Robert W. Hurley, MD, PhD
Professor of Anesthesiology
Chief, Division of Pain Medicine
Medical Director, University of Florida Pain and Spine Center
University of Florida College of Medicine
Gainesville, Florida

ELSEVIER
MOSBY
To my family—Juliet, Hazel, Paul, Annalisa, Jonathan, Hubert, and Nathalie.
To those who helped me succeed—Ed Brunner, Ben Covino, Gerry Ostheimer, Dave Brown, Jim Rathmell, Admir Hadzic, and Tim Deer.
To my co-editors, your expertise is invaluable and your hard work is very much appreciated.

Honorio T. Benzon, MD

To Nori Benzon, who once again led this project with patience, persistence, and kindness; it is a privilege and pleasure to work with you always.
To Warren Zapol and Jeanine Wiener-Kronish, who have served as critical supporters and guides.
To my wife and children—Bobbi, Lauren, James, and Cara—thank you.

James P. Rathmell, MD

To my parents, Shy-Hsien and Tsai-Lien Wu and Chi-Jen and Sue-Yuan Lee, my wife, Lucia, and my children, Emily and Alex.

Christopher L. Wu, MD

To my many students, collaborators, and colleagues who have contributed to my understanding of the plight of “normal” people who find themselves in unimaginable circumstances. They have truly enriched the journey. And to Lorraine M. Turk, more than a wife, a partner, and my best friend, for her consistent and unyielding patience, tolerance, sacrifices, and understanding throughout our marriage.

Dennis C. Turk, PhD

To my wife and best friend, Pat, for your constant understanding and incessant patience throughout our relationship. To our children, David, Melanie and Emily. Your support of my professional activities is so appreciated, and I look forward to your continued development of those interests and activities that you are truly passionate about.
To Nori Benzon for asking me to be a part of this amazing project and for his determination and diligence in assuring its completion.
To Robert Y. Moore, MD, PhD, Roscoe Brady, MD, John Halperin, MD, and Michael Gruenthal, MD, PhD, for your encouragement and counsel throughout my career.

Charles E. Argoff, MD

To my wife, Meredith, and my two children, Gibson and Alexandra, who make me smile every time they enter my thoughts.
To Nori Benzon, MD, Steve Cohen, MD, Chris Wu, MD, and Donna Hammond, PhD, who are mentors and friends.
I feel nothing but gratitude for their support and guidance over the years.
To Nori and all of the co-editors, it has been an honor and privilege to work on this project.

Robert W. Hurley, MD, PhD

This, the fifth edition of the *Practical Management of Pain*, provides cutting-edge developments in pain medicine and reflects maturity of this medical specialty as it has progressed since earlier editions. As in the previous edition, the Editors represent the specialties of anesthesiology, psychology, and neurology that, together with physical medicine and rehabilitation and psychiatry, provide the core of pain medicine. In addition, we recruited Robert Hurley, MD, PhD, to join us as an editor. Rob brings an added perspective to the book. He is knowledgeable in the pharmacological management of acute and chronic pain, performs interventional techniques, and has conducted basic science pain research.

The current edition retains the format of the previous volume. It includes sections on general considerations, basic aspects, evaluation and assessment, clinical conditions, pharmacologic, psychological, and physical medicine treatments, nerve block techniques, interventional techniques, and pain management in special situations. The topics represent the multidisciplinary nature of pain medicine. Similar to the previous edition, the fifth includes an international group of authors, recognizing the scientific contributions of experts from around the world. We have expanded the number of chapters from 72 to 83 with the new chapters covering ultrasound-guided techniques in regional anesthesiology and pain management procedures. In addition to the suggested reading list, there is an extensive set of references in supplementary materials accompanying the published volume.

This volume is intended for the diverse range of pain clinicians looking for applications in their daily practice, pain researchers seeking extensive background on relevant topics, fellows reviewing for the pain medicine boards, and residents who want a complete discussion of the breadth of the field. Each chapter provides practical applications of the various and diverse acute and chronic pain syndromes. Throughout the volume there are distillations of research on all relevant aspects of pain medicine, including current knowledge of mechanisms involved and strategies for assessing and treating patients with chronic pain.

A project of this magnitude could not come to fruition without the efforts and assistance of a large number of people, and the result is truly a team effort. The contributors took time out of their busy academic, clinical, and administrative responsibilities to prepare their chapters. The editors spent an enormous amount of time finalizing the book. Our publishing team at Elsevier, led by Publishing Manager Michael Houston, Senior Content Developmental Specialist Joan Ryan, and Senior Project Manager Sharon Corell, did an excellent job of developing the book and keeping it on track. On a personal note, it is a delight to work with Michael Houston again as he was Dr. Benzon’s executive publisher in the first book that he edited, *Essentials of Pain Medicine*. We hope that you will agree that our collective efforts have resulted in an up-to-date, practical, and comprehensive volume worthy of your attention.

*The Editors*
The History of Pain Medicine

Winston C.V. Parris | Benjamin W. Johnson, Jr.

Management of pain, like management of disease, is as old as the human race. In the view of Christians, the fall of Adam and Eve in the Garden of Eden produced for man (and woman) a long life of suffering disease and pain. This one act allegedly set the stage for several disease concepts, including the experience of pain in labor and delivery; the concept that hard work is painful; the notion that blood, sweat, and tears are needed to produce fruit; the introduction of pain and disease to human existence; establishment of the fact that hell and its fires are painful; and the expectation that heaven is pure, delightful, spiritually pleasing, and of course, pain free. In these concepts, pain is viewed as a negative experience and one that is associated with disease, morbidity, and the dying process. Many diseases, including infections, plagues, metabolic disorders (e.g., diabetes mellitus), endocrine disorders, hypertension, and cancer, of course, afflict mankind spontaneously and usually cause significant pain without any wrongdoing, negligence, or irresponsibility on the part of the afflicted person.

As we consider the historical perspective, humans have deliberately and knowingly inflicted on one another many experiences associated with pain—from the earliest wars to the more recent irrational shooting incidents in the Arkansas and Oregon public school systems, from the scourging of Jesus to contemporary strife in the Middle East, the Rwandan genocide, the Irish “religious” fratricide, and the conflicts in Bosnia and the Balkans. All wars, including the great wars, World War I and World War II, the American Civil War, the Korean War, and the Vietnam War, have been associated with untold pain, suffering, and death.

Although we as human beings have not learned from these painful episodes and continue to inflict pain on others, the advances and increasing sophistication of the 21st century have brought about new concepts of disease and the painful states that diseases produce. The social illnesses—venereal diseases; the pulmonary, cardiovascular, and neoplastic consequences of smoking; the trauma associated with automobile accidents; the pathology caused by drug abuse and misuse; and the proliferation of viral illnesses (e.g., acquired immunodeficiency syndrome)—have all contributed further pain and suffering to our lot. Therefore, any review of history and politics, economics, and the social interrelationships of the world is inevitably a review of the history of pain. This chapter focuses on some of the major historical events that have influenced pain, its development, and its management and highlights the important phases that have led to the current conceptualization of pain and its treatment as an independent specialty in modern medicine.

PAIN AND RELIGION

The early concept of pain as a form of punishment from supreme spiritual beings for sin and evil activity is as old as the human race. In the book of Genesis, God told Eve that following her fall from grace she would endure pain during childbirth: “I will greatly multiply your pain in childbearing; in pain you shall bring forth children, yet your desire shall be for your husband and he shall rule over you” (Genesis 3:16). This condemnation led early Christians to accept pain as a normal consequence of Eve’s action and to view this consequence as being directly transferred to them. Thus any attempt to decrease the pain associated with labor and delivery was treated by early Christians with disdain and disapproval. It was not until 1847, when Queen Victoria was administered chloroform by James Simpson for the delivery of her eighth child, Prince Leopold, that contemporary Christians and in particular Protestants accepted the notion that it was not heretical to promote painless childbirth as part of the obstetric process.

From the Old Testament, Job has been praised for his endurance of pain and suffering. Yet Job’s friends wondered whether these tribulations were an indication that he had committed some great sin for which God was punishing him (Job 5:17). Nonetheless, Job was considered a faithful servant by God and was not guilty of any wrongdoing. In fact, he was described as a man who was “blameless and upright” and one who feared God and turned away from evil.

In the 5th century, St. Augustine wrote that “all diseases of Christians are to be ascribed to demons; chiefly do they torment the fresh baptized, yea, even the guiltless newborn infant,” thus implying that not even innocent infants escape the work of demons. Today, major typhoons, hurricanes, fires, earthquakes, volcanoes, tsunamis, floods, and droughts destroy hundreds and at times thousands of innocent, defenseless people. One ponders the rationale of such pain and suffering endured by otherwise good people while seemingly ruthless and evil persons apparently triumph and prosper in an atmosphere of luxury and comfort.

This paradox can be discouraging at times but is usually upheld by firm Christian belief. In the 1st century, many people who belonged to the Catholic Church were rebuked and suffered ruthless persecution, including death, because of their belief in Jesus as the Messiah. Some who were subsequently described as martyrs endured their suffering in the
belief that they did it for the love of Christ, and they felt that their suffering identified them with Christ’s suffering on the cross during his crucifixion. This may be the earliest example of the value of psychotherapy as an important modality in managing pain. Thus, many present-day cancer patients with strong Christian beliefs view their pain and suffering as part of their journey toward eternal salvation. This concept has led to several scientifically conducted and government-sponsored studies evaluating intercessory prayer as an effective modality for controlling cancer pain.

To fully appreciate the historical significance of pain, it is important to reflect on the origins of the “pain patient.” The word pain comes from the Latin word poena, which means “punishment.” The word patient is derived from the Latin word patior, meaning “to endure suffering or pain.” Thus, it is not too outrageous to appreciate that in ancient days persons who experienced pain were interpreted to have received punishment in the form of suffering that was either dispensed by the gods or offered up to appease the gods for transgressions.

As spinal and epidural modes of anesthesia have developed and the techniques have been refined so that mortality and morbidity from them are negligible, childbirth and delivery are increasingly considered relatively painless in most developed societies. Unfortunately, in many countries neither the personnel nor the technology for obstetric regional analgesia is available, and resources to provide such personnel and technology are inadequate, thus making childbirth a primitively painful and at times disastrous event. The history of anesthesia is full of instances wherein attempts to relieve pain were initially met with resistance and sometimes violence. In the mid-19th century, Crawford Long from the state of Georgia in the United States attempted to develop and provide anesthesia, but contemporary Christians of that state considered him a heretic for his scholarly activity. As a result, he literally had to flee for his life from Georgia to Texas. Although surgical anesthesia was well developed by the late 19th century, religious controversy over its use required Pope Pius XII to give his approval before anesthesia could be used extensively for surgical procedures. Pope Pius XII wrote, “The patient, desirous of avoiding or relieving pain, may without any disquietude of conscience, use the means discovered by science which in themselves are not immoral.”

