potential benefits must be enhanced, and the risks and benefits must be commensurate.

When considering the potential benefit side of the balance, discussions should pertain to the benefits received by the subject or the subject’s population and, except in unusual circumstances, not those gained by society at large. Potential benefits do not include providing proper medical care. The Tuskegee Study of Untreated Syphilis highlights this point in that the men in this study were thought to be receiving a “benefit” that more properly should have been considered standard health care. Finally, benefits such as money or gifts could conceivably be increased to the point, particularly in certain subjects, that even the most risk-laden endeavors will be outweighed by the non–health-related benefit. In pain research, potential benefits are manifested as the potential to benefit future patients or more immediately benefit the patient or the patient’s population with either access to medications or access to study results that may help the patient choose between medications.

Conceptually, the requirement for assessment and minimization of risk in research is derived from the principle of nonmaleficence. Most would agree that limiting the harm imposed by research activities is appropriate and necessary for the protection of all subjects. U.S. federal regulations governing research on human subjects require that risk to subjects be minimized “(i) by using procedures which are consistent with sound research design and which do not unnecessarily expose subjects to risk, and (ii) whenever appropriate, by using procedures already being performed on the subjects for diagnostic or treatment purposes.” The regulations also place large responsibility for the oversight of this standard in the hands of review bodies, such as IRBs.

Even though minimizing risk has accepted value, dissenion arises in defining risks for any individual subject and study. Delineating risk includes consideration of both the probability and magnitude of the harm. It is meant to include physiologic, psychological, social, economic, and legal risks and to represent aggregate risk for participation, not for any single individual potentially harmful encounter. In light of this, it is difficult to quantify risk, and attempts have been made to create categorical distinctions to guide researchers and review bodies in assessment of the appropriateness of the research activity.

“Minimal risk” is a categorical distinction of risk that is delineated in the federal regulations. The purpose of the category of minimal risk is to set a threshold that triggers closer examination of the risks and benefits of the research. It is defined as follows: “the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.” As with defining risk itself, the ambiguity inherent in making such a distinction has sparked criticism of the concept. Difficulty in defining minimal risk complicates weighing...
whether the risks and benefits of a study meet the minimal risk standard. Operationally, the presence of minimal risk can be a reason for altered or “expedited” review processes for research approval.28

In pain research, examples of risks include potential medication side effects, persistence of pain symptoms if randomized to the placebo arm without breakthrough dosing available, risks associated with sham procedures, and pain associated with travel and paperwork.20 It may also include the intentional use of noxious stimuli to test potential pain relief mechanisms.30

Those involved in research and oversight should systematically analyze and define the risks and benefits as much as possible to allow the risk-benefit relationship to be elucidated.5 In the end, potential benefits need to be commensurate with potential risks.17

Informed consent is a process that has at its core the principle of respect for autonomy. The purpose of the informed consent process is to ensure that the subject understands the purpose, methods, risks, benefits, and alternatives to the research to the extent that the subject can make a voluntary informed decision about participation.17 The quality of the informed consent is married to good study design20 and involves the remaining six requirements.

The initial step in the process of informed consent is the interactive and iterative process of conveying information and discussing all aspects of the research. This interaction also requires the ethereal but essential assessment of sufficient comprehension. Finally, the potential participant may agree to participate.31

Consent must be free of coercion. Coercion can take the form of obvious pressure or inducement to participate or may be more subtle in the form of perceived pressure that the potential participant may feel in light of an existing clinical relationship with the investigator on whom the participant depends for medical care.19 Another form of coercion is offering better medical care not otherwise available. Consider the pressure to participate on a patient in unremitting chronic pain, who has vulnerabilities that would particularly predispose them to therapeutic misconception.24

A few ethical concerns are particularly germane to research on pain medicine. Tait delineated three characteristics that render pain research challenging: pain is highly subjective, it is composed of sensory, affective, and cognitive elements, and its correlation with actual injury is uncertain and variable.24 These characteristics, among others, contribute to the potential classification of these research subjects as vulnerable. This is particularly pertinent to patients with chronic pain, whose complexity complicates the design and ethics of research.24,35 Notably, included in this is the common comorbidity of psychiatric disturbance in the chronic pain population, conditions that may affect cognition in a way that threatens the informed consent process.24 However, similar to other vulnerable populations, patients in pain should be entitled to the same opportunities for research on behalf of their condition, and efforts should be made to manage these tensions.

**PLACEBOS**

Placebos are often necessary for sound research design and are often required by the FDA for studies evaluating efficacy.24,36 In line with the prevailing principles that have already been discussed, the ethical use of placebo-controlled studies assumes that the following conditions have been met: no effective treatment is available that can be used for comparison, the risks potentially incurred by use of a placebo are acceptable, study validity requires its use, and informed consent includes disclosure of the potential use of placebo.24,36-38 Some studies may benefit from a placebo arm that involves an intervention, such as inserting an epidural catheter and infusing a sham drug so that clinicians do not realize what the patient is receiving. Determining whether the benefits of a placebo arm are necessary for study validity depends on the incremental improvement in the validity of the study and the potential harm of the intervention. Although minimal risk with the intervention requires that the intervention be done if it improves study validity, more significant risks must hurdle greater standards, such as a study result that would directly benefit the patient subsequently.38

Particular attention has been paid to the use of placebo-controlled trials in pain research. The highly subjective nature of pain and the related tendency toward powerful placebo responses in patients who experience pain make the use of placebo particularly compelling in research involving interventions directed at the pain experience.24,37 Although further discussion of the merits of placebo use in research design is beyond the scope of this chapter, several threats to ethical integrity are relevant to the use of placebo in analgesia research on patients with chronic pain, namely, therapeutic misconception, coercion related to a reliant relationship with the physician, and risk for irreversible exacerbation of symptoms when withholding therapies.24 These risks are not absolute barriers to the use of placebo; however, they do suggest the need for more oversight at the level of the investigator and regulatory parties.

**INDUSTRY AND CONFLICTS OF INTEREST**

Conflicts of interest in performing and publishing research may rise from external or internal pressure. It is important to think of conflict of interest not as a statement of fact (i.e., the researcher is doing something wrong because of external benefits), but as a potential situation. It is, of course, impossible to know the intent of a researcher. Nonetheless, we can certainly recognize situations that may potentially lead to conflict.

External pressure, such as continued funding from industry, is a well-recognized concern, and procedures are in
place to publicly identify such conflicts in an attempt to prevent them. However, public identification is not a panacea. In one study, only 80% of physicians reported industry funding related to their research. Fewer reported funding from the same company but unrelated to the specific product.39

Perhaps more insidious than the conflicts that may arise from industry’s financial pressure is the unrecognized desire for academic promotion and enhanced reputation. In our view, one of the most dangerous conditions is the ownership that physicians feel for their ideas, which may lead to the well-meaning conviction that their idea is the right answer. This can lead to bias, overlooking of contrary data, and even “correcting” of data because they have the solution. Investigators must be mindful of this phenomenon.

The subjectivity of pain assessment puts an investigator at risk for potential conflicts of interest throughout a study—inclusion/exclusion criteria, risk-benefit ratios, overestimating responses to treatment, and underestimating symptoms. In light of the increasingly complex relationships between pain physicians and industry, the American Academy of Pain Medicine has published recommendations related to conflicts of interest in research, with a particular focus on disclosures and review.25

Pain management has recently had two scandals that show the potential harm related to research and conflicts of interest. In 2009, the lead researcher who was responsible for publishing influential data that encouraged multimodal pain therapy was found to have significant irregularities in data that required retraction of multiple articles. Pain management physicians were left without data to support their current clinical practices.40

Researchers must also be sure that agreements with industry permit publication of data regardless of the outcomes. Although it is widely accepted that industry-provided materials and representatives overstate the benefits and underestimate the risks associated with a drug, it is perhaps less appreciated that drug companies may do the same on a larger scale. This is most clearly seen with the anti-inflammatory drug rofecoxib (Vioxx), in which Merck intentionally distorted and obfuscated the risks associated with a drug, it is perhaps less appreciated that drug companies may do the same on a larger scale. REFERENCES

Significant progress in the management of postoperative pain has been made since the 1990s. Increased awareness of the undertreatment of postoperative pain, improved analgesic techniques, and new analgesic agents have contributed in part to improvements in its management. Despite the advances made in the management of postoperative pain, many challenges remain in improving the quality of pain control for patients.

**CURRENT STATUS OF POSTOPERATIVE PAIN MANAGEMENT**

Although a comprehensive overview of the current state of postoperative pain management is beyond the scope of this chapter, many facets are described elsewhere in this book. One of the persistent issues in the management of postoperative pain is that a relatively high percentage of patients still experience moderate to severe levels of pain, despite increased awareness by health care providers of the issue (e.g., pain as the “fifth vital sign”). Data suggest that postoperative pain continues to be undermanaged. For instance, one survey found that 80% of United States (U.S.) adult patients experienced acute pain postoperatively after outpatient surgery with approximately 85% of these patients experiencing moderate to severe pain.1 A similar assessment in Europe noted that 41% of adult surgical patients experienced moderate to severe pain on the day of surgery. 2 The parents of pediatric patients undergoing tonsillectomy and adenoidectomy felt that 86% of their children experienced significant overall pain. 3 The reasons for the continued relative undertreatment of postoperative pain is uncertain but may be related to multiple factors including heightened awareness leading to an improved identification of undertreatment of pain, the continued lack of pain assessment or documentation, underutilization of more effective analgesic techniques such as regional analgesic techniques, and the lack of adherence to available pain management guidelines.4-7

Our current understanding of the perioperative pathophysiology basically is that a wide range of pathophysiologic responses are initiated when nociceptors are activated after tissue injury that ultimately results in a local inflammatory, behavioral, and physiologic responses. 8 Sympathoneural and neuroendocrine activation and postoperative pain resulting from tissue injury may eventually produce potentially detrimental responses, 8 which may be especially harmful in high-risk patients or those undergoing high-risk procedures and lead to increases in morbidity or even mortality.

Because the use of regional techniques utilizing a local anesthetic-based analgesic solution may attenuate these pathophysiologic responses to a greater extent than that seen with systemic analgesics, it is possible that use of these techniques may be associated with an improvement in some patient outcomes as well as patient satisfaction. For instance, several meta-analyses suggest that the use of regional analgesic techniques is associated with a decreased risk of postoperative pulmonary complications in patients undergoing abdominal-thoracic procedures. 9,10 In addition, several systematic reviews in patients undergoing high-risk cardiothoracic-vascular procedures suggest that a decrease in pulmonary complications, cardiac dysrhythmias, and overall cardiac complications may be seen with perioperative thoracic epidural analgesia with a local anesthetic-based analgesic regimen.11,12 In patients undergoing abdominal surgery, the perioperative use of thoracic epidural analgesia with a local anesthetic-based regimen is associated with faster resolution of postoperative ileus. 9,13,14 Finally, numerous randomized controlled trials indicate that utilizing continuous peripheral regional catheters may facilitate postoperative rehabilitation and decrease costs associated with surgery.15,16

Different analgesic agents may have different effects when compared to one another with respect to patient-centered outcomes such as analgesia or patient satisfaction. When compared to conventional “as needed” opioid analgesia, the use of intravenous patient-controlled analgesia with opioids for postoperative pain control results in superior analgesia and greater patient satisfaction.17 Regional analgesic techniques utilizing a local anesthetic-based regimen provide superior postoperative analgesia versus systemic opioids.18,19 Despite the analgesic benefits of regional analgesic techniques, it is not clear whether this improved analgesia can be translated to improvements in some other patient-centered outcomes such as quality of life and quality of recovery.9,20

To improve postoperative analgesia, utilization of multimodal analgesia, typically a combination of an opioid and nonopioid analgesic with or without a regional anesthetic
block, has been encouraged to concurrently reduce opioid-related side effects.\textsuperscript{21} In one survey, 23\% of in- and outpatient experienced side effects, mainly drowsiness, nausea, and constipation. Approximately 70\% of patients would choose a nonopioid drug as they are perceived to be less addictive (49\%) and have fewer adverse effects (18\%).\textsuperscript{1} The literature on multimodal analgesia is not consistent with regard to analgesic efficacy; however, the case of academic fraud that resulted in several multimodal analgesia studies being retracted did not appear to significantly affect the overall conclusions from the literature.\textsuperscript{22}

**MACROTRENDS**

Future directions for investigation in the area of postoperative pain management need to account for macrotrends that have been in place for decades and may influence not only this specific area but also health in general. Although several macrotrends are present, the ones that may affect the investigation of postoperative pain including the aging of the population, the increasing percentage of obese patients, the changing demographics of outpatient surgical patients, and the presence of a large and worsening U.S. federal deficit.