PAIN AND THE ANCIENT CULTURES

Disease, pain, and death have always been considered undesirable. The principles on which medicine was founded were based on measures to overcome human suffering from disease. Thus pain was usually thought of as either emanating from an injury or originating from the dysfunction of an internal organ or system. Traditionally, pain after physical injury (e.g., a gunshot wound or spear injury) was not considered problematic since as soon as the offending injurious agent was removed or once the consequences of the offending injury were corrected, the patient either recovered rapidly or, on occasion, died. On the other hand, pain from disease (e.g., the pain of an inflamed gallbladder or ruptured appendix) was regarded with more mystique, and treatment was usually tinged with superstitious tradition. The tribal concept of pain came from the belief that it resulted from an “intrusion” from outside the body. These “intruders” were thought to be evil spirits sent by the gods as a form of punishment. It was in this setting that the role of medicine men and shamans flourished because these were the persons assigned to treat the pain syndromes associated with internal disease. Since it was thought that spirits entered the body by different avenues, the rational approach to therapy was aimed at blocking the particular pathway chosen by the spirit.

In Egypt, the left nostril was considered the specific site where disease entered. This belief was confirmed by the Papryri of Ebers and Berlin, which stated that the treatment of headache involved expulsion of the offending spirit by sneezing, sweating, vomiting, urination, and even trephination. In New Guinea it was believed that evil spirits entered via a spear or an arrow, which then produced spontaneous pain. Thus it was common for the shaman to occasionally purge the evil spirit from a painful offending wound and neutralize it with his special powers or special medicines. Egyptians treated some forms of pain by placing an electric fish from the Nile over the wounds to control the pain.

The resulting electrical stimulation that produced relief of pain actually works by a mechanism similar to transcutaneous electrical nerve stimulation (TENS), which is frequently used today to treat pain.

The Papyrus of Ebers, an ancient Egyptian manuscript, contains a wide variety of pharmacologic information and describes many techniques and recipes, some of which still have validity. This papyrus describes the use of opium for the treatment of pain in children. Other concoctions for treating pediatric pain have included wearing amulets filled with a dead man’s tooth (Omnibonus Ferraruis, 1577) as a treatment for teething pain. Although early documents specifically address the management of pain in children, it is unfortunate that even today treatment of pediatric pain is far from optimal. This glaring deficiency was highlighted in 1977 by Eland, who demonstrated that in a population of children 4 to 8 years of age, only 50% received analgesics for postoperative pain. The results are even more unsatisfactory for the treatment of chronic pain and cancer pain in children. It is unfortunate that the observations of earlier scholars have been ignored. Two erroneous assumptions—that children are less sensitive to pain and that the central nervous system is relatively undeveloped in neonates—are partially responsible for this deficiency.

Early Native Americans believed that pain was experienced in the heart, whereas the Chinese identified multiple points in the body where pain might originate or might be self-perpetuating. Consequently, attempts were made to drain the body of these “pain points” by inserting needles, a concept that may have given birth to the principles of acupuncture therapy, which is well over 2000 years old.

The ancient Greeks were the first to consider pain to be a sensory function that might be derived from peripheral stimulation. In particular, Aristotle believed that pain was a central sensation arising from some form of stimulation of the flesh, whereas Plato hypothesized that the brain was the destination of all peripheral stimulation. Aristotle advanced the notion that the heart was the originating source or processing center for pain. He based his hypothesis on the concept that an excess of vital heat was conducted by the blood to the heart, where pain was modulated and perceived.
Because of his great reputation, many Greek philosophers followed Aristotle and embraced the notion that the heart was the center for pain processing. Another Greek philosopher, Stratton, and other distinguished Egyptians, including Herophilus and Eistratus, disagreed with Aristotle and proposed the concept that the brain was the site of pain perception as suggested by Plato. Their theories were reinforced by actual anatomic studies showing the connections of the peripheral and central nervous systems.

Nevertheless, controversies between the opposing theories of the brain and the heart as the center for pain continued, and it was not until 400 years later that the Roman philosopher Galen rejuvenated the works of the Egyptians Herophilus and Eistratus and greatly re-emphasized the model of the central nervous system. Although Galen’s work was compelling, he received little recognition for it until the 20th century.

Toward the period of the Roman Empire, steady progress was made in understanding pain as a sensation similar to other sensations in the body. Developments in anatomy and, to a lesser extent, in physiology helped establish that the brain, not the heart, was the center for the processing of pain. While these advances were taking place, simultaneous advances were occurring in the development of therapeutic modalities, including the use of drugs (e.g., opium), as well as heat, cold, massage, trephination, and exercise, to treat painful illnesses. These developments brought about establishment of the principles of surgery for treating disease. Electricity was first used by the Greeks of that era as they exploited the power of the electrogenic toadfish (Scribonius longus) to treat the pain of arthritis and headache. Electrostatic generators were used in the late Middle Ages, as was the Leyden jar; these developments resulted in the re-emergence of electrotherapy as a modality for managing medical problems, including pain. There was a relative standstill in the development of electrotherapy as a medical modality until the electric battery was invented in the 19th century. Several attempts were then made to revive its use as an effective medical modality, but these concepts did not catch on and were largely used only by charlatans and obscure scientists and practitioners. Throughout the Middle Ages and the Renaissance, debate on the origin and processing center of pain raged. Fortunes fluctuated between proponents of the brain theory and proponents of the heart theory, depending on which theory was favored.

Heart theory proponents appeared to prosper when William Harvey, recognized for his discovery of the circulation, supported the heart as the focus for pain sensation. Descartes disagreed vehemently with the Harvey hypothesis, and his description of pain conducted from peripheral damage through nerves to the brain led to the first plausible pain theory, that is, the specificity theory. It is interesting to note that the specificity theory followed Descartes’ description by some 2 centuries. Several other theories followed the specificity theory and contributed to the foundation for understanding pain and pain mechanisms.

### PAIN AND PAIN THEORIES

The specificity theory, originally proposed by Descartes, was formally revised by Schiff based on animal research. The fundamental tenet of the theory was that each sensory modality, including pain, was transmitted along an independent pathway. By examining the effect of incisions in the spinal cord, Schiff demonstrated that touch and pain were independent sensations. Furthermore, he demonstrated that sectioning of the spinal cord deferentially resulted in the loss of one modality without affecting the other. Further work along the same lines by Bliz, Goldscheider, and von Frey contributed to the concept that separate and distinct receptors exist for the modalities of pain, touch, warmth, and cold.

During the 18th and 19th centuries, new inventions, new theories, and new thinking emerged. This period was known as the Scientific Revolution, and several important inventions took place, including discovery of the analgesic properties of nitrous oxide, followed by the discovery of local anesthetic agents (e.g., cocaine). The study of anatomy was also developing rapidly as an important branch of science and medicine; most notable was discovery of the anatomic division of the spinal cord into sensory (dorsal) and motor (ventral) divisions. In 1840 Mueller proposed that based on anatomic studies, there was a straight-through system of specific nerve energies in which specific energy from a given sensation was transmitted along sensory nerves to the brain. Mueller’s theories led Darwin to propose the intensive theory of pain, which maintained that the sensation of pain was not a separate modality but instead resulted from a sensory overload of sufficient intensity for any modality. This theory was modified by Erb and then expanded by Goldscheider to encompass the roles of both stimulus intensity and central summation of stimuli. Although the intensive theory was persuasive, the controversy continued, with the result that by the mid-20th century, the specificity theory was universally accepted as the more plausible theory of pain.

With this official, though not unanimous blessing of the contemporary scientific community, strategies for pain therapy began to focus on identifying and interrupting pain pathways. This tendency was both a blessing and a curse. It was a blessing in that it led many researchers to explore surgical techniques that might interrupt pain pathways and consequently relieve pain, but it was a curse in that it biased the medical community for more than half a century into believing that pain pathways and their interruption were the total answer to the pain puzzle. This trend was begun in the late 19th century by Letievant, who first described specific neuractomy techniques for treating neuralgia. Afterward, various surgical interventions for chronic pain were developed and used, including rhizotomy, cordotomy, leukotomy, tractotomy, myelotomy, and several other operative procedures designed to interrupt the central nervous system and consequently reduce pain. Most of these techniques were abysmal failures that not only did not relieve pain but also on occasion produced much more pain than was previously present. A major consequence lingers today—the notion that pain can be “fixed” by a surgical procedure or other modality.

### PAIN AND DISEASE

The cardinal features of disease as recognized by early philosophers included calor, rubor, tumor, and dolor; the English translation is heat, redness, swelling, and pain. One of the important highlights in the history of pain medicine was the

---

**PAIN AND DISEASE**

The cardinal features of disease as recognized by early philosophers included calor, rubor, tumor, and dolor; the English translation is heat, redness, swelling, and pain. One of the important highlights in the history of pain medicine was the
realization that even though heat, redness, and swelling may disappear, pain can continue long after and be unresponsive on occasion to different therapeutic modalities. When pain continues long after the natural pathogenic course of disease has ended, a chronic pain syndrome develops with characteristic clinical features, including depression, dependency, disability, disuse, drug misuse, drug abuse, and of course, “doctor shopping.” John Dryden once wrote, “For all the happiness mankind can gain is not in pleasure, but in rest from pain.” Thus many fatal nonpainful diseases are not as feared as relatively trivial painful ones.

Throughout the ages, physicians and healers have focused their attention on managing pain. Thus in managing cancer, an important measure of successful treatment is the success with which any associated pain is managed. Although many technological advances have been made in medicine, it is only within the past 10 to 20 years that significant strides have been made in dealing with chronic pain as a disease entity per sé—one requiring specialized study, specialized evaluation, and specialized therapeutic interventions. As better techniques and more effective methods for evaluation and treatment of pain, especially chronic pain, are developed, management of pain will be considered more complete and an important supplement to the great strides made in other areas of chronic disease management.

**PAIN IN THE 20TH CENTURY**

General anesthesia was formally discovered by William Morton in 1846, in 1847, Simpson used chloroform to provide anesthesia for the labor pains of Queen Victoria during the delivery of her eighth child, Prince Leopold.9 This action helped legitimize the practice of pain relief during childbirth. Heretofore, even the concept of analgesia for the relief of labor pain was considered heretical and unchristian. Around the same time the hollow needle and the syringe were invented. Many local anesthetic agents were also discovered in this era. In 1888, Corning described the use of a local anesthetic, cocaine, for the treatment of nerve pain. Techniques for local and regional anesthesia for both surgery and pain disorders proliferated rapidly.

In 1907, Schlosser reported significant relief of neuralgic pain for long periods with injection of alcohol into damaged and painful nerves. Reports of similar treatment came from the management of pain resulting from tuberculous and neoplastic invasion.25 In 1926 and 1928, Swetlow and aged and painful nerves. Reports of similar treatment came with cancer.26 In 1926 and 1928, Swetlow and

One consequence of war has been the development of new techniques and procedures to manage injuries. In World War I (1914-1918), numerous injuries were associated with trauma (e.g., dismemberment, peripheral vascular insufficiency, and frostbite). In World War II (1939-1946), not only peripheral vascular injuries but also phantom limb phenomena, causalgia, and many sympathetically mediated pain syndromes occurred. Leriche developed the technique of sympathetic neural blockade with procaine to treat the causalgic injuries of war.27 John Bonica, himself an army surgeon during World War II, recognized the gross inadequacy of managing war injuries and other painful states of veterans with the existing undisciplinary approaches.28 This led him to propose the concept of multidisciplinary, multimodal management of chronic pain, including behavioral evaluation and treatment. Bonica also highlighted the fact that pain of all kinds was being undertreated; his work has borne fruit in that he is universally considered the “father of pain,” and he was the catalyst for the formation of many established national and international pain organizations. The clinic that he developed at the University of Washington in Seattle remains a model for the multidisciplinary management of chronic pain. As a result of his work, the American Pain Society (APS) and the International Association for the Study of Pain (IASP) have been formed, are still active, and continue to lead in pain research and pain management. Bonica’s lasting legacy is his historic volume *The Management of Pain,* first published in 1953.

Anesthesiology as a specialty developed but was still associated with significant mortality and morbidity. Anesthesiology departments were considered divisions of surgery and did not reach full autonomy until after World War II. As a result of the morbidity associated with general anesthesia and because several new local anesthetics were being discovered, regional anesthesia and its associated techniques began to flourish in the United States. Bonica also played a major role in advancing the use of epidural anesthesia to manage the pain associated with labor and delivery. Regional anesthesia suffered a significant setback in the United Kingdom with the negative publicity surrounding the 1954 cases of Wooley and Roe, in whom serious and irreversible neurologic damage occurred after spinal anesthesia. It took 3 more decades to fully overcome that setback and to see regional anesthesia widely accepted as safe and effective in the United Kingdom. Several persons contributed significantly to the development of regional anesthesia, including Corning, Quincke-August Bier, Pitkin, Etherington-Wilson, Barker, and Adriani.

As recent society has developed and science has prospered, the general public has come to consider pain to be unsatisfactory and unacceptable. Consequently, demands have been made that resulted in the development of labor and delivery anesthesia services, acute pain services, and more recently, chronic pain clinics. Bonica’s vision was not only the development of these clinics but also the founding and maintenance of national and international pain organizations to promote research and scientific understanding of pain medicine. As a result, a tremendous amount of research continues, almost quadrupling each year.

An outstanding contribution in the field of research was the development and publication of the *gate control theory* by Melzack and Wall in 1965.29 This theory, built on the preexisting and prevalent specificity and intensive theories, provided a sound scientific basis for understanding pain mechanisms and for developing other concepts on which sound hypotheses could be developed. The gate control theory emphasizes the importance of both of ascending and descending modulation systems and laid down a solid framework for the management of different pain syndromes. The gate control theory almost single-handedly legitimized pain as a scientific discipline and led not only to many other research endeavors building on the theory but also to the
maturity of pain medicine as a science.\textsuperscript{30} As a consequence, the APS, the American Academy of Pain Medicine (AAPM), the American Society of Regional Anesthesia and Pain Medicine, the IASP, and the World Institute of Pain (WIP) flourish today as serious and responsible organizations that deal with various aspects of pain medicine, including education, science, certification, and credentialing of members of the specialty of pain medicine.

**PAIN AND THE IMPACT OF PSYCHOLOGY**

The history of pain medicine would be incomplete without acknowledging the noteworthy contributions of psychologists. Their influential research and clinical activities have been an integral part of a revolution in conceptualization of the pain experience.\textsuperscript{31} For example, in the early 20th century the role of the cerebral cortex in the perception of pain was controversial because of a lack of understanding of the neuroanatomic pathways and the neurophysiologic mechanisms involved in pain perception.\textsuperscript{32,33} This controversy largely ended with introduction of the gate control theory by Wall and Melzack in 1965.\textsuperscript{29} The gate control theory has stood the test of time in that subsequent research using modern brain-imaging techniques such as positron emission tomography, functional magnetic resonance imaging, and single-photon emission computed tomography has also described the activation of multiple cortical and subcortical sites of activity in the brain during pain perception. Further elaboration of the psychological aspects of the pain experience includes the three psychological dimensions of pain: sensory-discriminative, motivational-affective, and cognitive-evaluative.\textsuperscript{34}

Psychological researchers have greatly advanced the field of pain medicine by reconceptualizing both the etiology of the pain experience and the treatment strategy. Early pain researchers conceptualized the pain experience as a product of either somatic pathology or psychological factors. However, psychological researchers have convincingly challenged this misconception by presenting research that illustrates the complex interaction between biomedical and psychosocial factors.\textsuperscript{35-37}

This biopsychosocial approach to the pain experience encourages the realization that pain is a complex perceptual experience modulated by a wide range of biopsychosocial factors, including emotions, social and environmental contexts, and cultural background, as well as beliefs, attitudes, and expectations. As the acutely painful experience transitions into a chronic phenomenon, these biopsychosocial abnormalities develop permanency. Thus, chronic pain affects all facets of a person’s functional universe, at great expense to the individual and society. Consequently, logic dictates that this multimodal etiology of pain requires a multimodal therapeutic strategy for optimal cost-effective treatment outcomes.\textsuperscript{38,39}

Additional contributions from the field of psychology include therapeutic behavioral modification techniques for the management of pain. Such techniques as cognitive-behavioral intervention, guided imagery, biofeedback, and autogenic training are the direct result of using the concepts presented in the gate control theory. In addition, neuromodulatory therapeutic modalities such as TENS, peripheral nerve stimulation, spinal cord stimulation, and deep brain stimulation are also logical offspring of the concepts presented in the gate control theory.

Evaluation of candidates for interventional medical procedures is another valuable historical contribution from the field of psychology. Not only is the psychologist’s expertise in the identification of appropriate patients valuable for the success of therapeutic procedural interventions for the management of pain, but the psychologist’s expertise is also helpful in identifying patients who are not appropriate candidates for procedural interventions. Thus, psychologists have contributed positively toward the cost-effectiveness and utility of diagnostic and therapeutic pain medicine.

**PAIN AND PAIN INSTITUTIONS**

**THE INTERNATIONAL ASSOCIATION FOR THE STUDY OF PAIN**

The IASP is the largest multidisciplinary international association in the field of pain. Founded in 1973 by John J. Bonica, MD, the IASP is a nonprofit professional organization dedicated to furthering research on pain and improving the care of patients experiencing pain. Membership is open to scientists, physicians, dentists, psychologists, nurses, physical therapists, and other health professionals actively engaged in pain and to those who have special interest in the diagnosis and treatment of pain. The IASP has members in more than 100 national chapters.

The goals and objectives of the IASP are to foster and encourage research on pain mechanisms and pain syndromes and to help improve the management of patients with acute and chronic pain by bringing together scientists, physicians, and other health professionals of various disciplines and backgrounds who have interest in pain research and management. Goals of the IASP also include mandates to promote education and training in the field of pain, as well as to promote and facilitate the dissemination of new information in the field of pain. One of the instruments of dissemination is sponsorship of the journal *Pain*. In addition, the IASP promotes and sponsors a highly successful triennial world congress, as well as other meetings. The IASP encourages the development of national chapters for national implementation of the international mission of the IASP. In addition, the IASP encourages the adoption of a uniform classification, nomenclature, and definition of pain and pain syndromes. Development of a uniform records system in regard to information related to pain mechanisms, syndromes, and management is also a stated goal of the IASP, and education of the general public on the results and implications of current pain research is another mission of the IASP.

The IASP has partnered with the World Health Organization in providing guidelines for assessment and management of chronic pain, especially in developing countries. Cancer pain awareness and its management have been noteworthy contributions of the IASP.

Special interest groups (SIGs) within the IASP have successfully promoted research, understanding, education, and enhanced pain management of the particular special
interest. Areas of interest include pain in children, neuropathic pain, herbal medicine, and cancer pain, among others. The IASP also promotes and administers Chronic Pain Fellowship programs for deserving candidates all over the world.

THE AMERICAN PAIN SOCIETY

Spurred by burgeoning public interest in pain management and research, as well as by formation of the Eastern and Western USA Chapters of the IASP, the APS was formed in 1977 as a result of a meeting of the Ad Hoc Advisory Committee on the Formation of a National Pain Organization. The need for a national organization of pain professionals was realized as growth of the IASP continued. The APS became the first national chapter of the IASP and has constituent regional and state chapters. The APS has its own journal, *The Journal of Pain*, and holds national meetings. Its main function is to carry out the mission of the IASP on a national level.

COMMISSION ON THE ACCREDITATION OF REHABILITATION FACILITIES

As pain clinics developed, it became clear that there was a need for credentialing, not only of pain centers and pain clinics but also of pain clinicians. In 1983, the Commission on Accreditation of Rehabilitation Facilities (CARF) was the first to offer a system of accreditation for pain clinics and pain treatment centers. The CARF model was based on the rehabilitation system, and it quickly became clear that the orientation of the CARF would be physical and psychological rehabilitation of patients suffering pain, in contrast to modality treatment to reduce pain sensation. CARF standards mandated that multidisciplinary pain management programs offer medical, psychological, and physical therapy modalities for the management of pain. Pain clinicians were not accredited by CARF, and it quickly became apparent that one could have an accredited pain center without having accredited pain clinicians. The CARF model gained modest acceptance among insurance carriers and third-party payers, primarily because of its emphasis on accountability and program evaluation. Its major goals included such objective measures as increased physical function, reduced intake of medication, and return-to-work issues.

THE AMERICAN ACADEMY OF PAIN MEDICINE

As CARF gained prominence, many pain clinicians realized that neither CARF nor the APS completely met their practice and professional needs. Furthermore, it became obvious that there was a major deficiency in evaluating the competence of pain physicians in that there were no uniform standards for training and credentialing of these pain clinicians. Thus in 1983, at a meeting of the APS in Washington, DC, a group of physicians (of whom chapter author Winston Parris was privileged to be a member) formed the American Academy of Algology (the term algology is derived from the words algos [Greek for “pain”] and logos [Greek for “study”]). The name was changed 2 years later to the AAPM, a name that is more acceptable in mainstream medicine.