**AGING**

In industrial nations, the median age of the population is increasing as a result in part of an increase in average life span.\textsuperscript{24} For example, in the United States alone, there is an expected increase in the proportion of the population \( \geq 65 \) years of age from 12.4\% (35 million) in 2000 to 19.6\% (71 million) in 2030 with the number of persons \( \geq 80 \) years of age expected to increase from 9.3 million in 2000 to 19.5 million in 2030.\textsuperscript{24,25} Although the sex distribution with increasing age is not expected to change significantly, more significant changes are expected in the ethnic composition of persons \( \geq 65 \) years of age. Elderly members of minority groups is expected to increase from 11.3\% to 16.5\% with the proportion of people of elderly Hispanic origin increasing from 5.6\% to 10.9\% between 2000 to 2030.\textsuperscript{24,26}

Older adults generally utilize a greater proportion of health care resources as the presence of chronic conditions affects this population disproportionately. For instance, in the United States, approximately 80\% of all persons \( \geq 65 \) years of age have at least one chronic condition with approximately 50\% having at least two chronic conditions.\textsuperscript{27} In terms of specific diseases, almost 20\% of persons \( \geq 65 \) years carry the diagnosis of diabetes and approximately 10\% have Alzheimer’s disease.\textsuperscript{27}

With regard to the perioperative period, one of the more significant complications for older patients is the development of postoperative delirium. Although the etiology of postoperative delirium and postoperative cognitive dysfunction is uncertain, it is clear that a major risk factor is age, with a higher incidence of postoperative delirium with increased age.\textsuperscript{28} Certain drugs or classes of drugs (e.g., meperidine, benzodiazepines) have been associated with an increase in postoperative delirium.\textsuperscript{29,30} A prospective study including 1359 consecutive patients of which 64 (4.7\%) developed delirium found an association between preoperative benzodiazepine administration and acute postoperative delirium, in which the use of benzodiazepines before surgery nearly doubled the risk of emergence delirium.\textsuperscript{29} In a prospective cohort study where 91 patients developed delirium during the postoperative period, delirium was significantly associated with postoperative exposure to meperidine.\textsuperscript{30} In addition, an increase in the level of postoperative pain has been shown to correlate with an increased incidence of postoperative delirium.\textsuperscript{31} The literature on the safety and efficacy of drug therapy in delirium is lacking in terms of high-quality, well-designed randomized, double-blind, placebo-controlled trials investigating drug management of various aspects of delirium.\textsuperscript{32}

**OBESITY**

The increase in the percentage of people classified as obese has significant implications for perioperative pain management and health care overall. It has been estimated that approximately one third of adults in the United States and approximately 17\% of children are obese.\textsuperscript{33} The trend for obesity indicates that there continues to be an increase in the incidence of obese adults.\textsuperscript{34,35} An examination of the U.S. National Health and Nutrition Examination Survey revealed that the age-adjusted prevalence of obesity (defined as a body mass index of \( \geq 30 \)) was 33.8\% overall (32.2\% for men and 35.5\% for women).\textsuperscript{34} This increase in obesity is associated with an increase in health care costs and utilization and overall economic impact including direct medical costs, productivity costs, transportation costs, and human capital costs.\textsuperscript{36} The significant economic impact highlights the importance of the obesity epidemic for future health policy and clinical research.\textsuperscript{36}

It is recognized that perioperative patients who are obese are potentially at higher risk for postoperative complications. Obesity is one of the major risk factors for obstructive sleep apnea.\textsuperscript{37} The prevalence of sleep-related breathing disorders may be increasing due in part to the increasing prevalence of obesity. The presence of obesity and obesity-related issues may influence postoperative pain management as there are guidelines for management of postoperative pain for patients who have obstructive sleep apnea.\textsuperscript{38} Opioid-induced ventilatory impairment (OIVI) is a more complete term encompassing opioid-induced central respiratory depression (decreased respiratory drive), decreased level of consciousness (sedation), and upper airway obstruction, all of which, alone or in combination, may result in decreased alveolar ventilation and increased arterial carbon dioxide levels. Concerns about OIVI are warranted, as deaths related to opioid administration in the acute pain setting continue to be reported. Risks are often said to be higher in patients with obstructive sleep apnea. Unfortunately, many surgical patients who have obstructive sleep apnea have not been formally diagnosed (e.g., sleep study).\textsuperscript{37}

**GOVERNMENT DEBT**

Possibly the most significant factor affecting the delivery of U.S. health care is the increasing federal debt level. As the government currently pays for approximately 50\% of all health care costs in the United States with the proportion of health care constituting a greater percentage of the gross domestic product (GDP) over time, federal debt and
U.S. health care policy are in essence intertwined, which may have implications for the future reimbursement for postoperative pain management. Although U.S. health care spending grew at a historically low 4% in 2009, the proportion of the GDP spent on health care increased to approximately 18% with the growth rate of health care continuing to outpace the growth in the overall economy. If current trends are extrapolated into the future, the United States will be spending approximately 40% of its GDP on health care by 2075. Because of the unsustainable increase in health care spending, there has been much political pressure to control health care spending, presumably in part through the inevitable implementation of clinical programs that allow for the delivery of high-quality clinical care in an environment of slower spending growth. Despite the lack of solid evidence, there have been many general proposals to “bend the curve” in an attempt to decrease the rise of health care costs including reducing consumer demand for health care services, decreasing payments to health care providers, reorganizing the payment for and delivery of care (e.g., accountable care organizations), and implementing cost-effectiveness standards for delivery of clinical care.

PATIENT-CENTERED ASSESSMENTS

The evaluation of postoperative pain management involves the assessment of its efficacy and determination of side effects. Clinically, these are typically assessed by asking the patients to rate their pain on a scale 0 (no pain) to 10 (most severe pain) during rest and movement, and the presence of side effects such as nausea, vomiting, pruritus, and sedation. The research measurement tools include the use of visual analog scores (VAS), verbal rating scores (VRS: none, mild, moderate, severe), or time to first analgesic request and observation of side effects. Unfortunately, these tools are not sophisticated enough and do not reflect the multidimensionality of pain perception; patient satisfaction and functional and emotional components are not assessed.

The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) group recommended outcome measures for pediatric postoperative pain research but not for adults. Some measurement tools are available to measure the other domains of pain perception and have been utilized in previous studies. These include the Opioid-Related Symptoms Distress Scale to assess symptoms related to opioid intake including difficulty passing urine, headache, feelings of lightheadedness, fatigue, or weakness. The Mini-Mental Status examination measures sedation as well as the cognitive ability of the patient. Physical/functional conditioning is measured by the Short Form (SF)-36 and its variations SF-12 and SF-8, measurement of activities of daily living, the 6-minute walking test, and evaluation of the functions of the arm, shoulder, and hand. Emotional functioning can be assessed with a simple VAS or Likert scales as well as sophisticated scales for anxiety such as the Profile of Mood States (POMS) or the Yale Preoperative Anxiety scale. The POMS, a measurement tool recommended by the IMMPACT Group, assesses the six aspects of mood including depression, fatigue, anxiety, hostility, vigor, and confusion. Patient satisfaction as assessed by the patient or the parents, in terms of overall global efficacy and patient global assessment, can be measured by simple VAS or Likert scales. The IMMPACT group recommended the Patient Global Impression of Change in studies on chronic pain. The Patient Global Assessment of Response to Therapy (PGART) is a categorical scale that combines pain relief and side effects. Some of the recommended measurement tools are noted in Box 82.1.

Sophisticated tools are available to evaluate most of the domains involved in pain perception. These include the McGill Pain Questionnaire (MPQ), modified Brief Pain Inventory (BPI), Quality of Recovery (QoR) scoring system, American Pain Society Quality Improvement Patient Outcome Questionnaire, and the Health Outcomes Recovery Survey. None of the sophisticated measurement tools measures all five domains, and emotional functioning and physical conditioning were superficially studied in some of the questionnaires. Only the Quality of Recovery (QoR)-10 and the Health Outcomes Recovery Survey evaluate side effects, and only the Quality Improvement Patient Outcome Questionnaire measures patient satisfaction. The QoR-40 assesses all the domains of pain perception except patient satisfaction. Patient satisfaction can therefore be evaluated together with the QoR-10. The inability of the sophisticated measurement tools to assess all the domains of pain perception calls for a multidimensional tool that measures all such domains.

ASSESSMENT OF POSTOPERATIVE PAIN IN CHILDREN

For pediatric pain, measurement tools include the Beyer’s Oucher Scoring System, the Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS), the Children and Infants Postoperative Pain Scale (CHIPS), and the Crying Requires oxygen for saturation < 95%, Increased vital signs, Expression, Sleepless Score (CRIES) Scale. Some of the tests observe the emotional and vital signs to assess the patient’s degree of pain. These involve several characteristics of the child, including alertness, crying, facial expression, restlessness, body movement, posturing of the trunk and legs, and vital

signs. For children with cognitive impairment, the revised Face, Legs, Activity, Cry, and Consolability (FLACC) tool and the Nursing Assessment of Pain Intensity (NAPI) may have higher utility than the Non-Communicating Children’s Pain Checklist-Postop Version (NCCPC-PV).61

The IMMPACT group recommended the following self-report measures for acute pain intensity: (1) poker chip tool for patients 3 to 4 years of age, (2) Faces Pain Scale Revised for patients 4 to 12 years of age, and (3) visual analog scale for patients 8 years of age or older.63 For observational pain scales, the IMMPACT group recommended the FLACC, CHEOPS, Parents Postoperative Pain Measure (PPPM), and the COMFORT Scale for patients 1 year and older and the Toddler-Preschooler Postoperative Pain Scale for patients 1 to 5 years. For the cognitively impaired children, the Non-Communicating Children’s Pain Checklist-Postop Version (NCCPC-PV)62 may be useful. The COMFORTneo Scale appears to be a promising tool for the assessment of pain in neonates.64

For emotional assessment in pediatric patients, the IMMPACT group recommended the Adolescent Pediatric Pain Tool for use in children 8 years of age or older and the Facial Affective Scale as the single-item scale of the affective component of pain.43 For observational measures of the assessment of behavioral distress during procedures, the Procedure Behavior Checklist (PBCL) and Procedure Behavioral Rating Scale Revised (PBRS-R) was recommended. Both measurement tools can be used for patients 1 year of age or older. The VAS Anxiety Scale in children aged 7 to 16 years compares favorably with other measures of preoperative anxiety in children.64

**FUTURE AREAS FOR INVESTIGATION**

Although there are in essence endless possibilities for research in the area of postoperative pain management, we have highlighted areas in the prior section where the greatest need appears to be in upcoming decades. The trends that we have described appear to be sustainable (e.g., increase in the percentage of the elderly or obese, increase in the U.S. federal deficit) for the foreseeable future; however, we also discuss other areas of potential interest for investigation.

**POSTOPERATIVE DELIRIUM AND POSTOPERATIVE COGNITIVE DYSFUNCTION**

Increasing age is one of the primary risk factors for the development of postoperative delirium.28 The prevention (if possible) of postoperative delirium is a significant health care concern, as the presence of this complication is a predictor of mortality and increased length of hospitalization.28 With the growing percentage of elderly in the population, we would expect that the incidence of this complication will only increase.

Several avenues for investigation in this area would be needed. In terms of the correlation of the postoperative pain and postoperative delirium, this general correlation would have to be evaluated and the severity of postoperative pain per se should be confirmed as an independent risk factor for the incidence or severity of postoperative delirium or postoperative cognitive dysfunction. Once this has been confirmed, the utilization of different analgesic regimens or perioperative interventions should be investigated to examine their effect on influencing the incidence or severity of postoperative delirium. For instance, it is clear that regional analgesic technique (either epidural or peripheral nerve catheter) utilizing a local anesthetic-based regimen provides superior analgesia compared to systemic opioids including those delivered via intravenous patient-controlled analgesia.18,19 The superior analgesia along with the minimization of opioid use would lead one to believe that utilization of this regimen in elderly postoperative patients would result in a lower incidence or severity of postoperative delirium. However, a somewhat related systematic review examined the incidence of postoperative cognitive difference after general versus neuraxial anesthesia noted no difference between the techniques, although the authors elucidated several methodological issues (e.g., perioperative use of benzodiazepines) in the available published literature.

A more recent systematic review examined prospective and retrospective clinical trials and case studies on delirium and drug therapy in all adult patients.32 The authors indicated that the quality of available evidence was limited and called for additional well-designed randomized, double-blind, placebo-controlled trials investigating the drug management of delirium, including dose-ranging studies and optimal duration of therapy.32 In addition to avoidance of medications known to increase the risk of postoperative delirium and providing superior pain control, prophylactic interventions with antipsychotic and cholinesterase inhibitors in high-risk patients may be investigated in an attempt to minimize drug-induced delirium potential.33 Ultimately, successful attempts to decrease the incidence or severity of postoperative delirium and cognitive dysfunction will most likely require a multimodal approach including optimal drug/analgesic therapy, physical rehabilitation, and other nontraditional approaches. (e.g., cognitive stimulation).

**ECONOMIC CONSIDERATIONS**

It is clear that there will be more emphasis on cost control in the delivery of health care, and the arena of postoperative pain management will most likely not be exempt from scrutiny. Although health care workers who manage postoperative pain most likely would tend to believe in the added value of a discrete postoperative pain management service, there are few meaningful cost data on these services.66 It is likely that postoperative patients who are managed by an acute pain service will have superior pain control and decreased analgesic-related side effects,66 but whether this translates into improved satisfaction, quality, or duration of recovery is uncertain at this time.