This academy was formed to meet the needs and aspirations of pain physicians in the United States. Its major focus was to address the specific concerns of pain physicians and to enhance, authenticate, develop, and lead to the credentialing of pain medicine specialists. As a medical specialty society, the academy is involved in education, training, advocacy, and research in the specialty of pain medicine. The practice of pain medicine is multidisciplinary in approach and incorporates modalities from various specialties to ensure comprehensive evaluation and treatment of patients with pain. The AAPM represents the diverse scope of the field through membership from a variety of origins, including such specialties as anesthesiology, internal medicine, neurology, neurologic surgery, orthopedic surgery, psychiatry, and psychology. Goals of the AAPM include the promotion of quality care of both patients experiencing pain as a symptom of a disease and patients with the primary condition of pain through research, education, and advocacy, as well as advancement of the specialty of pain medicine.

As we enter the managed care era, it is clear that issues such as reimbursement, contract negotiations, fee scheduling, practice management, mergers, acquisitions, and other business-related matters are becoming increasingly important to pain practitioners. The political and business arms of the AAPM are becoming instrumental in helping guide physicians through the murky waters of managed care and pain medicine.

In an attempt to provide creditable credentialing in pain medicine, the AAPM sponsored the American College of Pain Medicine (ACP), which organized, developed, and administered the first credentialing examination in 1992. Successful candidates received the Fellowship of the American College of Pain Medicine. In the process of attempting to receive recognition of the American Board of Medical Specialties (ABMS), the name was changed on the recommendation of the ABMS to the American Board of Pain Medicine (ABPM).

Since the development of AAPM, most of the organization’s goals have been met:

2. Successful establishment of a credentialing body, the ABPM (formerly the ACP), which offers annual credentialing examinations for eligible physicians. Among the many criteria, the minimum criterion is that candidates be ABMS-certified in their primary specialty.
3. Establishment of *The Clinical Journal of Pain*, which initially served as the official journal of the AAPM and has now been replaced by the journal *Pain Medicine*.

Additional goals include an attempt to establish uniform practice parameters and outcome measures for different pain modalities.

THE AMERICAN BOARD OF PAIN MEDICINE

The ABPM is the examination division of the AAPM and serves the public by improving the quality of pain medicine through certification of pain specialists. It evaluates candidates who voluntarily appear for examination after a credentialing process and certifies them as *Diplomates in Pain Medicine* if they successfully pass the examination process.
This mission serves the public by helping ensure that physicians passing the examination have an approved level of expertise and currency of knowledge in pain medicine. More than 2000 physicians have become diplomates of the ABPM.

**THE AMERICAN SOCIETY OF REGIONAL ANESTHESIA AND PAIN MEDICINE**

The American Society of Regional Anesthesia (ASRA) is the preeminent society on regional anesthesia. The society is based in the United States; other societies on regional anesthesia are based in Europe, Asia, and Latin America. Cognizant of the fact that anesthesiologists account for the majority of pain medicine practitioners and interventional pain physicians and perform translational and clinical research, the ASRA started another annual meeting dealing exclusively with pain medicine. The annual meeting of the ASRA that deals with regional anesthesia is held in the spring, whereas its annual meeting on pain medicine is held in the fall. To better fulfill its mission, the ASRA has changed its name to the American Society of Regional Anesthesia and Pain Medicine and the name of their highly cited journal, *Regional Anesthesia, to Regional Anesthesia and Pain Medicine*. This journal is the official publication of the American, European, Asian and Oceanic, and Latin American Societies of Regional Anesthesia.

**THE AMERICAN SOCIETY OF INTERVENTIONAL PAIN PHYSICIANS**

The American Society of Interventional Pain Physicians (ASIPP) is a national organization that represents the interests of interventional pain physicians in the United States. The society was founded in 1998 by Dr. Laxmaiah Manchikanti and associates for the purpose of improving the delivery of interventional pain management services to patients across the United States, whether in hospitals, ambulatory surgical centers, or medical offices. The ASIPP has an active political action committee that has been instrumental in achieving numerous legislative victories benefiting its constituents and their patients. Goals of the ASIPP include the preservation of insurance coverage, coverage for interventional pain procedures, advancement of patient safety, advancement of cost-effectiveness, and establishment of accountability in the performance of interventional procedures. Also included in the goals of the ASIPP are the pursuit of excellence in education in interventional pain management, improvement of practice management, enhancement of regulatory compliance, and elimination of fraud and abuse. The ASIPP journal is indexed and called *Pain Physician*.

**THE AMERICAN ACADEMY OF HOSPICE AND PALLIATIVE MEDICINE**

The American Academy of Hospice and Palliative Medicine (AAHPCM) was founded in 1988 to advance the specialty of hospice medicine in the United States. Goals of the AAHPCM include providing education and clinical practice standards, fostering research, facilitating personal and professional development, and sponsoring public policy advocacy for the terminally ill and their families. The academy's philosophy includes the belief that the proper role of the physician is to help the sick, even when cure is not possible. In addition, the AAHPCM aims to help patients achieve an appropriate and easy passage to death as one of the most important and rewarding services that a physician can provide. The academy endorses the philosophy that the medical profession should attend to all the needs of the dying patient and family and should encourage and promote patient autonomy.

**THE AMERICAN ACADEMY OF OROFACIAL PAIN**

The American Academy of Orofacial Pain (AAOP) is an organization of health care professionals dedicated to the alleviation of pain and suffering through education, research, and patient care in the field of orofacial pain and associated disorders. Goals of the AAOP include the establishment of acceptable criteria for the diagnosis and treatment of orofacial pain and temporomandibular disorders, sponsorship of annual meetings and a medical journal, and encouragement of the study of orofacial pain and temporomandibular disorders at undergraduate and postgraduate levels of dental education.

**THE AMERICAN ACADEMY OF PAIN MANAGEMENT**

The American Academy of Pain Management (AAP Management), founded in 1988, is an inclusive interdisciplinary organization serving clinicians who treat people with pain through advocacy and education and by setting standards of care. AAP Management is open to a diverse group of pain clinicians and emphasizes inclusivity of all health care specialties. The organization boasts a large, diverse membership and an online University of Integrated Studies that offers graduate-level online courses for health practitioners. In addition, various levels of pain credentialing are available, depending on the level of education of the student or practitioner.

**AMERICAN SOCIETY FOR PAIN MANAGEMENT NURSING**

Founded in 1990, the American Society for Pain Management Nursing (ASPMN) is an organization of professional nurses dedicated to promoting and providing optimal care of individuals with pain through education, standards, advocacy, and research. Their goals include providing access to specialized care for patients experiencing pain, providing education of the public regarding self-advocacy for their pain needs, and providing a network for nurses working in the pain management field. This society also sponsors educational conferences and is formulating a means of adding compensational value to the specialty of pain management nursing. The ASPMN has published a number of scholarly position papers regarding best-practice nursing standards for such situations as male infant circumcision, procedural analgesia and sedation, patients who are unable to self-report pain complaints, and others.

**THE NATIONAL HEADACHE FOUNDATION**

Founded in 1970, the National Headache Foundation (NHF) works to create an environment in which headaches are viewed as a legitimate health problem. Goals of the NHF
include promotion of research into the causes and treatment of headache and education of the public regarding the legitimacy of headache as a biologic disease.

THE WORLD INSTITUTE OF PAIN

The WIP is an international organization that aims to promote the best practice of pain medicine throughout the world. Its goals are to educate and train personnel of member pain centers by the use of local hands-on training international seminars and exchange of clinicians. Updating member pain centers with state-of-the-art pain information via newsletters, scientific seminars, and journal and book publications is an additional goal. One of the most important goals of the WIP is to develop an international examination process for testing and certifying qualified interventional pain physicians. After showing proficiency in both general pain knowledge and safe performance of interventional procedures, successful candidates are awarded the designation of Fellow of Interventional Pain Practice (FIPP). The journal of the WIP, Pain Practice, is indexed and has a very respectable initial impact factor.

THE WORLD SOCIETY OF PAIN CLINICIANS

The World Society of Pain Clinicians (WSPC) is an international organization whose goals are to bring together clinicians with a common interest in the treatment of pain. Additional goals are to stimulate education and learning in the field of pain and to encourage dissemination of information on pain throughout the world. The WSPC also endorses and encourages auditing and scientific research on all aspects of pain, especially treatment. The WSPC sponsors a biannual international congress on the clinical aspects of pain and has its own journal, Pain Clinic.

THE INTERNATIONAL SPINE INTERVENTION SOCIETY

The International Spine Intervention Society (ISIS) is a society of physicians interested in the development, implementation, and standardization of percutaneous techniques for precision diagnosis of spinal pain. The organization sponsors forums for exchange of ideas, encourages research undertaking, and holds public lectures. The mission of the ISIS includes consolidation of developments in diagnostic needle procedures, identification and resolution of controversies, public dissemination of developments, and recommendation of standards of practice based on scientific data.

THE INTERNATIONAL NEUROMODULATION SOCIETY

Founded in 1989, the International Neuromodulation Society (INS) is a multidisciplinary international society that promotes therapeutic neuromodulation at a clinical and scientific level. The primary means of exchanging knowledge consist of regular scientific meetings and the journal Neuromodulation. The first national chapter of the INS was the American Neuromodulation Society.

AMERICAN PAIN FOUNDATION

Founded in 1997 by three past presidents of the APS, the American Pain Foundation (APF) was an independent, nonprofit, grassroots organization serving people with pain through information, advocacy, and support. Its goals included serving as an information clearinghouse for people with pain, promoting recognition of pain as a critical health issue, and advocating for changes in professional training regulatory policies and health care delivery systems to ensure that people with pain have access to proper medical care. The APF was the first pain organization specifically formed to serve the interests of people with diverse disorders associated with the presence of significant pain. Regrettably, the organization was dissolved in early 2012 because of financial difficulties.

THE NATIONAL PAIN FOUNDATION

Founded in 1998, the National Pain Foundation (NPF) seeks to advance the recovery of persons in pain through education, information, and support. The NPF empowers patients by helping them become actively involved in the design of their treatment plan. The organization’s website has interactive features that encourage patients to identify the information that they need to manage their pain in the most understandable way. The NPF strives to fill the gap in the understanding, awareness, and accessibility of pain treatment options.

PAIN AND THE HOSPICE MOVEMENT

Hospice is a medieval term representing a welcome place of rest for pilgrims to the Holy Land. The concept of hospice dates back to the reign of Emperor Julian the Apostate, when Fabiola, a Roman matron, created a place for sick and healthy travelers and cared for the dying. Hospitals in general were regarded as Christian institutions, and in medieval times most hospitals were used as hospices and vice versa.

During the 11th century, several hospices were based in and operated by monasteries. The 17th century Catholic priest St. Vincent DePaul founded the Sisters of Charity in Paris as a home for the poor, the sick, and the dying. St. Vincent DePaul’s work for the poor and the sick created a significant impact not only on the Catholic Church but also on other contemporary religions. The Protestant pastor Fliedner was so influenced that he founded Kaiserwerth 100 years later. Nuns from the Sisters of Charity and Kaiserwerth accompanied Florence Nightingale to Crimea to care for wounded soldiers and other citizens who were either sick or dying.

In 1902, the Irish Sisters of Charity founded St. Joseph’s Hospice, which was staffed by Cecily Saunders 50 years later. Dr. Saunders was the first full-time hospice medical officer, and she was regarded as the founder and medical director of St. Christopher’s Hospice in England. She was initially trained as a nurse and served in World War II. After becoming injured, she received training as a medical social worker. She subsequently developed a keen interest in terminal cancer patients and underwent training in medical school to become a physician. She emphasized the
importance of taking patients at their word during pain assessment and of scheduling the dosing of opioids on a time-contingent basis as compared with an as-needed dosing schedule. She also advocated the need for frequent pain assessment to effectively manage cancer patients’ pain. In addition, she sought to convince the medical community that it was totally unnecessary and inhumane for cancer patients to die in pain.43 For all her efforts and leadership, she is regarded as the “mother of palliative care” and was knighted for her contributions to the hospice movement and care of dying cancer patients. Dame Saunders’ views and works are widely taught in medical and nursing schools today and form the basis of palliative care.

PAIN AND THE FUTURE

Pain medicine has come a long way. A review of the history of pain demonstrates that until the time of Bonica, pain management was considered to be unimodal and unidisciplinary and was largely managed haphazardly and without any clear structural organization. Today, new drugs, innovative techniques, and creative procedures have expanded the scope of pain medicine. In addition, new research is contributing daily to modern concepts of pain and its management; these concepts are having positive effects on the development of pain medicine. Evidence-based guidelines on neuropathic pain by distinguished groups such as the IASP Neurop SIG, European Federation of Neurological Sciences, and Canadian Pain Society have been published.

The contributions of the IASP, WIP, WSPC, APS, AAPM, ASRA, and the many other international, national, regional, state, and local organizations devoted to pain and pain management are all having a significant impact on the dissemination of knowledge, promotion of research, and realization of networking on local, national, and international levels. Pain practitioners and investigators are no longer isolated, and a flurry of published manuscripts and textbooksonly cover a wide array of topics on pain medicine. Credentialing is well on its way, and two credible organizations are responsible for credentialing pain physicians in the United States. They include the diploma offered by the ABPM and the Certificate of Added Qualification by the American Board of Anesthesiology. Diplomas are offered by examination. In addition, the WIP offers a FIPP certification by examination.

With the recent trend of adverse changes in the global economy, including changes in medical economics, such as the realities created by managed care and the different health maintenance organizations, pain medicine has had to redirect its strategies for effective delivery and fair reimbursement for services rendered. These developments have also spawned new health care provider relationships and payment models for more cost-effective delivery of pain evaluation and treatment services. Many pain-oriented SIGs are dealing with these issues, and it is clear that the scientific community concerned with pain must develop reliable and reproducible outcome measures to maintain high quality, credibility, integrity, and competence in the management of chronic pain.

To this end, training of pain specialists is being given serious consideration, and a matching program for pain medicine fellowship positions is on the horizon. It is likely that in addition to the current 1-year pain medicine fellowships, attempts will be made to establish residencies in pain medicine. It is clear that in addition to offering these postgraduate measures, administrators of medical schools must re-evaluate their educational programs and make their curricula more inclusive of pain medicine. With such changes taking place, the future of pain medicine looks bright as a result of major contributions at all levels by dedicated and committed pain clinicians and researchers.

KEY POINTS

• The word pain comes from the Latin word poena, which means “punishment." The word patient is derived from the Latin word patior, meaning “to endure suffering or pain.”
• The history of anesthesia is full of instances in which attempts to relieve pain were initially met with resistance and at times violence.
• Developments made in anatomy and physiology helped establish that the brain, not the heart, was the center for processing pain.
• The tenet of the specificity theory, proposed by Descartes and revised by Schiff, was that each sensory modality, including pain, was transmitted along an independent pathway.
• The use of chloroform to provide anesthesia for the labor pains of Queen Victoria helped legitimize the practice of pain relief during childbirth.
• The clinic that Bonica developed at the University of Washington in Seattle remains a model for the multidisciplinary management of chronic pain.
• Regional anesthesia suffered a significant setback with the negative publicity surrounding the 1954 cases of Wooley and Roe, in whom serious and irreversible neurologic damage occurred after spinal anesthesia. It took 3 decades to overcome this setback and establish regional anesthesia as safe and effective.
• An outstanding contribution in the field of research was development and publication of the gate control theory by Melzack and Wall in 1965.
• Psychological researchers have greatly advanced the field of pain medicine by reconceptualizing both the etiology of the pain experience and the treatment strategy.
• Several organizations advance the science and practice of pain medicine, including the International Association for the Study of Pain (IASP), American Pain Society (APS), American Society of Regional Anesthesia and Pain Medicine, American Academy of Pain Medicine (AAPM), World Institute of Pain (WIP), International Spine Intervention Society (ISIS), National Headache Foundation (NHF), and the American Society of Interventional Pain Physicians (ASIPP).
• Pain medicine practitioners are certified by the American Board of Anesthesiology and the American Board of Pain Medicine (ABPM).
• Changes in the pain medicine fellowship program related to the length of training and a matching program are being considered.

Taxonomy and Classification of Chronic Pain Syndromes

Harold Merskey

DEFINING PAIN

The first task of the authors of any taxonomy is to know what they are talking about. Sometimes knowledge is taken for granted. A taxonomy of pain needs some understanding of the term itself. We all assume that we know the meaning of the word pain—and indeed we do. Nevertheless, for a long time there was no unanimity about how to define pain. There is still no absolute unanimity, but a consensus appears to have formed in favor of the definition of pain offered by the International Association for the Study of Pain (IASP) in 1979 and subsequently published in the Classification of Chronic Pain produced by the IASP. The definition of pain—“an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage”—was based on an earlier one that had achieved some recognition; it was intended to deal with the situation that although pain was normally understood to be the consequence of physically damaging stimulation or a disorder in the body, many patients appeared to have pain but did not have overt tissue damage.

Morris observed that the key to the IASP definition is to dissolve any necessary connection between pain and tissue damage. It depends on use of the word pain regardless of whether physical change is apparent. It is important to recognize that pain is always a subjective psychological state. At the same time, the note on this definition emphasized that pain “most often has a proximate physical cause.” The IASP definition has been adopted fairly broadly and helps minimize the idea that there is some sort of pain that patients imagine and that is not the same as the pain of “real injury or disease.” In the personal opinion of this writer, much pain that is primarily organic in origin has an organic basis that is incompletely explained. Sometimes this happens for reasons of mere convenience; that is, every-day transient pain is not usually investigated, nor does it need to be. At other times it may happen because of difficulties in diagnosis, even with chronic severe disorders. The lack of physical proof should never be taken on its own as a sufficient indicator of a psychological cause of pain.

THE NATURE OF CLASSIFICATION

Taxonomy means the arrangement of rules. Taxonomy as a term is derived from two Greek words—lasso and nomia—meaning “arrangement” and “rules.” In other words, it deals with the principles of classification and not with the content of classifications. It is about how to set up a classification and not about the detail of what goes into it. It ordinarily applies to the science of classification of living organisms. Classifications are also produced for nonliving organisms and material that was never alive.

There are two types of classification, natural and artificial. A natural classification deals with the material of physics and biology and anything else in the natural world, such as types of stars or forms of animals—in other words, the material world. An artificial classification deals with arrangement of the products of human activity, for example, a telephone directory.

In an artificial classification there is no necessary connection between the basis on which the classification is produced and the inherent nature of the subject matter. Thus, the list of names in a telephone directory by alphabetical order is arbitrary but works extremely well.

An ideal classification should not only be comprehensive but should also locate each item within it in a place of its own without overlap. The periodic table in chemistry is a wonderful example of scientific beauty and a perfect or almost perfect classification wherein every element belongs in its own place relative to the other elements. In biology, a superior form of classification is a phylogenetic one based on evolutionary relationships.

Medical classifications are established on a very different basis. In the International Statistical Classification of Diseases and Diagnostic Guidelines, 10th Revision (ICD-10), the classification is arranged by causal agents, such as infectious diseases or neoplasms; by systems of the body, such as cardiovascular or musculoskeletal; by symptom pattern and type of symptoms, as in psychiatric illnesses; and even by whether the condition or event is related to the artificial intervention of an operation. Illnesses or categories may be grouped by time of occurrence, such as congenital or perinatal disorders, and at the basic level are grouped as symptoms, signs, and abnormal clinical and laboratory findings.

In the ICD-10 there is code 080 for delivery in an uneventful case, including spontaneous breech delivery. Major groups are subdivided by system (e.g., neurology), by symptom pattern (e.g., epilepsy or migraine), by the presence of hereditary or degenerative disease (e.g., Huntington’s disease and hereditary ataxia), by location of the disorder (e.g., extrapyramidal disorders), by anatomic and physiologic characteristics (e.g., extrapyramidal and movement disorders, such as Parkinson’s disease and dystonia), by...
location (e.g., polyneuropathies), and by infectious and chemical causes. With these approaches, categories overlap repeatedly. Pain is found in the group of symptoms, signs, and clinical and laboratory findings as “R52—pain not elsewhere classified.” This particular code excludes some 19 others that reflect pain in different parts of the body and excludes “psychogenic” pain (code F45.4) and renal colic (N35). Thus, pain occurs at various levels of diagnosis and categorization in the ICD-10.

The overlap found in medicine is inevitable. There must always be some provision for conditions that are not well described and will overlap with others that are well described. The purposes of medicine require attention to the many different aspects of disease that enter into the classifications. That should be apparent from the examples cited.

**WHICH TYPES OF PAIN NEED CLASSIFICATION**

From the point of view of a pain practitioner, only some types of pain need classification, and indeed it would be inappropriate to classify all types of pain in a chronic pain classification. A large proportion of the pain that human beings and other creatures experience in the world is brief and transitory. As a rule, it is accompanied by overt damage that needs its own appropriate treatment or it passes quickly. Pain is the most common symptom in the whole of medicine. Therefore, any attempt to classify all types of pain would inevitably lead to an overall classification of medicine that would have a particular focus that is unnecessary for most medical cases. Illnesses with pain that have needed a special classification are those in which pain is a significant persistent problem. This conclusion still leaves a large field for a classification of pain but saves the pain specialist from having to write the classification for all the rest of medicine as well.