There has been an increasing interest by policymakers on cost-effectiveness despite potential resistance from current stakeholders (e.g., health care providers, insurance companies, drug manufacturers, patients, and legislators).57 Cost-effectiveness data have been used in other countries to guide health care decisions. For instance, Britain’s National Institute for Health and Clinical Excellence’s (NICE) decision-making process utilizes cost-effectiveness thresholds based in part on the number of quality-adjusted life-years (QALYs) gained with a particular intervention such as a drug, device, or procedure.58 It is important to note that the goal of NICE
is not to ration health care per se and the decisions made incorporate not only cost-effectiveness data but also social values.\textsuperscript{68} There are many fears regarding cost-effectiveness, including a possible shift of medical decision making by organizations from individual physicians, lack of transparency of the decision-making process, and suspicion of the methods utilized in a cost-effectiveness analysis.\textsuperscript{69} Although there are concerns regarding the implementation of cost-effectiveness data and research, cost-effectiveness analysis is not a cost-containment tool but a method to improve value when implemented properly.\textsuperscript{69}

With increased funding for cost-effectiveness research available (approximately $1 billion to support research on the comparative effectiveness of drugs and medical devices in 2009),\textsuperscript{70} are there any areas for postoperative pain research that would be particularly amenable for this type of analysis? Although comparative/cost-effectiveness analysis is more common in other areas of medicine, it has been infrequently used in pain management or anesthesiology, and analgesic drugs and techniques/devices lend themselves to this type of analysis. For instance, the use of a regional analgesic technique is associated with potential benefits (e.g., superior analgesia, decreased morbidity)\textsuperscript{11,18-20} and complications (e.g., failure of technique, neurologic injury, infectious complication).\textsuperscript{70,71} Clinicians generally will present these benefits and risks during the informed consent process to allow patients to decide whether to choose or decline this technique; however, it is often difficult to combine both benefits and risks into a meaningful single analysis. Inserting the currently available data into this type of analysis may demonstrate a preferred method of treatment (i.e., to choose or decline the technique or drug),\textsuperscript{72} although patient preferences would need to be incorporated into any meaningful analysis.\textsuperscript{72} Nevertheless, both efficacy (high internal validity, low generalizability) and effectiveness (low internal validity, high generalizability) studies will be needed in the future.

Although there has been a relative paucity of research on the effect of postoperative pain on economic outcomes, there are several examples in the literature. For instance, a multivariate regression analysis was used in a prospective observational/surveillance study to determine how acute pain contributes to recovery and discharge. Pain was the most common cause of delayed discharge from postanesthesia care units, affecting 24% of patients in this study. Pain was a significant independent predictor of total recovery duration, and patients who did require analgesics were discharged 54 minutes later than patients who did not require analgesic therapy.\textsuperscript{74} The use of regional analgesic techniques instead of general anesthesia with volatile anesthetics is associated with a reduction of postoperative nausea and vomiting, pain, and the need for postoperative intravenous opioids. Ultimately, recovery room length of stay is reduced (if not eliminated). Reductions in recovery room use, including via recovery room bypass, has been shown to lead to a decrease in hospital cost due in part to including reduced postoperative nursing interventions, reduced unanticipated admissions, and faster discharge times.\textsuperscript{75}

**OBSTRUCTIVE SLEEP APNEA**

Surgical patients with obstructive sleep apnea pose significant challenges for the management of postoperative pain. This issue is complicated by the fact that a large percentage of patients with obstructive sleep apnea are not diagnosed at the time of surgery.\textsuperscript{37} The standard tool to diagnose obstructive sleep apnea is polysomnography (i.e., sleep study); however, the accuracy of making the diagnosis of obstructive sleep apnea based on preoperative history is under investigation. The postoperative management of these patients is also somewhat nebulous.

Although it would seem intuitive to avoid opioids and sedatives postoperatively as has been recommended in published guidelines,\textsuperscript{58} it should be recognized that there are few data to guide clinicians in managing these patients. Guidelines recommended using regional analgesic techniques with only a local anesthetic-based regimen when possible, yet there are no high-quality data to support a decreased incidence of complications with use of this technique. It should be recognized that using adjuvant agents (e.g., nonsteroidal anti-inflammatory agents, acetaminophen) to produce an opioid sparing effect may not necessarily translate into a decrease in severe adverse events such as respiratory depression.\textsuperscript{76,77} Clearly, well-designed and -executed randomized controlled trials are needed to compare perioperative regional analgesic techniques utilizing a local anesthetic regimen to systemic opioids; however, these trials will need to be adequately powered and designed to assess the adverse events of interest (i.e., respiratory complications).

**PREVENTION OF CHRONIC PAIN AFTER SURGERY**

Persistent postsurgical pain (PPP) is a persistent pain state that occurs more than 2 months postoperatively that cannot be explained by other causes such as disease or inflammation.\textsuperscript{78} The incidence of PPP ranges from 5% to 50%, and the mechanisms causing it are multifactorial.\textsuperscript{79,80} Potential mechanisms include inflammatory (release of inflammatory prostaglandins and cytokines) and neuropathic (sustained ectopic activity of injured nerve and changes in spinal inhibition and facilitation) causes.\textsuperscript{81} The factors involved in PPP are either patient or surgery related.\textsuperscript{79,82} Preoperative causes include psychological factors, presence of pain, genetic factors, gender, and age.\textsuperscript{78,83,84} Intraoperative factors include the type of anesthesia, surgical approach, and nerve injury. Most studies on PPP have been retrospective.

The FDA, through its critical path initiative, embarked on a project to help facilitate the development of novel analgesics for the prevention of PPP. The Analgesic Clinical Trial Innovations, Opportunities, and Network (ACTION) initiative was designed as a public-private partnership to bring together experts from academic, government, and private organizations to share data, nest practices, and innovative ideas.\textsuperscript{85} Under the ACTION initiative, the Food and Drug Administration (FDA) anticipates that projects will be developed among the stakeholders, resulting in expedited development of drugs that are effective in preventing and treating PPP. Preclinical applications involving long-term neurobiologic and behavioral changes have been proposed.\textsuperscript{81} An ideal clinical study design has been proposed (Box 82.2), and the criteria for clinically meaningful improvements and the factors to consider in determining the clinical importance of the results of clinical trials on
Box 82.2 Elements of an “Ideal” Study Design of Persistent Postsurgical Pain

**Preoperatively**
- Presence of preexisting pain (locally and remote)
- Measurement of the functional consequences of preexisting pain
- Neuropathologic assessment
- Psychological assessment
- Analysis of “pain genes”

**Intra-operatively**
- Descriptive characteristics about the incision
- Descriptive characteristics about handling of nerves and muscles
- Information about the disease being treated
- Early postoperatively
- Pain intensity and character
- Pain treatment modality used
- Neuropathologic assessment
- Late postoperatively
- Psychological consequences
- Neuropathologic assessment

From Kehlet H, Rathmell JP. Persistent postsurgical pain: the path forward through better design of clinical studies. Anesthesiology. 2010;112:514-515.

There are limited human clinical data on this issue. One study showed learning disabilities after several anesthetics given before the child was 4 years of age.97 Another study showed a lower than expected normative academic achievement test value and more than expected scores below the fifth percentile in academic achievement.98 It should be noted that the duration of surgery and anesthesia correlated negatively with achievement scores.98 To make anesthetic drugs as safe as possible for infants and children, the FDA launched the SAFEKIDS Initiative in March 2009. It is a partnership between the FDA and nongovernmental organizations with the International Anesthesia Research Society managing the initiative and fundraising efforts (www.fda.gov/…/SAFEKIDS%20FAQ%20FINAL%2010101609.pdf, accessed December 8, 2012).

**SUMMARY**

There have been significant improvements and awareness of the prevalence and importance of postoperative pain and its potential deleterious effects on patient outcomes. Surveys suggest that postoperative pain is still undermanaged. The use of more effective analgesic techniques such as regional analgesic techniques and multimodal analgesia may help to improve postoperative analgesia. Outcome domains and measurement tools have been recommended in clinical trials on chronic pain and pediatric acute pain. Several measurement tools have been identified to assess the functional and emotional domains of pain as well as patient satisfaction.

The future areas of potential research in the area of postoperative pain management may be reflected in the macrotrends that are already in place. Additional research is needed to examine the effect of postoperative analgesia on obstructive sleep apnea (obesity), postoperative delirium (elderly), and economic outcomes. It is hoped that drugs to prevent persistent pain after surgery will be developed from the FDA’s Analgesic Clinical Trials Innovations, Actions, and Networks (ACTION) initiative. The FDA’s SAFEKIDS initiative will optimistically make anesthetic drugs safe for infants and children.

**KEY POINTS**

- Postoperative pain is still undertreated. The reasons may be related to multiple factors including heightened awareness leading to an improved identification of undertreatment of pain, the continued lack of pain assessment or documentation, underutilization of more effective analgesic techniques such as regional analgesic techniques, and the lack of adherence to available pain management guidelines.
- The use of regional techniques utilizing a local anesthetic-based analgesic solution may attenuate these pathophysiologic responses to a greater extent than that seen with systemic analgesics. The use of these techniques may be associated with an improvement in some patient outcomes as well as patient satisfaction.
- Utilization of multimodal analgesia, typically a combination of an opioid and nonopioid analgesic with or without a regional anesthetic block, has been encouraged to concurrently reduce opioid-related side effects. Studies on the use of multimodal techniques appear to improve pain management, but the results are not consistent.
KEY POINTS—cont’d

• An increasing number of elderly individuals are having surgery, and there is a higher incidence of postoperative delirium with increased age.
• There continues to be an increase in the incidence of obese adults. Perioperative patients who are obese are potentially at higher risk for postoperative complications.
• The increasing federal debt results in an unsustainable increase in health care spending. There is political pressure to control health care spending, partly through the implementation of clinical programs that allow for high-quality and cost-effective standards in the delivery of clinical care.
• Outcome domains and measurement tools have been recommended by the IMMPACT group. Appropriate measurement tools have been identified for pain, side effects, functional conditioning, emotional functioning, and patient satisfaction.
• The FDA, through its ACTION initiative, promotes public-private partnership to develop drugs and interventions to prevent and treat persistent pain after surgery.
• The FDA’s SAFEKIDS initiative, in partnership with the International Anesthesia Research Society, is a multiyear research endeavor to make anesthetic drugs safer for infants and children.

This chapter is divided in two main sections. The first section addresses the future of pain medicine, and the second tackles the newest trends in pain treatment. The overarching principle guiding the authors of this chapter is the delivery of the highest quality of pain care in a manner that is most consistent with empirical medical evidence. Although the comprehensive treatment of pain has long been a goal of the profession, the practice of pain medicine has become laden with divisions, sub-specialization that has resulted in a field with an unclear core mission. It is also challenged by the definitions imposed by nonpain clinicians. The future of the field of pain medicine relies on greater rigor in at least three domains: (1) defining the medical specialty of pain medicine, (2) educating future pain medicine clinicians, and (3) advancing the basic, clinical, and translational sciences related to the etiology and treatment of pain.

As in this textbook, the practice of pain medicine is often divided into acute, recurrent, and chronic pain medicine (or management). The historical application of this terminology has equated brief episodes of pain (e.g., post-surgical pain) with being an “acute” pain, recurrent, episodic acute pain (e.g., migraine, sickle cell disease), and most other pain conditions with “chronic” pain (associated with persistent cancer and noncancer-related painful disorders). This subtyping by duration is no longer helpful when it is applied to the current, complex, and highly specialized health care environment. For instance, the outpatient pain clinician manages the pain of patients who have recent injuries, thereby fitting the definition of acute pain, not just persistent pain. The hospital “acute” pain service often takes care of patients with persistent pain conditions. As acute, recurrent acute, and chronic (persistent) pain patients are seen in the inpatient and outpatient settings and the employed treatment modalities differ among the populations, the more appropriate distinction may be between the treatment of hospitalized patients with pain and that for nonhospitalized patients with pain.

**RECENT HISTORY OF OUTPATIENT PAIN MEDICINE**

In the late 1960s, an anesthesiologist, John J. Bonica, founded the first multidisciplinary clinic for the treatment of patients with chronic pain. The practice approached pain from biologic models involving neurologists, internists, orthopedists, and neurosurgeons. After much frustration in treating patients debilitated by their persistent pain, Dr. Bonica, at the urging of the behavioral scientist Wilbert E. Fordyce, adopted the biopsychosocial model of the treatment of pain. The behavioral psychology approach of not rewarding pain behaviors (and, in some instances, ignoring the verbal pain complaints and related behaviors such as moaning and facial grimaces) but focusing on rehabilitation and increased function of the patient was integrated into a multidisciplinary pain clinic. Throughout the 1970s, this clinic and others that incorporated the principles used in the original pain clinic were very successful in treating patients with persistent pain. In the early 1980s, the neurosurgeon John Loeser took over Bonica’s pain clinic and credited the interactions between the providers as the reason why patients did so well.

It would be a logical extension to believe that this model would be adopted by pain treatment facilities throughout the United States because of the revolutionary success the multidisciplinary pain clinic had in treating this challenging patient population. The reality was, unfortunately, far from that assumption. Currently, in the United States, there are relatively few truly multidisciplinary pain clinics that involve management of pain in patients in the inpatient and outpatient settings. The architecture and economics of medicine have been redirected in a way that undermines this successful treatment model. The changes that occurred include the increasing cost of health insurance, the shifting of health insurance costs from employers to employees, and the decreasing coverage of a number of health and mental health care services. These changes have negatively impacted the practice of multidisciplinary pain medicine. The health care economic bottom line meant that physicians had to practice reimbursable medicine for pain treatment clinics to remain viable. The paradox is that there is more evidence supporting the clinical effectiveness and cost-effectiveness of multidisciplinary rehabilitation than any traditional medical or surgical treatment for patients with problems of persistent pain.

This economic shift promoted the unidisciplinary model of pain care in the 1990s, in which physicians focused on the treatment algorithm most closely associated with their medical training and specialty. Anesthesiologists focused on interventional analgesic procedures, and opioid and non-opioid adjuvant medications to treat pain reports, taking the biologic approach to pain care. Psychiatrists (physical medicine and rehabilitation) focused on musculoskeletal exams, electrodiagnostic tests, and medical management of pain with opioids. Psychiatrists focused on the medical management of pain, the treatment of addiction disorders resulting from the treatment of pain with opioids and benzodiazepines, and the treatment of psychiatric comorbidities. Psychologists continued to follow behaviorist or cognitive-behaviorist approaches in concert with group...
therapy to teach pain patients coping skills to live with their chronic daily pain in those institutions where financial support existed, but often as adjuncts to biologically based treatments rather than as components of an integrated approach that had been shown to be effective.

In the late 1990s and 2000s, the continued contraction of medical and health care services covered by government and private insurance and a shift in emphasis even further from the integrated, rehabilitation approach to procedures performed have changed the pain medicine landscape again. Across the United States, anesthesiologists further specialized in interventional pain medicine procedures (transforaminal epidural steroid injections, facet joint interventions, radiofrequency procedures, spinal cord stimulation, and intrathecal pump therapy) with a more modest medical management clinic where opioid and nonopioid medications were recommended to others to prescribe. Physiatrists began performing interventional pain therapies copying the anesthesiologist’s interventional model. Psychi- atrists, neurologists, and neurosurgeons reduced or elimi- nated their pain management practices. Pain psychologists became fewer and fewer, and those who remained focused on pain research and small clinical practices. This less inte- grated, silo approach that focused on interventional ther- apies has provided good (though not ideal) care to some patients because of the advancement in some of the pain procedures employed, such as spinal cord stimulation. How- ever, this fundamental conflict has left few options for the significant set of patients with pain that is not amenable to these therapies.

WHERE TO GO FROM HERE?

In going forward, it is essential to reduce the confused termino- logy and purpose:

1. Pain is a distinct disease entity when it is no longer associ- ated with an ongoing injury or the immediate repercus- sions of the injury.
2. The treatment of pain with medications, procedural or surgical therapies, and psychological and physical reha- bitilation are all components of the integrated practice of pain medicine.
3. The goal of pain treatment is not simply to relieve pain but to return the patient to satisfactory physical and psy- chological function.
4. Clinicians with appropriate medical, psychological, or rehabilitative (e.g., physical therapy, social work) training, certification, and credentialing practice within the field of pain medicine. The use of the descriptor “pain management” for the field has led to an overly broad definition of who is able to safely provide these complex pain services and should therefore be retired as a descrip- tor of the practice.

PAIN MEDICINE EDUCATION OF PHYSICIANS

Comprehensive and multidisciplinary education of future pain medicine physicians is paramount to the optimal care of patients. Unfortunately, the training of physicians in pain treatment traditionally had a narrow focus on pharmacological or interventional management, with little more than passing reference to the psychological and physical rehabilitative components of pain treatment. This deficit was recognized on a national level, and in 2007 the Accredita- tion Council for Graduate Medical Education (ACGME) redefined the pain medicine fellowships by setting new stan- dards for achieving the goal of comprehensive pain training. The four medical specialty boards (Anesthesiology, PM&R, Neurology, Psychiatry) administering pain medicine board examinations agreed to a single ACGME-approved pain medicine training fellowship curricula and a single pain medicine subspecialty board examination. In a post-2007 pain medicine fellowship, trainees are required to have training in pain medicine from the medical, rehabilitative, and psychological perspectives. This change in education and certification has been a step in the right direction and has been responsible for the closure of “pain” fellowships that had a predominant or exclusive focus on interventional training. Unfortunately, this unidisciplinary approach to training continues in some of those closed programs as non-ACGME-approved “Interventional Spine” fellowships. This shift has been a disservice to those who train in these programs for numerous reasons including the inability to take the pain medicine board exams as well as to the patients who believe they are receiving care from a comprehensively trained pain physician. Even with these exceptions, the changes made by the ACGME in 2007 have been a good step toward the patient-centered model of multidisciplinary pain medicine developed by John Bonica. However, it is only a single piece of the puzzle.

Additional changes include a future match program for pain medicine fellowship positions that has been approved by the Association of Pain Program Directors. The match should provide a better opportunity for applicants to get their desired training program. For pain medicine clini- cians, patient simulation will be included in future mainte- nance of certification accreditation (MOCA) requirements. Although simulation training is now offered in regular anesthesiology recertification testing and has been proven to be successful, it is new in pain medicine. The American Society of Anesthesiologists Committee on Simulation has already approved simulation centers and aims to establish testing centers in different regions in the country. The cur- riculum and case scenarios for simulation in pain medicine have been aptly described by Brenner and colleagues.

FUTURE OF PAIN MEDICINE

The appropriate changes in pain medicine education have not been accompanied by reform of the reimbursement methodologies. Our insurance system is still heavily biased toward remunerating for procedures and not for clinician decision making. It is also biased toward reports of pain relief and not toward the increased functionality of pain patients. The face of pain medicine will likely change to more of a patient-centered model of reimbursement. We have seen the beginnings of this shift, in which Medicare has begun to associate payment to physicians and hospitals with qual- ity metrics (e.g., refusing to pay for readmission resulting...
from iatrogenic infections). The future of pain medicine will progress to paying for therapeutic approaches that have successfully returned patients to function and a resumption of their activities of daily living. Based on the positive historical experience of the Bonica-style pain programs, the multidisciplinary model with inpatient and outpatient treatment might be the best goal. The challenge of revisiting this model is the costs associated with these programs in light of little or no reimbursement for these services. The questions that remain include, can the cost-efficiencies of modern medicine be applied to the old model of comprehensive pain medicine, and will the insurance companies recognize its long-term cost savings and pay for the services in order to make the old model fiscally viable? With respect to chronic low back pain, the answer may be yes.3

The manner of education and the modalities used in pain medicine will continue to change, as previously addressed, and the manner in which research or lack thereof influences our practice will become foremost concerns. Physician experience and medical teaching are becoming less and less acceptable rationales for the treatments pain physicians employ. The question is that a substantial number of treatments have few rigorous data to support their use. And unfortunately, even when evidence exists, it is often ignored. One of the most common procedures in pain medicine, the epidural steroid injection for back and extremity pain, has been shown to have no benefit for axial low back pain, minimal benefit for back pain associated with spinal stenosis, and moderate short-term benefit for extremity pain related to disk herniation.4 Yet a subset of physicians continue to perform steroid injections for low back pain and promise long-term benefit for radicular symptoms in spite of studies that showed its short-term efficacy.5 The medicinal treatment of radicular symptoms is managed as though they are the same as neuropathic pain of disparate etiology including diabetic and postherpetic neuralgia, yet evidence of the efficacy of the most commonly used medications is minimal.6 These are only two examples of misguided therapies. The challenge will be to produce evidence of effectiveness and safety for medications and procedures that are etiology specific, cost-effective, and widely applicable.

PHARMACOLOGICAL MANAGEMENT OF CHRONIC PAIN

This section deals with topics that were not discussed or emphasized in the previous chapters on pharmacological management. The management of cancer pain will probably remain as it has been (i.e., opioid as the mainstay of treatment in combination with other medications including the anticonvulsants). It is in the area of chronic noncancer pain (e.g., osteoarthritis, diabetic painful neuropathy) where drugs that are effective with minimal side effects are being constantly sought. Guidelines from groups of well-respected experts have been proposed in the management of neuropathic pain. These include the European Federation of Neurological Sciences (EFNS), the International Association for the Study of Pain (IASP) NeuPSIG, and the Canadian Pain Society.7,9 The guidelines recommended the anticonvulsants, serotonin and norepinephrine reuptake inhibitors (SNRIs), and antidepressants as the first-line treatments for neuropathic pain. More recent data, coupled with the SNRIs reduced side effects, made the EFNS and the IASP NeuPSIG recommend these as the first-line drugs. These guidelines continue to evolve based on the results of randomized controlled studies.

Pregabalin, with its linear pharmacokinetics, quicker analgesic onset than gabapentin,10 and efficacy with lower doses,11 will continue to be used. Although pregabalin and gabapentin are well known, lacosamide has been shown to be effective in diabetic painful neuropathy (DPN).12 Its clinical use in DPN is awaiting approval from the United States Food and Drug Administration (FDA).

The SNRIs are definite improvements over the tricyclic antidepressants, particularly in their side effect profiles. Milnacipran lacks anticholinergic, antihistaminic, and alpha-adrenergic receptor blocking activity; is weakly protein bound; and has no effect on the P450 system, resulting in fewer drug interactions.13,14 Randomized controlled studies in fibromyalgia showed positive results with improvements in fatigue, physical conditioning, and discomfort.14,15 A combination of drugs with different mechanisms of action maybe more effective than any drug alone. Randomized controlled studies showed beneficial effects when drugs with different mechanisms of action are combined. The combination of gabapentin and morphine in patients with postherpetic neuralgia (PHN) and DPN resulted in less pain, lower doses, and fewer side effects from the drugs.16 The same salutary effects were noted with the combination of gabapentin and nor- triptyline,17 gabapentin and lidocaine plaster for PHN/DPN,18 and gabapentin and oxycodone in DPN.19 For neuropathic cancer pain, a combination of opioid and gabapentin was noted to be more effective than opioid monotherapy.20 However, not all drug combinations showed positive results. No beneficial effects were noted when pregabalin and oxycodone were combined in the treatment of PHN or DPN21 or with morphine and nor-triptiline for lumbosacral radiculitis.22 Whether the lack of additive effects with the combination was due to the dosages used (the doses of pregabalin in the study by Zin and colleagues were up to 600 mg/day, whereas the oxycodone dose was 10 mg/day) or to inappropriate drugs being used (radiculitis may not respond to antidepressants) is not known. More studies are needed to determine which drug combinations work best in which chronic pain syndrome. Moreover, in addition to concerns about the side effects of individual medications, with drug combinations there is the added concern about potential drug-drug interactions among some of the medications most frequently combined (such as opioids that also have serotonergic effects, e.g., tramadol and tapentadol, and selective serotonin reuptake inhibitors [SSRIs] and SNRIs where serotonin syndromes may be created by the combination).

For neuropathic pain, clinicians are using nonsteroidal anti-inflammatory drugs (NSAIDs).23 Although animal models showed the efficacy of NSAIDs for neuropathic pain treatment,24 clinical studies showed some efficacy,25,26 no efficacy,27 or inconclusive results.28 The unequivocal results call for randomized studies on the role of NSAIDs in neuropathic pain. However, there are significant concerns about NSAIDs because of their gastrointestinal and renal toxicities, and there are concerns about the cardiac effects of the newer cyclooxygenase-2 inhibitor (COX2) drugs.29
It is important to note that regardless of the medication used to control pain, the actual benefits, while statistically significant, are modest, with fewer than 35% of patients obtaining at least a 50% reduction in pain. Moreover, the effects of even the most recently developed medications have shown that they do little to improve physical functioning.

**INTRAVENTOUS INFUSIONS AND TOPICAL ANALGESICS**

Intravenous infusions, especially ketamine, are being used more frequently and studies have shown their efficacy. Unfortunately, these publications were either case series or retrospective studies or consisted of patients with different pain syndromes. It is in the treatment of complex regional pain syndromes that controlled studies showed the efficacy of ketamine infusions. Randomized controlled studies are welcome. These studies should involve specific pain syndromes (e.g., spinal cord injuries) and the doses and duration of infusions sought, especially as there may be hepatotoxicity from the infusion; the mechanism of hepatic injury should also be investigated.

The high-dose capsaicin patch is an improvement over the low-dose patch and needs to be applied only every 3 months. The patch has been shown to be effective in the treatment of PHN, DPN, and human immunodeficiency virus (HIV) neuropathy. However, it is expensive and its application is painful even when a local anesthetic cream is pre-applied. Topical clonidine gel was noted to be effective in DPN patients with functional (and possibly sensitized) nociceptors in the affected skin. The use of topical dextropin or topical doxepin and capsaicin was noted to be superior to placebo in treating neuropathic pain. A randomized study showed topical ketamine, amitriptyline, or a combination to be effective for patients with neuropathic pain. Open-label studies on topical amitriptyline and ketamine for neuropathic pain showed encouraging results. The same results were noted with topical ketamine for PHN. More controlled studies are required, especially in view of the advantages of drugs applied topically or as patches in patients who cannot tolerate oral medications.

**PRESCRIPTION PATTERNS OF PAIN MEDICINE PHYSICIANS**

It is gratifying to note that the prescription patterns of pain physicians reflect evidence-based treatments. Most ask for opioid agreements, electrocardiograms (ECGs) are ordered when methadone is prescribed, the maximum dose of acetaminophen is decreased in moderate alcohol drinkers, opioids are prescribed for cancer pain, and the majority follow the guidelines recommended by the EFNS and the IASP’s NeuPSIG (i.e., anticonvulsants and SNRIs followed by drug combinations). However, several gaps in knowledge were also identified, including the prescription of codeine for patients who have difficulty metabolizing codeine to its active morphine metabolite (i.e., Caucasians, Asians, and pediatric populations). Although only a small percentage responded that they prescribe carisoprodol, this drug is metabolized to meprobamate, which causes dependence and has been shown to be no more effective than placebo. It would be interesting to know the prescription patterns of primary care physicians who take care of most pain problems.