Among specific systems of classification, the ICD-10 is used worldwide for the purpose of documenting mortality and morbidity. In the United States, a slightly modified version of the previous international system of classification, namely, ICD-9CM, is used. (CM stands for Clinical Modification.) This modification was promoted by the U.S. government to provide the additional data required by clinicians, researchers, epidemiologists, medical record librarians, and administrators of inpatient and outpatient community programs. In the United States, ICD-9CM is published by the Department of Health and Human Services, Public Health Services, Health Care Financing Administration.

The international ICD-10 system comprises a table of names and numerical codes for these names. The ICD-10 consists of three volumes. Volume I is a tabular list that contains the report of the International Conference for the 10th Revision, the classification itself at three- and four-character levels, a classification of the morphology of neoplasms, a special tabulation list for mortality and morbidity, definitions, and the nomenclature regulations. Volume II includes an instruction manual, and Volume III is an alphabetical index. The latter also includes expanded instructions on use of the index.

In the United States, ICD-9CM coding has particular importance because of the 1988 Medical Catastrophic Coverage Act, which although later repealed, required the use of ICD-9 codes on “Medicare Part B” claims. This requirement continued with ICD-9CM, and to date, ICD-9CM has not been replaced in the United States. Pain specialists in the United States may believe that the ICD-9CM classification does not cover their requirements for appropriate billing of work done and may prefer a pain-based classification.

Of course, classifications have a number of purposes besides billing. The primary one is to exchange standardized information so that “stroke,” “cholecytitis,” and “depressive disorder,” for example, have the same meanings to different colleagues. Meanings should be the same both within the same country and throughout the world. This should facilitate statistical comparisons of the occurrence and management of disease and serve as a basic tool for scientific progress by establishing standards of diagnosis and description that can be compared between workers within countries and internationally.

Such classification can help provide an understanding of disorders, but it does so only by giving shape to the advances of investigators, whether alone, in working groups, or in national and international organizations. Classifications also serve as a means of recognizing work done and providing standards for payment. This is one of the reasons for their relative popularity with both medical professionals and administrators.

Classifications, of necessity, cannot provide “absolute truth.” Thus even when a classification recognizes a disorder as a “condition,” a “disorder,” or a “disease,” it is not the classification that provides the knowledge that justifies these various titles but rather the existing level of scientific knowledge. To the extent that a classification identifies current scientific knowledge and claims it to be acceptable, it may establish unity, but classifications as a rule only follow scientific knowledge.

This also means that just as classifications take material as they find it, they are not expected to provide perfect decisions or standards by which we can state that something is “a disease,” a “disorder,” a “syndrome,” or merely a “symptom.” The one word of these four for which the meaning is not in dispute is *symptom*, the patient’s statement of a complaint. All four words involve or have involved some dispute regarding whether they reflect the true nature of the phenomena with which physicians deal. Physicians become concerned about whether they recognize something as a disease or “only a syndrome” or “just a symptom.” It is not the function of a classification to determine the answers to such questions. In fact, it can be extraordinarily hard to determine what constitutes a syndrome and whether diseases should have a fixed standard.

**THE INTERNATIONAL ASSOCIATION FOR THE STUDY OF PAIN CLASSIFICATION**

The IASP classification focuses on chronic pain. A small number of pain syndromes that are not necessarily chronic were included for comparative purposes because they might be relevant to pain specialists (e.g., acute herpes zoster, burns with spasm, pancreatitis, prolapsed intervertebral disk) or because the acute version frequently becomes chronic. The classification is based on five axes. The first
axis is anatomic localization, which was chosen for both historical and practical reasons. The historical reasons are that there was previously difficulty in establishing a chronic pain classification based on etiology and that there was too much argument or potential argument about causes. It was also recognized that in essence pain is referred to parts of the body and it is always a somatic symptom, whatever its cause. In addition, location provides a useful means of distinction between different conditions. Accordingly, the IASP classification presents a list of relatively generalized syndromes followed by regional ones. Relatively generalized syndromes include peripheral neuropathy, stump pain, phantom pain, complex regional pain syndrome, central pain, syringomyelia, polymyalgia rheumatica, fibromyalgia, rheumatoid arthritis, and so forth. Pain of psychological origin is also included. Relatively localized syndromes are subdivided according to whether they affect the head and neck, limbs, thorax, or abdomen or whether they have a spinal or radicular distribution or origin.

The IASP classification set out to provide categories and codes for all the relevant conditions. Not all pain is continuously chronic. Some pain that is severe and chronic renews between episodes (e.g., migraine and cluster headache), but these types of pain are also included under the rubric of chronic pain. Some chronic pain consists of pain that persists past what has usually been considered to be the normal time needed for healing. However, this is not always the case, and the decision of what constitutes the normal time for healing is much argued. Indeed, it is now understood—but not so well understood in 1986 when the first edition of the classification was published—that pathophysiologic processes may well maintain pain long after the normal expectation of pain from injury has ended. I personally question whether we should even mention the normal time needed for healing when discussing chronic pain.

Be that as it may, the IASP Taxonomy Committee recognized that some pain persists despite no apparent explanation, other pain persists with an explanation (e.g., the pain of osteoarthritis), and still other pain, which is not always continuous, can recur. Patients with these types of pain, by virtue of their intractability, were considered proper subjects for a classification of chronic pain.

**MULTIPLE AXES**

An anatomic classification alone is not sufficient. Some effort has to be made, even if it is tentative, to describe the nature of the pain and different types of pain, to note the system in which it occurs, to set up a system that indicates which disturbance seems to be most responsible for the pain, to describe the features of the pain even though they might vary within diagnoses, and to attribute cause when possible. Accordingly, the classification of chronic pain specifies five axes for describing pain.

The first axis is the anatomic axis, and the second axis is the system most related to the cause of the pain (besides the nervous system, which is always involved in pain). The systems identified were (1) the central, peripheral, and autonomous nervous systems and special senses; (2) psychological and social function of the nervous system (which was given a separate coding); (3) respiratory and vascular systems; (4) the musculoskeletal system and connective tissue; (5) cutaneous and subcutaneous tissue and associated glands (e.g., breast, apocrine), the gastrointestinal system, the genitourinary system, and other organs or viscera (e.g., thyroid, lymphatic); and (6) unknown systems. A code was also allowed wherein more than one system was found to contribute to the pain.

The third axis describes the temporal characteristics of the pain and its pattern of occurrence. A code was allowed for instances in which temporal patterns were not recorded but distinctions were made as follows: single episode, continuous or nearly continuous, nonfluctuating or fluctuating, recurring irregularly, paroxysmal (e.g., tic douloureux), occurring regularly (e.g., premenstrual pain), sustained with superimposed paroxysms and other combinations, and none of the above.

The fourth axis accepts statements of intensity, and the fifth axis identifies etiology. Causes can include genetic or congenital disorders; operations; burns; infections; inflammation; neoplasms; toxic, metabolic, degenerative, mechanical, or functional (including psychophysiological) causes; or those resulting from ideas (e.g., conversion hysteria or depressive hallucination—both of which are either hard to show or particularly rare).

The actual system has served well as a guide for making a diagnosis and establishing priorities in making a diagnosis. It has served poorly as a means of exchanging information on certain cases of different sorts. Thus, I do not think that I have seen any example of a study in which pain was selected solely on the basis that it had a particular pattern on the third axis, such as continuous or nearly continuous. These features have of course been found and reported frequently in studies in which the patients were selected on the basis of other criteria (e.g., the anatomic location or the etiologic diagnosis, to take the first and the fifth axes). The system does, however, provide fairly well for individual codes to be given if they are required for a specific study of a group, mainly relying on the anatomic, systemic, and diagnostic axes (e.g., I, II, and V). The third axis (i.e., the temporal characteristics) serves well only for identifying continuous or discontinuous pain, which is often merely a feature of the diagnosis and not a feature of the selection of cases or the exchange of information. The fourth axis has also contributed relatively little in its present shape, with intensity frequently being recorded separately from the diagnosis.

The codes can serve as a means of identifying unique patterns. Each of the five axes provides a place in the code for a condition. However, Vervest and Schimmer showed that not all the codes are unique, and allowance for this is made by adding the letters a, b, c, and so forth to the five-number code when necessary.

Chronic pain was defined as pain that had been present for more than 6 months. It was thought that although many types of pain become persistent and chronic at 3 months, a 6-month division did not present difficulties in practice, was fairly characteristic, and served as a good entry to the population treated by pain specialists. The term chronic pain was not intended—and still is not intended—to mean a particular syndrome or pattern, and the notion of “chronic pain syndrome,” which tends to mix the physical and psychological consequences of pain, was not accepted by the Taxonomy Committee of the IASP. In its deliberations the
committee proceeded to adopt an anatomic classification as the starting point for its classification of chronic pain on a model originally developed by John Bonica.9

PARTICULAR DIAGNOSES

The provision of categories is particularly useful when existing knowledge of painful syndromes is weak. For example, the understanding of reflex sympathetic dystrophy, whose name was changed on the advice of a special subcommittee to complex regional pain syndrome (CRPS) type 1, has served as a means for identifying criteria that would provide either a clinical means for agreement between different investigators or a special sample for research purposes. In this case, the first step taken in conjunction with the classification system was to define CRPS type 1 merely by its clinical phenomena and not by its theoretical relationship to the sympathetic nervous system. The second step, taken more recently, proposed changes in the diagnostic criteria that provided both clinical diagnostic criteria for general use and more stringent research diagnostic criteria for specific research investigations. This seems to be a satisfactory solution to the problem of how many people may claim the label and what sort of cases should be concomitantly studied to establish convincing evidence of the research findings. Other examples in which the classification has been useful include pioneering the spread of understanding about relatively new syndromes (e.g., the syndrome of painful legs and moving toes [see Merskey and Spear3] or the syndrome of paroxysmal hemicrania). In these cases, the classification has given an appropriate place to syndromes that have not yet entered the general lexicon although they are described in the literature.

PSYCHIATRIC ASPECTS OF CHRONIC PAIN

The psychiatric aspects of chronic pain may be coded in two ways. The first recognizes that patients seen in clinical practice often have some degree of emotional difficulty in association with chronic pain. In such cases the psychological changes are most often anxiety or depression and may be attributed to the persistence of pain causing distress, loss of employment, altered marital relationships, decline in self-image, and so forth, as well as independent events that cause depression or anxiety (e.g., bereavement or illness in a close relative). In these circumstances it is important to describe the psychological status of patients, to understand why they are troubled, and to provide appropriate treatments, which first of all may consist of better analgesia but in addition may include antidepressant medication and social support. Whenever psychological help is requested, it should include assistance with emotional difficulties, whether it be supportive or cognitive therapy. Behavioral therapy usually has only a very limited role in managing the secondary effects of pain, but assistance in adjustment to pain can be of great importance and can involve rehabilitation experts.