Although opioids are the most commonly prescribed medication for pain, prescriptions for chronic, noncancer pain patients are more controversial. This class of medication may have significant and unintended effects on immune and hormonal function and there is some evidence of the paradoxical effect of opioid-induced hyperalgesia. There are also growing concerns about the misuse and abuse of these drugs. Moreover, opioids appear to have little effect on improving physical functioning. Finally, there is no long-term evidence of the analgesic benefits of opioids.

**INTERVENTIONAL PAIN PROCEDURES**

**DISK HERNIATION, SPINAL STENOSIS, AND INFLAMMATORY MARKERS**

Disk herniation results in the release of phospholipase A2 (PLA2), resulting in the production of prostaglandins. Increased levels of inflammatory cytokines interleukin (IL)-6 and IL-8 were noted in disk materials taken from patients with known disk disease. Cytokines such as IL-1 and IL-6 and tumor necrosis factor alpha (TNF-α) have been strongly linked to radicular pain. IL-1 beta, IL-6, and TNF-α have been noted to increase the discharge rates and mechanosensitivity of the dorsal root ganglion and peripheral receptive fields in rats. Disks express TNF-α, which causes morphologic and functional changes when applied to spinal nerve roots. Levels of IL-6 in the cerebrospinal fluid (CSF) of patients with radicular pain from spinal stenosis correlated with the degree of spinal stenosis.

These studies led investigators to inject TNF-α inhibitors into the epidural space of patients with a herniated disk or spinal stenosis. Studies of epidural etanercept or tocilizumab, a TNF-α inhibitor and an anti-IL6 receptor antibody, respectively, showed some efficacy. The epidural injection of etanercept has been shown to have salutary effects, in terms of pain and numbness, in patients with a herniated disk or spinal stenosis. The epidural injection of tocilizumab decreased low back pain and numbness in patients with spinal stenosis. The follow-ups in these studies were for 1 month or 6 months. These beneficial results should be contrasted with the findings that intravenous infliximab had similar efficacy as placebo in relieving lumbar radicular pain from a herniated disk. More studies are needed in this area, especially to evaluate the risks involved; patients on TNF-α inhibitors are prone to infection.

**EPIDURAL STEROID INJECTIONS**

**CNS INJURIES AFTER TRANSFORAMINAL EPIDURAL STEROID INJECTIONS**

Epidural steroid injections (ESIs) are given to patients to relieve low back and radicular pain. It has been postulated that inflammatory changes in the nerve root cause the pain, and nerve root edema has been demonstrated on computed tomography (CT) scans of patients with herniated disks. The rationale for ESIs includes their anti-inflammatory effect and a specific anti-nociceptive effect. The results
of studies on epidural steroids were not uniform. Overall, the studies showed short-term relief.\(^5\)

There have been reports of central nervous system (CNS) injuries, including spinal (paraplegia) and brain (brainstem hemorrhage and cerebellar infarct) events. These unfortunate events are probably secondary to arterial injury (trauma or spasm) or embolism of the particulate steroid.\(^6\)\(^1\) The ascending and deep cervical arteries have been shown to send medullary branches to the anterior spinal artery; these two arteries anastomose with the vertebral artery and are very close to the superior articular process, a landmark in transforaminal epidural steroid injections.\(^6\)\(^2\) Intravascular injection of the contrast into the radicular artery accompanying the nerve root has been demonstrated.\(^6\)\(^3\) Injection of the particulate steroid into the anterior spinal artery (through the medullary branches or the radicular artery) or into the vertebral artery (through the ascending and deep cervical arteries) is possible.

Particulate steroids cause more problems than nonparticulate steroids. The CNS injuries reported with nonparticulate injectates were temporary,\(^6\)\(^4\)\(^6\)\(^5\) compared to permanent injuries with the particulate injectates.\(^6\)\(^1\) Animal studies support the catastrophic lesions/events associated with particulate steroids in comparison to nonparticulate injectates. Animals injected with the particulate steroid became unconscious and required ventilator support\(^6\)\(^6\) or showed cerebral hemorrhage.\(^6\)\(^7\) In contrast, the animals injected with dexamethasone, a nonparticulate steroid, had no evidence of injury and had full recovery.

The reported cases of CNS injuries led a Working Group of Experts and the FDA Safe Use Initiative to formulate recommendations on the prevention of these injuries. The recommendations will probably include knowledge of the anatomy, use of live fluoroscopy or digital subtraction technology (DST), ability to correctly interpret the images, use of nonparticulate steroids in cervical transforaminal injections, and others. Obviously, particulate steroids are acceptable in interlaminar injections. These recommendations will come out in late 2013 or early 2014.

**COMPOUNDING STEROIDS**

Some physicians use compounded depot steroids for epidural injections to avoid the vehicles and preservatives in the depot steroid and for reasons of price. Avoidance of the preservatives is unnecessary, as the studies on the neurolytic lesions caused by these preservatives used concentrations that were 8- to 10-fold higher than the concentrations of these preservatives in the depot steroids.\(^5\)\(^8\)\(^7\) A case report of flaccid paralysis occurred after an unintentional subarachnoid injection of 40 mL of 0.9% NaCl that contained 1.5% benzyl alcohol.\(^7\)\(^1\) In addition to the lower concentrations of the preservatives in the commercially available steroids, the steroid is diluted with 1 to 3 mL of saline or local anesthetic, further decreasing the concentrations of the preservatives.

An outbreak of fungal meningitis occurred after an epidural injection of compounded methylprednisolone.\(^7\)\(^2\)\(^7\)\(^3\) The episode was traced to contaminated steroid produced by the New England Compounding Company, exposing the lax regulations that oversee compounding companies.\(^7\)\(^4\)\(^7\)\(^6\) Clinicians will continue to use compounded medications because of the lack of availability of other medications (e.g., oral ketamine, intrathecal pump drugs) or because of their lower cost. Pain medicine interventional physicians can assure themselves of a safe product by purchasing compounded drugs from companies accredited by the Pharmacy Compounding Accreditation Board. A list of accredited companies is available on the agency’s website (www.pcab.org). There are now bills pending in Congress mandating supervision of compounding companies by the FDA instead of the state where they are located.

**OTHER INTERVENTIONAL PROCEDURES**

Minimally invasive lumbar decompression (MILD) procedures for symptomatic central lumbar canal stenosis have been described, wherein the hypertrophied ligamentum flavum is thinned percutaneously. An initial review of the safety of MILD showed no incidents of dural puncture, nerve injury, hematoma, or blood transfusion.\(^7\)\(^7\) A 1-year follow-up of results showed a decrease in pain scores and improvements in the Oswestry Disability Index.\(^7\)\(^8\) Zurich Claudication Questionnaire, and SF-12 Health Survey.\(^7\)\(^9\) There were no major device-related or procedure-related complications. These great results were questioned by a single-center experience of complications including nondecompression of supposedly decompressed levels, persistent neurogenic complications, cerebrospinal fluid (CSF) leak, and transected nerve roots.\(^8\)\(^0\) Obviously, more prospective studies are required to determine the long-term efficacy and complications associated with this procedure.

For intrathecal pain management, an interdisciplinary panel of experts published recommendations that included the proper methods of trialing for long-term intrathecal drug delivery; an update of the algorithms for the rational use of intrathecal medications for the treatment of neuropathic and nociceptive pain; guidance on the how to minimize the risk of respiratory depression, infection, granuloma, device-related complications, endocrinopathies, and human error; and instruction on the prevention, diagnosis, and management of intrathecal granulomas.\(^8\)\(^1\)\(^8\)\(^4\) No new pharmacological developments are anticipated in the near future.

**PSYCHOLOGICAL TREATMENT OF PATIENTS EXPERIENCING PAIN**

Research performed since the 1990s confirms that psychology-based pain treatments (e.g., cognitive-behavior therapy, relaxation, positive reinforcement of activity, exposure to activities avoided, realistic goal setting) are more effective than no treatment, standard care, and treatment conditions that control for the effects of time, therapist attention, and treatment outcome expectancies (such as pain education or relaxation training only). However, despite the fact that different treatments are often based on different theoretic perspectives, most psychological treatments result in similar outcomes,\(^8\)\(^5\) and not one of them completely eliminates pain for the majority of patients.\(^8\)\(^6\) However, this is not unique to psychological treatment. Of all treatment modalities, the pharmacological and nonpharmacological, the best evidence for pain reduction averages approximately 30% to 40% in approximately half of treated patients, and this does not always occur with concurrent improvement in physical and emotional function.\(^8\)\(^7\) Thus, none of the most commonly prescribed treatment regimens, by themselves,
are sufficient to eliminate pain and to have a major impact on physical and emotional functioning in the majority of patients with persistent pain. This is hardly surprising given the complexity of pain and the myriad of psychological, contextual, historical, and genetic along with neurophysiologic factors involved. In the absence of a cure, there is a need to maximize symptom relief so that patients are able to lead the highest quality of life possible.

Although psychological factors have been demonstrated consistently to play an important role in one’s perception and response to acute and postsurgical pain, the greatest emphasis of psychological treatments has been to help patients manage, cope with, and adapt to the presence of persistent pain and its associated symptoms. Consequently, rarely are psychological treatments applied in the absence of medical and pharmacological treatments for patients with chronic pain.

We anticipate several trends and directions for the application of psychological treatments and psychological principles in the management of patients with persistent pain in the future, specifically (1) combination treatments, (2) matching of treatment components to specific patient characteristics, (3) development and use of maintenance-enhancing strategies based on psychological principles and technological advances, and (4) availability of psychologists and reimbursement. We outline these approaches in the following sections.

**COMBINATION TREATMENTS: PHARMACOLOGICAL AND NONPHARMACOLOGICAL TREATMENTS**

Turk\(^{88}\) suggested that the combination of pharmacological and nonpharmacological interventions (somatic, behavioral) might be particularly advantageous given the nature and impact of pain syndromes and the fact that cure is rarely possible and therefore patients will need to learn to cope with at least some level of pain. Several studies have reported on the additive benefits of pharmacological and psychological treatments\(^{89-91}\) where combinations had a greater effect than either the pharmacological or the psychological treatments alone.

Interdisciplinary pain rehabilitation programs, by definition, are combination treatments in that they often combine psychological and physical treatment approaches, medications, and at times other interventions.\(^{92}\) Meta-analyses and systematic reviews have provided support for both the clinical effectiveness and cost-effectiveness of such interdisciplinary treatment programs.\(^{93,94}\) However, to date few studies have been designed to dismantle these comprehensive treatments in order to determine the necessary and sufficient treatment components or identify the characteristics of patients most likely to benefit from intensive rehabilitation programs.

One systematic review recommended cognitive interventions combined with exercise for chronic low back pain,\(^{95}\) and two evidence-based clinical practice guidelines recommended the combination of medication, exercise, and cognitive-behavioral therapy (CBT) for fibromyalgia patients.\(^{96,97}\) If research confirms the initial positive results, various combination treatments may become common practice.

**RESPONDERS AND TREATMENT MATCHING**

Pain patients are typically bundled into classifications based on pain location (e.g., head, neck, back) or known pathology (e.g., neuropathic) and treated as if they were a homogeneous group. Patients with persistent pain, however, even when they have the same diagnosis, are heterogeneous and differ from one another on many important variables (e.g., demographic, symptom presentation, psychosocial style, and adaptation).\(^{98}\) Indeed, patients’ responses to a standardized interdisciplinary treatment vary based on each individual’s psychosocial and behavioral characteristics.\(^{99,100}\)

It is important to consider that treatment responses depend on a range of individual differences, and no one approach is likely to benefit all patients. Matching patients to particular treatments based on relevant predictive characteristics would probably be ideal, if we had knowledge of the appropriate matching variable. Research can be conducted to identify treatment responders (e.g., 30% improvement in pain severity, 20% improvement on a functional outcome) and then use regression analyses to identify the characteristics (predictors) of treatment response. For example, Thieme and colleagues\(^{101}\) identified different pretreatment characteristics that were associated with different response rates to cognitive-behavior therapy, relative to a treatment based on operant conditioning. A prospective study can then be conducted to determine whether treatments customized to address specific patient characteristics do, indeed, produce the desired effects. Research in this area can provide an empirical basis for prescribing treatments to those most likely to benefit, and it can serve as an impetus for the development of treatments that will match the characteristics of patients who may not have responded. This strategy would improve patient outcomes and would be more cost-effective than the current approach of treating all patients with the same treatment—the treatment selected based on the preferences and training of the providers rather than the results of clinical trials. There is a great need for research that goes beyond asking whether a particular treatment is effective to addressing what treatment is effective for which patients, and under what circumstances.

To maximize efficiency, improve outcomes, control costs, and reduce patient burden, the research needs to identify treatment responders and the components of the treatment that make the greatest contribution to successful outcomes. In the future, clinicians need to focus more on patient-centered approaches so that they can tailor treatment approaches to patient characteristics. We anticipate that this will be a focus of great interest.

**ADHERENCE AND MAINTENANCE OF EFFECTS**

A general caution about all symptomatic treatments is that of maintenance. Treatments that are tested in clinical trials are rehabilitative, not curative, and rely for their continued success on patient self-management. It is reasonable to assume that patients will continue to manage some pain and disability and that they will experience inevitable flare-ups. Maintenance of therapeutic efforts by patients is critical for
long-term success. However, significant problems can arise related to adherence to self-management programs and maintenance of initial positive benefits over long periods of time—years, if not decades. Studies that have examined maintenance of lifestyle changes (e.g., weight loss, smoking reduction, reduction of substance abuse) have demonstrated significant relapse rates. It is naïve to assume that benefits from brief treatments for patients with pain will be maintained unless the benefits are sufficiently reinforcing; otherwise, relapse will be a significant problem. Thus, strategies are needed to facilitate adherence to long-term change. Psychological principles have been used as the bases for maintenance enhancement strategies and may guide and be incorporated into treatments over time.

TECHNOLOGICALLY ENHANCED VIRTUAL TREATMENTS

It is inconvenient for some patients with significant physical impairments to travel to treatment programs that extend over time and that may be at great distances from their homes. Importantly, as noted previously, none of the currently available pharmacological, medical, or psychological treatments are able to provide cures for the majority of people who experience persistent pain, although many can offer patients a reduction in symptoms and improvements in psychological impairments to travel to treatment programs that extend over time—years, if not decades. Studies that have examined maintenance of lifestyle changes (e.g., weight loss, smoking reduction, reduction of substance abuse) have demonstrated significant relapse rates. It is naïve to assume that benefits from brief treatments for patients with pain will be maintained unless the benefits are sufficiently reinforcing; otherwise, relapse will be a significant problem. Thus, strategies are needed to facilitate adherence to long-term change. Psychological principles have been used as the bases for maintenance enhancement strategies and may guide and be incorporated into treatments over time.

The availability of appropriately trained therapists to provide psychological treatments for patients with pain is often limited to large urban areas and academic centers. Thus, in the future telehealth may become essential for patients who seek the services of psychologists. There are and will likely continue to be concerns about the availability of psychological services, whether remotely or at the point of care. This chronic problem occurs despite substantial evidence demonstrating both the clinical utility and cost-effectiveness of behavioral health strategies. How best to address the evidence-based paradox—more evidence to support the benefits of behavioral health interventions as part of interdisciplinary programs than most alternative treatments for chronic pain, coupled with a denial of payment—remains unresolved.

In addition to the use of advanced technologies to take advantage of psychological interventions, there are a number of important psychological principles that all health care providers can use—for example, paying attention to provider-patient communication, with particular attention placed on providing realistic expectations for treatment, identifying and addressing patient concerns and fears, emphasizing self-management in the absence of complete symptom elimination, stressing the importance of adhering to the treatment plan, and offering positive reinforcement to patient efforts, not just outcomes. Psychologists may serve as consultants to other health care providers even when they do not deliver services directly to patients. This consultant role may be an important one in the future.

SUMMARY AND CONCLUDING COMMENTS

There are exciting new developments in pain medicine, including the areas of education and training (e.g., the match program for pain medicine fellowships), accreditation (MOCA), pharmacological advances (guidelines from respected groups of experts), and interventional management approaches (patient safety, the MILD procedure, recommendations from the interdisciplinary expert panel on intrathecal drug management). The American Society of Regional Anesthesia (ASRA) is in the process of formulating guidelines on interventional pain procedures for patients on anticoagulants. When appropriate, a combination of psychological and nonpsychological (pharmacological, interventional, rehabilitative) treatments is more effective than either treatment alone. Rapidly evolving technologies may address the long-term maintenance of patients’ improvement. We cannot predict the specific areas where future developments will occur. However, some developments are on the horizon (Box 83.1). Pain medicine has become an exciting specialty. In view of the talented trainees, researchers, and young faculty entering the field of pain medicine, the future is promising.
pain are going to have to consider the psychosocial and environmental factors as well as the medical ones. By the time patients come to the attention of pain specialists, they have had long learning histories and unique phenotypes. Moreover, they do not live in isolation but in a psychosocial context with many external influences that have an impact on their reports of pain, their adaptation to their plight, and how they respond to treatment. It is not a body part that needs to be treated, but that body part as part of a whole person with a history, who lives in a societal context. Failure to adopt this broader, biopsychosocial perspective may explain the inadequacies of treatment for those with intractable chronic pain in contrast to inpatients with brief episodes of pain (e.g., postsurgical).

**Box 83.1 Possible Future Developments in Education and Pharmacological, Interventional, Rehabilitative, and Psychological Management in Pain Medicine**

**Education**
- Greater integration of psychological and rehabilitative modalities into education of pain medicine fellows
- Match program in pain medicine fellowships
- Maintenance of certification accreditation (MOCA) using simulation
- Eventual development of pain medicine into its own independent multidisciplinary specialty

**Pharmacological and Interventional Management**
- Update of the different guidelines on the treatment of neuropathic pain
- Controlled studies on intravenous infusions and topical treatments
- Studies on treatment combinations for different chronic pain syndromes
- Education of primary care physicians on evidence-based pharmacological management of the different chronic pain syndromes
- FDA Safe Use Initiative and Working Group recommendations on the safety of transforaminal epidural steroid injections
- Improved regulation of compounding companies
- ASRA recommendations on interventional pain procedures in patients on anticoagulants

**Psychological Rehabilitation Management**
- Combination with pharmacological and interventional modalities
- Identify predictors of favorable response to treatments
- Match treatment or components of treatment with patient characteristics
- Long-term maintenance of positive response to treatment

There is a growing awareness that single treatments are inadequate for patients with persistent pain. Combinations of medications and, perhaps even more important, of pharmacological and nonpharmacological modalities may provide the greatest outcome for the greatest number of patients with recalcitrant conditions. The pendulum appears to be swinging back to the patient-centered approach characteristic of multidisciplinary treatments from monotherapies. There is growing evidence of both the clinical benefit and cost-effectiveness of these programs for those who do not achieve sufficient relief from biomedical treatments alone. Cost-effectiveness is an important issue to address in research and to communicate to payers. Outcomes other than subjective ratings of pain reduction are becoming essential, and clinicians are going to have to provide evidence that the treatments they offer also reduce health care consumption, return people to improved function (including, when appropriate, to gainful employment), and close disability cases.

Comprehensive programs that adopt the biopsychosocial perspective and that are multidisciplinary may be the best alternative. Practitioners who treat patients with persistent pain can become a distinct disease entity when it is no longer associated with an ongoing injury or the immediate repercussions of the injury.

**KEY POINTS**
- The treatment of pain with medications and procedural or surgical therapies is probably inadequate, at least for patients with persistent pain, and thus the practice of pain medicine needs to be multidisciplinary and must include clinicians such as physical therapists and psychologists as well as representatives from a number of other medical specialties.
- Physicians with appropriate medical training, board certification, and credentialing do practice pain medicine, but as part of a multidisciplinary environment. The use of the descriptor “pain management” lacks precision and opens an inappropriate discussion on who may provide these health care services, and the term should therefore be retired.
- Integrated, rather than fragmented, treatment of pain patients ideally focuses on the multidimensional nature of pain within a biopsychosocial context.
- Favorable changes in the education of trainees and maintenance of accreditation include the adoption of a match program and the addition of simulation.
- Although the norepinephrine reuptake inhibitors and anticonvulsants are advancements over the traditional nonsteroidal anti-inflammatory drugs and opioids by themselves, they are often inadequate for the treatment of patients with persistent pain and need to be used in combination with other pharmacological and nonpharmacological interventions.
- There are gaps in the knowledge of pain medicine physicians regarding the safe and effective treatment of patients with persistent pain.
- The Food and Drug Administration Safe Use Initiative and a Working Group of Experts, together with some of the national pain organizations, will have recommendations on improving the safety of transforaminal epidural steroid injections.
- There will be improved regulations on the safety of compounding depot steroid and other drugs for pain management.

neuraxial. See Neuraxial analgesia
patient-controlled. See Patient-controlled analgesia (PCA)
for post-herpetic neuralgia, 352–353, 352t
for postoperative pain intermuscular, 285–286
perineural, 278–280, 281t, 283t. See also Nerve blocks for postoperative pain peripheral, 278–279
systemic opioid in, 272–274, 272t
systemic opioids in, 272–274, 272t
preemptive, 299t
preventive, 271, 299t
procedural sedation and, in emergency department, 1012–1014
at end of life.
Analgesic agents combination, for mild to moderate pain, 512
in emergency department, 1010–1014, 1011t
intrathecally, 286–287
minor, 508–529, 509f
over-the-counter, 508
for pain management in children, 305–306
at end of life
nonopioids, 1030–1032
opioids, 1031, 1032t–1033t
impaired driving due to, 74–75
increasing global access to, 49, 50f–52f
opioids, 509t
opioids for pain management during pregnancy, 477–480, 479t
for pain during pregnancy, 481
for post-herpetic neuralgia, 533–534
Amplitude, electromyographic, 166
Amygdala, excitability of, in persistent pain, 395–396, 395t
Antibiotics, prophylactic, in vertebral augmentation, 922–924
Anterior horn cell disease, EMG evaluation of, 173
Anterior View, 395–396, 395t
Anterolateral cordotomy, for intractable pain management, 330
Anthrakinic acid derivatives, 560
Antibiotics, prophylactic, in vertebral augmentation, 542
Antihistamines, 598
Antihypertensive agents
for CRPS type 1, 456–457
Anesthesia general, history of, 6–7
for intrathecal pump implantation, 958
for pain management, in children, 307–309
Anxiolytics, osteoarthrosis and, 433
Anulal fibrosis anatomy of, 886
denervation of, 915–916, 916f. See also specific procedures
Anterior horn cell disease, EMG evaluation of, 173
Anterior interosseous syndrome, 173
Anterior meniscus syndrome, 172
Anterior spinocerebellar, 1088
Anterior spinal artery syndrome, after epidural anesthesia, 1011t
Anterior tibial nerve syndrome, 1011t
Anterior View, 395–396, 395t

Anthrakinic acid derivatives, 560
Antibiotics, prophylactic, in vertebral augmentation, 542
Antihistamines, 598
Antihypertensive agents
for CRPS type 1, 456–457
INDEX

Bruxism, 435

BPI. See Brief Pain Inventory (BPI)

Brachial plexus, somatosensory evoked potentials and, 182

Brachial plexus anatomy of, 280f, 716, 717–718 stimulation of, expected motor response in, 717

Brainstem auditory evoked potentials (BAEPs), 177–179 abnormalities in, 179f clinical utility of, 178–179 method of, 177–178, 178f, 178t

Brainstem lesions, somatosensory evoked potentials and, 182–183

Breakthrough pain

Breast milk antidepreser excretion into, 481 drug accumulation in, 474–475, 477 opioid excretion into, 480. See also Lactation

Breast surgery chronic pain following, 300–301, 300t paravertebral nerve blocks for, 748, 748b

Brief Pain Inventory (BPI), 64, 247f–248t, 251

Bronchospasm, fluoroscopic contrast agent-induced, treatment of, 991t

Bruxism, 435

Budapest criteria, for diagnosis of CRPS, 346, 347b

Bulbospinal pathways activation of, 105, 106f projection systems, 109–110

Bupivacaine infusion of for knee surgery, 770, 771t for shoulder surgery, 771–772, 771t during pregnancy, 480

Buprenorphine in brachial plexus nerve blocks, 719 enzymes involved in metabolism of, 136f for opioid dependence in pregnancy, 478, 489–490 sublingual, in addiction treatment, 679 transdermal advantages of, 503 for pediatric pain, 462

Bupropion, analgesic effect of, 539, 540f

Burn injury analgesia for, 294–296, 295t nonopioids as, 295–296 opioids as, 295 psychological support after, 296

Burns

Burnings mouth/tongue disorder, 427–428, 428t

Calcium channel blockers for lumbar spinal stenosis, 321 for herniated disk, 317

Calcium channel subunits, voltage-sensitive, 586t

Calcium channel blockers for spinal cord injury pain, 389, 389t

Calcium channel blockers intraspinal analgesia as, 1004–1007 pharmacologic analgesia in, 1004–1007 for CPSP syndrome, 380–381 gabapentinoids as, 1006–1007 gabapentinoids as, 1006–1007 opioid respiratory depression as, 1007

Calcitonin gene–related peptide (CGRP) in inflammation, 118 in spinal cord dorsal horn, 90–91, 90f

Calcium channel blockers neuronal delivery of, 585–586, 585b, 586t for spinal cord injury pain, 389, 389t voltage-gated, for neuropathic pain, 543–547

Camphor, counterirritant activity of, 527t, 528

Canadian Occupational Performance Measure (COPM), 646–647

Capsaicin counterirritant activity of, 527t, 528 for neuropathic pain, 578 for post-herpetic neuralgia, 352t, 353, 578 studies of, 665 Carbamazepine (Tegretol) for CPSP syndrome, 380–381 dosing recommendations for, 544t properties of, 544t, 548

Cardiac causes, of chest pain, in children, 460, 460f

Cardiac pain, neuroimaging of, 125

Cardiac surgery, paravertebral nerve blocks for, 748, 748b

Cardiovascular disorders corticosteroid-induced, 602 NSAID-induced, 563–564, 564f, 566t CARF (Commission on Accreditation of Rehabilitation Facilities), 8