The second option in regard to psychiatry and pain would be to see the psychological illness as a cause of the pain. This is thought to be much less common as a sustained cause of pain than was originally suggested. Headache from emotional problems and precordial pain from anxiety are fairly typical examples of situations in which some pain, but less often chronic pain, may be due to depression or anxiety disorders. In such cases, psychiatric methods of care are appropriate after physical examination. However, these situations hardly ever account for the great majority of patients with chronic pain and emotional disturbance. One explanation that was formerly favored suggests that the pain solves a problem, but this explanation seems to be less and less realistic as time goes by, and psychiatry has failed to prove by systematic methods that sustained pain results from a chronic emotional disorder. We provided psychological categories notwithstanding; thus, the IASP system laid down the following categories: pain of psychological origin: muscle tension; delusional hallucinatory; hysterical conversion or hypochondriacal; and associated with depression. It appears that these categories are not used much. Factitious illness and malingering were not included as disorders as they were thought appropriate to describe as part of the psychiatric condition.

INTERNATIONAL PSYCHIATRIC CLASSIFICATIONS

The classification of mental and behavioral disorders recommended by the World Health Organization11 is a part of the overall international classification. Categories have been established with an eye to agreement with the layout of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), of the American Psychiatric Association (APA),12 which is well known in many countries. The ICD-10 classification of mental and behavioral disorders preserves categories parallel to those used in DSM-IV; although the descriptions are often different. However, the ICD-10 classification does not use the “checklist approach” but rather gives a general description and the major criteria required. The APA DSM-IV and DSM-IV TR (in which the explanatory text changed but not the codes) retain the same criteria as each other.

With respect to pain, the options in both systems are as follows: First, any particular diagnosis such as schizophrenia or depression of some sort may be made and indicated as a cause of the patient’s pain in cases in which it is understood that the diagnosis applies and pain may be accepted as resulting from such conditions. Then, the ICD-10 classification provides a category of Pain Disorder, Somatoform Persistent (F45.44). This category in essence corresponds to what the DSM-IV now calls Persistent Somatoform Pain Disorder. In the ICD-10 classification, the predominant complaint is persistent, severe, and distressing pain that cannot be explained fully by a physiologic process or a physical disorder. It is presumed to be of psychological origin, but pain occurring during the course of a depressive disorder or schizophrenia is not included. Pain that is due to known or inferred psychophysiologic mechanisms such as muscle tension pain or migraine but is still believed to have a psychogenic cause is coded under Psychological or Behavioral Factors Associated with Disorders or Diseases Classified Elsewhere (e.g., muscle tension pain or migraine). In ICD-10, the most common problem is to differentiate this disorder from the histrionic elaboration of organically caused pain. Thus, this category is essentially meant to deal with pain that serves an unconscious motive. For a number of practical reasons this is an extremely difficult proposition to prove clinically.
Under DSM-IV the criteria are similarly stringent but the diagnosis is made much more frequently, both in the United States and in Canada. According to the description of chronic pain disorder in DSM-IV, the word somatoform was dropped from the title. Pain disorder is the predominant focus of the clinical manifestation, and it must cause significant stress or impairment in social, occupational, or other important areas of functioning. Psychological factors must be judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain, and the symptom or deficit must not be intentionally produced. This condition is not to be diagnosed if the pain is better accounted for by a mood, anxiety, or psychotic disorder or if it meets the criteria for dyspareunia.

These criteria have the effect of limiting the condition to one that is not associated with significant depression or anxiety or that results from a physical illness. Within DSM-IV, two versions of pain disorder were allowed. One is “pain disorder associated with psychological factors,” wherein the necessary criteria are met as above but psychological illness is not present. The other is “pain disorder associated with both psychological factors and a general medical condition.” In this case the same rules apply as for pain disorder on its own, but it is thought that a physical condition may be present but not sufficient to account for a large part of the syndrome. It is stated as follows: “Both psychological factors and a general medical condition are judged to have important roles in the onset, severity, exacerbation, or maintenance of the pain.” The associated general medical condition or anatomic site of the pain is coded separately.

In my observation, many diagnosticians who are sincerely interested in the patient’s welfare welcome this category as a means of diagnosing a distressing psychological state for which they do not see an adequate physiologic or general medical explanation. In my view, however, this is not the way it should be used. It would only logically be justifiable with respect to the criteria for cognate diagnoses if it could be demonstrated that there was some psychological cause that was unconsciously producing the symptom at the same time as producing anxiety or depression—in other words, what used to be called hysteria. For reasons discussed elsewhere, the diagnosis of pain as “a conversion disorder” can rarely be made adequately. Persons with doubts should try to imagine whether they could produce, by thinking about it, a physical symptom such as paralysis that they would maintain consciously and whether they could produce a state of feeling of chronic pain in themselves by reflecting on it and then ask how is it possible that pain could be produced unconsciously if it cannot even be produced consciously? Overall then, psychological diagnoses as causes of pain are not favored by this writer except in very limited situations. Occasionally, patients with classic depressive illness suffer from severe headaches that go away when the depression is better. Occasionally, patients with post-herpetic neuralgia have much worse pain when they become depressed and much less pain when the depression is treated, but this situation is relatively rare and does not reflect the bulk of either general medical, neurologic, or psychiatric practice.

The diagnosis of chronic pain related to psychiatry is, at present, a controversial issue with respect to DSM-V, which has the category Pain Disorder. The current proposal of the APA is that there will be substantial changes in the pain disorder criteria involving both Pain Disorder and other so-called “Somatoform Disorders.” It appears that the “Somatic Symptom Disorder Work Group” is proposing radical changes in this category and will (or may) rename the Somatoform Disorders section as “Somatic Symptom Disorders,” eliminate four existing DSM-IV categories (Somatization Disorder, Hypochondriasis, Pain Disorder, and Undifferentiated Somatoform Disorder), replace these discrete categories and their criteria with a single new category (“Complex Somatoform Symptom Disorder”), and apply new criteria.

To receive a diagnosis of complex somatic symptom disorder, patients must complain of at least one somatic symptom that is distressing or disruptive of their daily lives. Also, patients must have at least one of the following from the E type criteria: “emotional/cognitive/behavioural disturbances: high levels of health anxiety, disproportionate and persistent concerns about the medical seriousness of the ‘symptoms,’ and an excessive amount of time and energy devoted to the symptoms and health concerns. Finally, the symptoms and later concerns must have lasted for at least six months.” There are some further qualifications, and the development of the system has been vigorously criticized by Dr. Allen Frances, the principal architect and editor in chief of DSM-IV, which has been widely used and officially adopted by various bodies.

The diagnosis of “Pain Disorder” in DSM-IV was not entirely satisfactory in this author’s view, and reasons have been given for not using it. Nonetheless (for reasons connected with funding the diagnosis on insurance claims from either side of the fence), many expert witnesses have tended to rely on the DSM-IV diagnoses. Some have also relied on the DSM-IV grading systems with respect to functional abilities. Others, like myself, who have treated pain—entirely—as a physical disorder for medicolegal purposes have made use of whichever version of the American Medical Association Guides to the Evaluation of Impairment was relevant in their particular jurisdiction. For psychiatric purposes in evaluating the disability caused by pain, one can reasonably apply the criteria for disability of the Somatoform Disorders Scale as published in DSM-IV by reference to the Global Assessment of Functioning scale. In jurisdictions outside the United States the same scale can also reasonably be used for both physical and psychological illness. Thus, rather than the questionable diagnosis of “Pain Disorder,” the Global Assessment of Functioning scale may be used independent of the diagnosis simply on the basis of what the patient can and cannot do—without necessarily applying a psychiatric diagnosis.

In my experience to date, similar situations have been interpreted in the medicolegal situation more often to the benefit of the defense than to the benefit of the injured party in compensation disputes. However, on a fair presentation it should work equally well for both sides of the argument and better than any arbitrary scaling unrelated to the life experience of the individual.

CONCLUSION

Classification is required in medical practice to identify like phenomena observed by practitioners. There is no absolute rule of what a syndrome or classification should be. The basis for the use of different classification systems is outlined in this chapter.

Organizing an Inpatient 
Acute Pain Service

Jennifer M. Lee | Alex Cahana | Gregory W. Terman

THE RATIONALE

An estimated 48 million inpatient surgical procedures are performed annually in the United States (National Center for Health Statistics, National Hospital Discharge Survey: 2009, cdcinfo@cdc.gov). Although it is to be expected that surgical treatment results in some degree of patient discomfort, acute postsurgical pain has been widely undertreated. In one survey, 80% of patients reported experiencing moderate to extreme pain after surgery.\(^1\) Ineffective postoperative pain management is associated with economic and medical implications, including extended lengths of treatment, readmissions, and patient dissatisfaction with medical care.\(^2,3\)

Consequently, in 2001 the American Pain Society (APS) declared the start of a “Decade of Pain Control and Research” and urged health professionals to treat pain as “the fifth vital sign.” Thereafter, a flood of practice guidelines emerged in the literature in an attempt to emphasize and provide instructions for realization of this proposal. Nonetheless, a decade later, the parent organization of the APS, the International Association for the Study of Pain (IASP), designated 2011 the Global Year Against Acute Pain. This campaign sought to highlight “the persistent problem of acute pain...the most commonly experienced pain (e.g., surgery, childbirth, trauma)...treatable with currently available medications and techniques [but with] a large gap between evidence and practice—resulting in widespread under-treatment” (http://www.iasp-pain.org/Content/NavigationMenu/GlobalYearAgainstPain/GlobalYearAgainstAcutePain/default.htm).

It turns out that achieving satisfactory acute pain management is quite challenging. It is often difficult to estimate what a patient’s postoperative analgesic requirements will be.

The following factors, for example, may influence postoperative opioid requirements:

- Preoperative pain sensitivity\(^4\)
- Coexisting medical conditions and associated multiple drug administration
- Presurgical opioid tolerance or a history of drug abuse
- Psychological factors, including catastrophizing and anxiety\(^5,6\)
- Age\(^7\)
- Type of surgery\(^8\)

Great care must be applied to consider all the aforementioned characteristics when deriving an analgesic plan for managing an individual’s response to a surgical insult.