Carisoprodol (Soma), properties/dosages of, 560–570, 570t
INDEX
Carpal tunnel syndrome, 157
acupuncture for, 655–656
oral glucocorticoids for, 522
Case-control studies, in clinical outcomes
research, 1060
Cataracts, corticosteroid-induced, 601
Catastrophic thinking, in chronic pain
patients, 145–146, 619

Intravenous ketamine infusion(s) for pain management, 1081
Standardized order set, 24f
Intravenous patient-controlled analgesia (IV PCA). See Patient-controlled analgesia (PCA)
Intravenous regional anesthesia, for postoperative pain, 281l, 282–283
Intrinsic inhibitory control, loss of, 110
Inventories, in pain assessment, 244–245
IOM. See Institute of Medicine (IOM)
Iontophoresis in drug delivery, 524–525
For pain relief, 635
Irritable bowel syndrome (IBS), properties of, 551
Ischemic injuries, during epidural steroid injections, 813–815, 814f
ISIS (International Spine Intervention Society), 10

J
Jendrassik maneuver, 153
Joint injections. See Intrathecal joint injections
Jones Act (Merchant Marine Act), 262t, 263
Justice, in research ethics, 1066

K
Karnofsky scale of performance status, 336t
Ketamine for burn pain, 295–296, 295t, 1005
For complex regional pain syndrome, 350
For CPSP syndrome, 38l
For ED procedural sedation and analgesia, 1013
Intrathecal delivery of, 778–779
Neuraxial delivery of, 589f, 590–591
For palliative sedation, 1036–1037
For postoperative pain, 272t, 275, 302–303
For trauma patient, during transport, 291–292
Ketoprofen
Properties/dosages of, 559
Topical, for osteoarthritis, 526
Ketorolac
Intrathecal delivery of, 286–287, 777, 777t
Neuraxial delivery of, 591, 591b
During pregnancy, 477
Properties/dosages of, 558–559

Kneading (pétissage), for pain management, 638
Knee
Anatomy of, 977
Examination of, 158–159
Special tests for, 159
Intrathecal injection of efficacy of, 979
Fluoroscopically-guided, 977–978, 978f
Indications for, 977
Palpation-guided, 977
Ultrasound-guided, 978–979, 978f
Knee pain, acupuncture for, 655
Knee surgery
Continuous femoral nerve block for, 737
Intrathecal analgesia for, local anesthetics as, 770, 771t
Intravenous regional anesthesia for, 282
Kummel’s disease, 928–929
Kyphoplasty
Injectable bone cement in, 610–611
For vertebral compression fractures, 923f
Balloon inflation in, 927f
Needle placement in, 925–926, 927f
Procedures for, 928

L
Labeling effect, in imaging studies of spine, 190
Lacosamide (Vimpat), properties of, 550
Lactation. See also Breast milk
Anticonvulsant use during, 482
Benzodiazepine use during, 481
Caffeine use during, 482
Corticosteroid exposure during, 482
Migraine headaches and, 488
NSAID use during, 566
Propranolol use during, 483
Sumatriptan use during, 483
Laminectomy, for lumbar spinal stenosis, 321
Lamotrigine (Lamictal)
Dosing recommendations for, 544t
Properties of, 544t, 548–549
Laségue’s sign, 157–158, 138f
Lateral epicondylitis, of elbow joint, 157
Lateral femoral cutaneous nerve, anatomy of, 732, 733f
Lateral femoral cutaneous nerve block, 735–736
Clinical applications of, 735
Techniques of, 735, 736f
Lateral recess stenosis, imaging of, 216–217, 218f
“Law of minimum dose,” in homeopathy, 665
“Law of similars,” in homeopathy, 665
LBP. See Low back pain (LBP)
Lead shield, as protection from radiation exposure, 324
Leapfrog Group, 68
Leg ulcers, in sickle cell disease, 999t
Legal liabilities, of physician testimony, 264–266, 265b
Leptomeningeal metastases, 339
Lesser occipital nerve (LON) block, for headache, 706–707, 706f
Technique of, 706f, 707
Leukemia, spinal pain in, 237
Levetiracetam (Keppra), properties of, 551
LFS. See Lumbar facet syndrome (LFS)
LHWCA (Longshore and Harbor Workers Compensation Act), 262t, 263
Lower extremity (Continued)
muscles, strength of, 153, 154t
nerve blocks of, 732–744
anatomy relevant to, 732
for postoperative pain, 283–285, 283t
techniques of, 734–743. See also specific nerve blocks.
LRS. See Lumbar radicular syndrome (LRS)
LSS. See Lumbar spinal stenosis (LSS)
Lumbar disk
anatomy of, 886–887, 887t
total replacement surgery for, outcomes of, 898, 901t–902t
for lumbar spinal fusion, effect of, 899t–900t
procedural preparation for, 906
radiologic studies vs., 908, 909t–910t
for lumbar spinal fusion, effect of, 899t–900t
procedural preparation for, 906
radiologic studies vs., 893–894, 895t–897t
standardization of, 904, 905t
Lumbar facet joint(s)
anatomy of, 324, 324f, 817, 819f–820f
injections, therapeutic, 326
pain in:
prevalence of, 822–824, 828t
radiofrequency treatment of, 858–861, 860f
referral patterns for, 824–826, 826f,
827t–828t
studies of, 819–820, 822t
Lumbar facet syndrome (LFS)
diagnosis of, 325, 325b
injection studies for, 325–326, 326f
facet denervation for, 326
historical background of, 324–325
pathophysiologic anatomy of, 325
therapeutic LFJ injections for, 326
Lumbarplexus, anatomy of, 732, 733f
Lumbar plexus blocks
clinical applications of, 734
complications of, 735
for postoperative pain, 283t, 284
sympathetic, 789
techniques of
blocks, 734, 735f
ultrasound-guided, 734–735, 735f
Lumbar radicular syndrome (LRS)
clinical features of, 313
definition of/terminology associated with, 312
diagnostic studies of, 314–315
electrodiagnostic studies of, 315–316
evaluation/differential diagnosis of, 312, 313f
Lumbar radicular syndrome (Continued)
imaging studies of, 315
nerve root irritation in, tests confirming, 313, 313b
patient’s medical history, “red flags” in, 313–314, 314t
prevalence of, 312
Lumbar spinal fusion, for degenerative disk disease, preoperative diskography and, 894–898, 899t–900t
Lumbar spinal stenosis (LSS) acquired, 223–224
clinical considerations of, 320–321
congenital, 222–223, 225f
diagnosis of, 321
gabapentin for, 545
interventional procedures for, studies of, 1081
natural history/treatment options of, 321
neurogenic intermittent claudication in, 222–224, 225b
nonoperative treatment of, 321
pathophysiology of, 320, 320f
somatosensory evoked potentials and, 182
surgical procedures for, 321
spinal fusion for, 320, 320t
Lumbar spine
anatomy of, 859f
epidural steroid injection of interlaminar, 812, 812f
transforaminal, 810, 810f–811f
radiofrequency procedures for facet joint pain, 858–860, 860f
for radicular pain, 860–861, 862f
Limacoxib, properties/dosages of, 562
Lympha, of spine, 237, 240f
M Magnesium, membrane-stabilizing effect of, 551
Magnetic resonance imaging (MRI) of degenerative disk disease, 893–894, 895t–897t
of facet joint degeneration, 829–830, 830t
of insufficiency fractures, 290
for low back/radicular pain, 315, 315f
during pregnancy, 486, 487b
of spinal infection, 234
for spinal pain assessment, 192–195
of spondylolisthesis, 230–231, 231t
Maitland (Australian) approach to manual therapy, 637
Malingering vs. pain behavior, 141
Malpractice
definition of, 265
independent medical examiners and, 265
Mandibular disorders, 427, 427t
Mandibular nerve block, for facial pain, 711
Manipulation, for pain relief, 637
Manual therapy
chiropractic care as, 664
massage as, 663–664
models of, 663
osteopathic manipulation as, 664–665
Manual therapy, for pain relief, 636–638
Maprotiline, 538, 538f
Marketing plan, for inpatient pain management services, 29–30
Massage
in pain management, 663–664
in palliative care, 1027, 1027f
of trigger points, in myofascial pain syndrome, 395
INDEX

Mastectomy muscle disorders, 432b
Maxillary dental night guard, 435f
Maxillary disorders, 427, 427t
Maxillary nerve block, for facial pain, 711
Maximum medical improvement, definition of, 257
MBBs. See Medial branch blocks (MBBs)
MBMD (Millon Behavioral Medicine Diagnostic), 935
McGill Pain Questionnaire (MPQ), 247t–248t, 249
McKenzie approach to manual therapy, 637, 660–661
Meditation, for chronic pain management, 660–662
Medical legal constructs/constraints, in disability assessment, 263–266
Medical impairment rating, 259, 260f
Medical model of disability, 257
Medications, 1082
Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), 64, 247t–248t, 253, 935
Medical Research Council scale of muscle strength, 153, 153t
Medical reversal, problems with, 54–55
Medication overuse headache (MOH), 1013
Medical impairment rating, 259, 260f
Medical model of disability, 257
Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), 64, 247t–248t, 253, 935
Medical Research Council scale of muscle strength, 153, 153t
Medical reversal, problems with, 54–55
Medication overuse headache (MOH), 1013
Medical impairment rating, 259, 260f
Medical model of disability, 257
Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), 64, 247t–248t, 253, 935
Medical Research Council scale of muscle strength, 153, 153t
Medical reversal, problems with, 54–55
Medication overuse headache (MOH), 1013
Medical impairment rating, 259, 260f
Medical model of disability, 257
Medical devices, regulatory process for, 928
Medial branch blocks (MBBs)
Meclofenamate, properties of, 560
Meditation, for chronic pain management, 660–662
Mind-body medicine, 660–662
Mood, experience of pain and, 122
Morphine, experience of pain and, 122
Morphine absorption/metabolism of, 501–502
enzymes involved in metabolism of, 136t during pregnancy, 479
problems with use of, 1011
Merchant Marine Act, 262t, 263
Metabolizer status, by racial/ethnic group, 134t
Metastatic disease
pain associated with, 338–339
spinal, 237–239
Metatarsalgia, 160, 160f
Metaxalone (Skelaxin), properties/dosages of, 570f, 571
Methadone
absorption/metabolism of, 502t, 503–504 for addiction treatment, 679
for burn pain, 1004
enzymes involved in metabolism of, 136t for opioid-dependent patients, during pregnancy, 489–490
for pain management, at end of life, 1032–1034, 1033t
Methocarbamol (Robaxin, Robaxisal), properties/dosages of, 570f, 571
Methohexital, for ED procedural sedation and analgesia, 1013
Methylprednisolone epidural injections of, 602–603 adverse CNS events after, 603–606, 604f, 604t properties of, 603t, 606t
Mexitelene
dosing recommendations for, 544t during pregnancy, 480 properties of, 544t, 551
Meyering classification, of spondylolisthesis, 230, 231f
MHBI (Millon Behavioral Health Inventory), 247t–248t, 249
Microglia, spinal, 105–107, 106f peripheral nerve injury and, 118–119, 119f
Microwave diathermy, for deep heat therapy, 635, 635b
Midazolam for ED procedural sedation and analgesia, 1013
Migraine Disability Assessment (MIDAS) questionnaire, 410–411, 411f
Migraine headache(s)
definition of, 411
diagnostic criteria for, 412, 412b
epidemiology of, 411
headache phase in, 412
management of, cost-effectiveness analysis of, 1062
neuroimaging of, 125
pharmacologic treatment of, 413–414
for acute, 413
botulinum toxin in, 608, 608t preventive, 413–414
during pregnancy/lactation, 488–489
variants, 412–413
without aura, 411–412, 412b
with aura, 411–412, 412b
acupuncture for, 655, 659–660
botulinum toxin in, 608, 608t
for acute, 413
pharmacologic treatment of, 413–414
without aura, 411–412

Mortality
antidepressant use and, 540t
methadone-related, 504
Morton’s neuroma, 160, 160f
Motivational interviewing, for chronic pain management, 624–625
Motor Activity Assessment Scale, 1021t
Motor cortex stimulation for CPSP syndrome, 382–383
for intractable pain management, 332–333
Minimal invasive procedures, for vertebral compression fractures, 922–923
antibiotic prophylaxis/skin preparation for, 924
bipedicul humanlike approach in, 928
cement placement in, 926
complications associated with, 930–931, 931b
conservative therapy in, 922
indications/contraindications for, 924–925b
intraosseous vacuum phenomenon and, 929
key points in, 932
malignant fractures and, 929
needle placement in, 924–926, 926f
outcomes associated with, 929–930
patient positioning for, 924
postprocedural care in, 931–932
preprocedure workup for, 925b–931b
safety of multilevel treatment in, 929
sedation for, 922–924
studies of, 1082
technical aspects of, 922–928
vertebra plana and, 928
volume of cement injected for, 928
Minnesota Multiphasic Personality Inventory-2 (MMPI-2), 247t–248t, 249, 935
Mirtazapine, 538, 538f
Modeling behavior, chronic pain and, 141–142
Modic end plate changes
differentiating spondylodiscitis from, 234t
in diskogenic pain, 199–200, 200f, 201t
Modified Ashworth Scale for spasticity, 957, 958f
Monoamine oxidase inhibitors (MAOIs), 538, 539f
Monoamines, analgesic effects of, 110
Mononeuropathies
EMG abnormalities in, 633t
EMG evaluation of, 171–173
tricyclic antidepressants for, 534
Mood, experience of pain and, 122
Morphine
absorption/metabolism of, 501–502, 502t
enzymes involved in metabolism of, 136t global consumption of, 49, 50f
intra-articular delivery of, 769t, 773–775, 779f
dose-response effect in, 774
injection method for, 773–774
intraoperative use of, 773
role of inflammation in, 775, 775f
systemic effect of, 774
use of inroutien in, 774–775
intracerebroventricular, 335–334
for pain management
in emergency department, 1018–1019
at end of life, 1031, 1033t
in postherpetic neuralgia, 352t, 353
for postoperative pain
extended-release epidural, 277, 278t
intra-articular delivery of, 286
patient-controlled dosage of, 273t, 274

Morton’s neuroma, 160, 160f
Motivational interviewing, for chronic pain management, 624–625
Motor Activity Assessment Scale, 1021t
Motor cortex stimulation for CPSP syndrome, 382–383
for intractable pain management, 332–333

Mortality
antidepressant use and, 540t
methadone-related, 504
Morton’s neuroma, 160, 160f
Motivational interviewing, for chronic pain management, 624–625
Motor Activity Assessment Scale, 1021t
Motor cortex stimulation for CPSP syndrome, 382–383
for intractable pain management, 332–333
Motor evoked potentials, 183
Motor nerves, normal conductivity values for, 169
Motor unit(s)
- analysis of, 166
- definition of, 164, 166
- interference patterns, 166f
- normal/abnormal, 164f
Movement disorders, pain in, 367–368
MPQ (McGill Pain Questionnaire), 247–248, 249
MRI. See Magnetic resonance imaging (MRI)
Multimodal analgesia, 271
Multimodal impatient pain management service, 28
Multiple sclerosis (MS)
- pain associated with, 366, 366b
Musculoskeletal injury pain
Musculoskeletal examination, 155–156
Muscle(s)
- muscle strength examination, 153, 153f–154f

INDEX

Post-herpetic neuralgia (Continued)
  analgesic therapy as, 352–353, 352t
capsaicin for, 578
  interventional therapies as, 353–354
lidocaine patch as, 577–578
pregabalin as, 546
  tricyclic antidepressants as, 533–534, 535t
Postsynaptic dorsal column pathway, 95
Post-traumatic trigeminal neuropathy, 439
Potassium channels, altered expression of, after nerve injury, 101, 111
Preanpuation pain, 369–370
Prednisone
  dosing schedules for, 520, 521b, 521t
  pharmacodynamics of, 520, 521t
  during pregnancy, 521
Preemptive analgesia, definition of, 299t
Pregabalin (Lyrica)
  for burn pain, 1006
  for complex regional pain syndrome, 549
  for critically ill patients, 1019
  dosing recommendations for, 544t
  for fibromyalgia syndrome, 404
  for neuropathic pain, 546
  for post-herpetic neuralgia, 352t, 353
  for postoperative pain, 272t, 275–276
  during pregnancy, 482
  for visceral pain, 448
Pregnancy, 522t
  pain during
    anticonvulsants for, 481–482
    antidepressants for, 481
    benzodiazepines for, 480–481
    beta blockers for, 483
    caffeine for, 482
    corticosteroids for, 480, 521, 522t, 602
    ergot alkaloids for, 482
  evaluation of
    abdominal wall/ligamentous considerations in, 483, 483f–484f
    back considerations in, 484–487, 484f, 486t. See also Back pain
    hip considerations in, 484
    pelvic girdle considerations in, 484, 484f, 485f
    local anesthetics for, 480
    migraine headache and, 487–488
    nonsteroidal anti-inflammatory drugs for, 475–477
    NSAIDs for, 506
    opioid analgesics for, 477–480, 479t
    in opioid-dependent patients, 489–490
    sickle cell disease and, 488–489
    sumatriptan for, 482–483
    use of medications during, 474, 475t, 540
Premature Infant Pain Profile (PIPP), 304, 305t
Prescription Drug Abuse Prevention Plan (PDMPs), 688
Prescription monitoring programs (PDMPs), 688
Prescription patterns, of pain medicine physicians, 1081
Preventive analgesia, 271, 299t
  Primary sensitization, definition of, 114
  Private disability systems, 263
  Procedural pain, in burn patients, 1004
  Procedural sedation and analgesia, in emergency department, 1012–1014
Profile of Mood States (POMS), 247–248t, 252–253
Progressive muscle relaxation, for pain management, 660
  Projection neurons, of spinal cord, 93–94
  PROMIS (Patient-Reported Outcomes Measurement Information System), 247–248t, 250
Pronator teres syndrome, 172
Pronovost’s four points, translating evidence into practice, 70, 70b
Propionic acid derivatives, properties/dosing schedules for, 520, 521b, 521t
Propofol, for sedation and analgesia in emergency department, 1013
Propoxyphene, enzymes involved in metabolism of, 136t
Propranolol, for pain during pregnancy, 483
Proprionecreption testing, 154
Prostaglandin cascade, 104, 104f
Prostaglandin receptors, expression/regulation of, 553, 554f
  Prostaglandin(s), inflammatory response of, 553, 554f, 555
  Prostration, in herniated disk, 213, 214f
Puritus, opioid-induced, 497
  in palliative care setting, 1038
Pseudarthrosis, postoperative axial pain in, 211–212, 212f
Pseudoaddiction, 671, 684b
Pseudogout, viscosupplementation injection and, 971
Pseudosepsis, viscosupplementation injection and, 971
PSIs (Patient Safety Indicators), 69
PSO (Patient Safety Organization), 67
PSOCQ (Pain Stages of Change Questionnaire), 247–248t, 253–254
Psoriatic arthritis, 236
Psychogenic causes, of chest pain, in children, 460, 460t
Psychogenic pain, in burn patients, 1004
Psychological and behavioral assessment clinical objectives of, 243
  domains of functioning in, 244
  overview of, 244
Psychophysical assessment, in clinical interventional therapies as, 353–354
Psychotropic aspects, of chronic pain, 16
Psychiatric aspects, of chronic pain, 16
Psychological therapy (Continued)
  for herniated disk, 318
  for pain management, studies of, 1082–1083
  pharmacologic interventions combined with, 1083. See also Pain management, psychological techniques of
Psychology, impact of, on pain research, 7
Psychoneuroendocrinology, chronic pain and, 620
Psychophysical assessment, in clinical interview, 246
Psychophysiology, chronic pain and, 620
Psychosocial impact assessment, 249–250
Pterygopalatine ganglion, radiofrequency treatment of, 849–850, 849f–850f
Publication bias, in clinical research, 1063–1064
Pulmonary causes, of chest pain, in children, 460, 460t
Pulp inflammation, dental pain and, 424, 426t
Pulsed radiofrequency (pRF) of dorsal root ganglion, 861
  for facet joint pain, 837
Pyrazolone derivatives, 560
Q
Qi gong, health effects of, 662
Quality, in health care assessment of, 255
  definition of, 56. See also Health care, quality in
Quality assessment tools, health care, 62–64, 63b–64b

for postoperative pain, 285–286
rectus sheath, 752, 752f
transversus abdominis plane, 753–754, 753f
Tuberculous spondylitis, 232–233
Urticaria, fluoroscopic contrast agent-
induced, treatment of, 991t
Ultrasonic, for deep heat therapy, 634, 634b
Ultrasonography-guided technique
for ankle nerve blocks, 742–743, 744f
for axillary brachial plexus block, 726, 727f
for brachial plexus block, 729–731, 721f
for celiac plexus block, 761–763, 762f–763f
for fascia iliaca block, 738, 738f
for femoral nerve blocks, 736–737, 737f
for ganglion impar block, 766–767, 766f
for ilioinguinal/iliohypogastric blocks, 751, 751f
for infraclavicular brachial plexus block, 724, 724f
for interfascicular nerve blocks, 749–750, 749f
for lateral femoral cutaneous nerve block, 735, 736f
for lumbar plexus blocks, 734–735, 735f
for paravertebral nerve blocks, 746–747, 747f
in popliteal nerve blocks, 741, 742f
for rectus sheath nerve blocks, 752, 752f
for sacroiliac joint injection, 870, 870f
for saphenous nerve block, 738–739
for sciatic nerve blocks, 740, 740f
for stellate ganglion block, 757–759, 758f–759f
for suprachlavicular brachial plexus block, 722–723, 722f
for transversus abdominis plane blocks, 753–754, 753f
United States disability systems, 261–263, 262t
Unscheduled injuries, 260
Upper extremity somatosensory evoked
potentials, 180, 180f
Upper extremity(ies)
examination of, 136–137
muscle strength of, 153, 153f
muscles of, segmental innervation of,
172–173, 173t
nerve blocks of, 716–717
See also Brachial plexus block(s)
asessment of, four P’s of, 719f
for chronic pain, 730
complications of, 727–730
pharmacologic considerations in,
716–719
for postoperative pain, 279–283, 281t
sensory innervation of, 716, 718f
Urinalysis screening, 674–675, 687
Uric acid, fluoroscopic contrast agent-
induced, treatment of, 991t
INDEX

V
Vagus nerve (X), examination of, 152
Valacyclovir, for herpes zoster, 352, 352t
Valdecoxib, properties/dosages of, 561–562
Valproic acid (Depakote)
dosing recommendations for, 544t
properties of, 544t, 550
Vancouver Interaction and Calmness Scale,
of sedation, 1022t
Variation, in health care, 56–57, 58f
Varicella-zoster virus, post-herpetic neuralgia after, 351
Varni-Thompson Pediatric Pain Questionnaire (VTPPQ), 449, 451t
VAS. See Visual analog scale (VAS)
Vasodilators, systemic, for CRPS, 456
VBA (Veterans Benefits Administration)
disability compensation, 261
Venlafaxine, 536, 537t
VEPs. See Visual evoked potentials (VEPs)
Verbal rating scale (VRS), of pain intensity,
247t–248t, 248
Vermian function, testing of, 154
Vertebra plana, in vertebral augmentation,
928
Vertebroplasty
for cancer pain, 343–344
injectable bone cement in, 610–611
for vertebral compression fractures
needle placement in, 923f, 924–926,
926f–927f
procedures for, 926–928
Vestibulocochlear nerve (VIII), examination of,
152
Veterans Benefits Administration (VBA), disability compensation, 261
Vibration sense, testing of, 154
Vignetting, 986–987
Viral vector-based gene therapy, for chronic pain management, 611–614, 613t
Virtual reality, for burn pain management, 1007
Viscera
afferent pathways in
anatomy/physiology of, 441–442, 442f
sensitization of, 442
sensation in
central processing of, 442
mucosal signaling and, 441
Visceral pain
in cancer patient, classification according to, 338
management of
nerve blocks in, 443–444
adverse effects of, 445
efficacy of, 444–445
neural ablation in, 444
efficacy of, 444–445
pharmacotherapy for, mechanism-oriented, 446–448, 448b
physiologic basis of, 441–443
spinal treatment targets for, 445–446, 446b
stimuli for, 442–443
Viscosupplementation
intra-articular, 970–971
adverse effects/complications from, 971
agent selection for, 971, 971t
contraindications to, 969b
dosing/postinjection protocols in, 971
Visual analog scale (VAS)
for ICU pain assessment, 1016f
of pain intensity, 247t–248t, 248
in prescreening for implantable SCS/PNS devices, 934–935
Visual evoked potentials (VEPs)
abnormalities in, 177b, 177f
clinical utility of, 176–177
stimuli for/responses to, 176, 176f
Volume-dependent outcome, as factor in persistent postsurgical pain, 299
Voluntary activity of muscle, EMG needle findings in, 165f, 166
Vomiting. See Nausea and vomiting
VRS (Verbal rating scale), of pain intensity,
247t–248t, 248
VTPPQ (Varni-Thompson Pediatric Pain Questionnaire), 449, 451t

W
Waveform, electromyographic, 166
Weight, effect of antidepressants on, 540
West Haven–Yale Multidimensional Pain Inventory (WHYMPI), 247t–248t,
249–250
Whiplash-associated disorders, botulinum toxin for, 609
White matter, of spinal cord, 91f
Wisconsin Brief Pain Inventory (BPI), 335
Withdrawal, from opioids, 499–500
Witness immunity, for independent medical examiners, 264–266
Work disability, 260, 260f
Workers’ Compensation, 261, 262t
World Alliance for Patient Safety, 68–69
World Health Organization (WHO)
international classifications of illness/functioning, 258f
three-step analgesic ladder, 509f, 1030f
World Institute of Pain (WIP), 10
World Society of Pain Clinicians (WSPC), 10
Wrist
examination of, 157
median/ulnar nerve stimulation at, 167, 168f–170f

X
X-ray tube position, for minimal radiation exposure, 984, 984f

Y
Yeoman’s test
for iliopsoas muscle pain, 879
for sacroiliac joint syndrome, 866–867, 868f
Yoga, for chronic pain management, 661–662

Z
Zen (mindfulness) meditation, 625–626, 660–661
Ziconotide
intrathecal, for complex regional pain syndrome, 350
neuraxial delivery of, 585–586
dosing recommendations for, 586t
Ziconotide (Prialt), properties of, 546–547
Zonisamide (Zonegran), properties of, 546
Zygopophyseal joint. See Facet joints