The sequelae associated with surgical procedures result from various components of the stress response and include cardiopulmonary, infectious, and thromboembolic complications; cerebral dysfunction; nausea and gastrointestinal paresis; fatigue; and prolonged convalescence. Throughout the process of organizing an acute pain program, it is helpful to keep the following statements in mind:

- The postoperative pain management regimen should be designed with attention to providing patient comfort and also inhibiting nociceptive impulses sufficient to allow a patient to participate fully in active rehabilitation when appropriate.
- A time-, energy-, and cost-effective acute pain program should optimally provide multimodal and multidisciplinary interventions, including systemic and regional pharmacological treatments, stress reduction, transcutaneous electrical nerve stimulation, music therapy, and acupuncture.\(^9,11\)
- Surgical stress responses are inhibited mostly by the neuraxial administration of local anesthetics; the administration of other agents—systemically, neuraxially, or perineurally—appears to contribute little additional reduction of the endocrine (metabolic and catabolic) stress response following operative procedures.\(^12,13\)
- Parenteral opioids exaggerate the perioperative immune system depression already triggered by the neuroendocrine response to surgery; although the clinical relevance of this observation is controversial.\(^14\) Opioids administered into the epidural space have minor suppressive effects on surgically induced proinflammatory cytokines.\(^15\)
- Effective analgesia can reduce postoperative morbidity. As an example, thoracic epidural analgesia has been shown to improve postoperative spirometry and reduce pulmonary infections and atelectasis.\(^16,17\) In many settings the routine and “gold standard” of care involves such facilitation of the patient’s recovery of pulmonary function.

The experience of a skilled anesthesiologist easily lends itself to providing leadership within an acute pain service. Anesthesiologists are proficient in the use of systemic and regional analgesic techniques, including peripheral and neuraxial blockade. They also often have an understanding of the surgical techniques and consequent insults that they impose. Additionally, anesthesiologists are well equipped with leadership skills for working within a multidisciplinary team; these are also vital skills within the operating theater. Nonetheless, an anesthesiologist-based team is not the only service model.

Nurse-based, anesthesiologist-supervised inpatient acute pain services have also been demonstrated to provide safe
and effective postoperative pain management.\textsuperscript{18,19} Regardless of the service model, nursing involvement in an acute pain service is essential. Bedside nurses' impression of a patient's analgesic needs and recovery is an invaluable element in the decision-making process for any given patient, and because it is the nurse who will ultimately be delivering the care, it is vital that the nurse understand the analgesic plan and goals.

Detailed practice guidelines and protocols can help streamline the ordering and implementation of patient care. Well-established protocols have been shown to reduce errors in realms outside pain management\textsuperscript{20} and decrease the cost associated with prescribing choices.\textsuperscript{21} At the University of Washington Medical Center, for example, we have instituted multiple protocols, including order sets for patient-controlled analgesia (PCA), continuous and patient-administered epidural analgesia, ketamine infusions, and continuous perineural catheter infusions (Figs. 3.1 to 3.4; we have recently switched to electronic order sets mirroring these past paper protocols). The PCA and epidural analgesia protocols must include titration and bolus instructions to treat breakthrough or incident pain. The order sets should also include routine and specific monitoring orders, as well as treatment options for common or dangerous side

![PAIN SERVICE: Parenteral (IV/SQ) Patient Controlled Analgesia (PCA) Orders](Image)

**Figure 3.1** A and B, University of Washington Medical Center parenteral (intravenous/subcutaneous) patient-controlled analgesia standardized order set. Courtesy of University of Washington Medical Center, Seattle, Washington.
effects (e.g., antiemetics or antipruritics and opioid receptor antagonists to reverse respiratory depression). Ketamine and perineural anesthetics are most frequently ordered as adjuncts to other analgesic therapies (e.g., PCA). Recovery room, intensive care unit, and medical/surgical floor nurses must be trained to be familiar with the order set parameters. In most cases, nurses are able to assess the patient and implement changes that successfully achieve adequate analgesia with minimal side effects autonomously.

An emerging area of concern for any anesthesiology-based pain service is the increasing complexity of invasive pain management techniques in an era of ever-increasing numbers of anticoagulants given as treatment or prophylaxis for an ever-increasing number of medical and surgical indications (including, for example, treatment of cardiac arrhythmias or valve disease and deep vein thrombosis prophylaxis). To aid in treating such patients with the least risk, the University of Washington Medical Center has designed institutional guidelines (based on national guidelines such as those of the American Society of Regional Anesthesia, for instance) for the management of indwelling neuraxial and peripheral nerve catheters in patients treated concomitantly with anticoagulants (Table 3.1). The document was designed to address placement, maintenance, and removal of catheters.
of the catheter in several common anticoagulation scenarios. The intention of such guidelines is to distill the existing scientific evidence and opinion into a format that is easily accessible and simple to apply to patient care.

**PERSONAL INVENTORY**

It is important to recognize at the outset that establishing a pain service is a major endeavor. Planning, design, and implementation of a successful service will require substantial human and material resources.

If the need and desire for an acute pain service exist within a hospital facility, one must first elicit the support of the department chairperson. Although multiple design models for an acute pain management service are possible, most will require that an anesthesiologist be made available for some level of participation in the service. Unless resources allow an anesthesiologist to be easily released from operating room obligations, the staffing conflict will present a certain challenge. An agreeable arrangement of service responsibilities must allow the anesthesiologist to be available to provide safe and consistent care to whomever he or she is responsible.

**PAIN SERVICE EPIDURAL INFUSION ORDERS**

Page 1 of 2

1. Discontinue current opioids and/or benzodiazepines except: ______________________________

2. Epidural Catheter: (check one)
   - ☐ Thoracic placement
   - ☐ Lumbar placement
   - ☐ Other: ______________________________

3. Infusion: (check one)
   - ☐ Continuous + Patient Controlled Epidural Analgesia (PCEA)
     - Continuous rate: 6 mL (standard) mL/hour (Maximum infusion rate is 14 mL/hr)
     - PCEA dose: 2 mL (standard) or ______ mL
     - PCEA dose lockout: 10 min (standard) or ______ min
   - ☐ Continuous Infusion ONLY
     - Continuous rate = ______ mL/hour

4. Drug(s): (check one)
   - ☐ FENTANYL 2 mcg/mL + BUP/VACAINE 1/16% (0.625 mg/mL)
   - ☐ FENTANYL 2 mcg/mL + BUP/VACAINE 1/10% (1 mg/mL)
   - ☐ FENTANYL 2 mcg/mL + BUP/VACAINE 1/8% (1.25 mg/mL)
   - ☐ BUP/VACAINE 1/16% (0.625 mg/mL)
   - ☐ BUP/VACAINE 1/10% (1 mg/mL)
   - ☐ BUP/VACAINE 1/8% (1.25 mg/mL)
   - ☐ BUP/VACAINE ______ % (______/mg/mL)
   - ☐ Opioid (specify) __________________________ mcg/mL or mg/mL + BUP/VACAINE ______ % (______/mg/mL)

5. VOLUME OF EPIDURAL SOLUTION = 250 mL in normal saline (standard)

6. BREAKTHROUGH PAIN MANAGEMENT (check one)
   - ☐ Continuous + Patient Controlled Epidural Analgesia (PCEA) (check box)
     - Give clinician bolus equal to ______ continuous hourly infusion rate or ______ mL into epidural catheter
     - Increase continuous hourly rate by 2 mL/hrs every 2 hours PRN
     - Maximum recommended infusion rate is 14 mL/hr.
   - ☐ Continuous Infusion only (NO PCEA – no patient controlled settings) (check box)
     - Use IV PCA clinician bolus dose orders to treat incident/breakthrough pain if patient has both epidural pain management AND IV PCA pain management (check box)
   - ☐ Other: ______________________________

**RN Independent Double Check:**

Check patient identifiers, drug, drug concentration, pump settings, and PCA connection to compatible IV line. Check with PCA initiation, change in drug, and change in concentration.

Initiated by: ____________________________ Date: ____________ Time: ____________

Verified by: ____________________________ Date: ____________ Time: ____________

Once the intradepartmental issues of resource allocation have been discussed with the chairperson, the proposal to begin an acute pain service should be brought to the medical director and team. Commitment of the medical director to the project will be necessary for provision of resources in the form of personnel and money.

Finally, appropriate leadership for the acute pain service must be selected. Operating the service will require a diverse constellation of skills. The individual must have knowledge of the mechanisms of acute postsurgical pain and the methods of treatment, including opioid and nonopioid analgesia, epidural placement and maintenance, peripheral nerve catheter placement and maintenance, and ketamine and other adjuvant drug therapies—as well as treatments of the side effects from these therapies. An anesthesiologist is often the best fit since he or she has experience with these therapies. Of course, as mentioned previously, a number of nonpharmacological therapies (e.g., physical and alternative or complementary medicine therapies) also have a role in acute pain management, and leaders of any acute pain service must likewise be aware of these therapeutic strategies.
In addition to expertise in analgesic therapies, the success and stability of any new acute pain service will require that the service director also possess certain nonclinical skills, including strong leadership, organizational, and administrative abilities. Clinical success demands the integration of multiple clinical disciplines, such as nursing, medicine, pharmacy, and others. These diverse professionals need to operate independently and in collaboration. Additionally, the leader will need to understand the place of the acute pain service within the structure of the hospital organization. The service should be structured so it is made both efficient and valuable to the hospital and its surgical services.

Selection of a qualified director of an acute pain service is vital to its success.

**ASSESSMENT OF NEED**

Once the challenge of organizing an acute pain service is accepted, assessment of need is mandatory. This might be accomplished by surveying the patient population, nurses, types of specialty services, procedures commonly performed, and the people performing these procedures. Furthermore, the Joint Commission on Accreditation of
Healthcare Organizations (JCAHO) has set forth standards declaring the patient's right to adequate pain assessment and treatment and has explicitly acknowledged that pain is a coexisting condition with a number of diseases and injuries that requires explicit attention. It is on this basis that the mission statement of the service should be defined.

Those constructing the service might also consider whether they wish to distinguish or separate different types of pain management challenges or manage them as a conglomerate. As an example, the University of Washington Inpatient Pain Services is divided into three factions: acute pain, chronic/cancer pain, and interventional pain. The service was separated into these groups to preserve continuity of care and more practically manage the high volume of patients. Admittedly, the boundaries between these categories are artificial and may overlap. As an example, consider a patient with acute postsurgical pain superimposed on chronic cancer pain or a patient who has recently undergone placement of an implanted epidural neuromodulating device for treating chronic pain.

Whatever the organization, an acute postoperative pain management service is likely to require 24-hour,

### Anticoagulants for VTE prophylaxis

- **Heparin unfractionated, 5000 unit q8h or q12h**: May be given; no time restrictions for catheter placement/removal or spinal injections. Do NOT call pain service.
- **Dalteparin (Fragmin), 5000 u/day SQ**: 8 hr
- **Enoxaparin (Lovenox), 40 mg/day SQ**: 12 hr (longer in renal impairment)
- **Enoxaparin (Lovenox), 30 mg SQ q12h or 40 mg SQ q12h**: 12 hr (longer in renal impairment)
- **Fondaparinux (Arixtra), < 2.5 mg SQ qday**: 48 hr (longer in renal impairment)
- **Rivaroxaban (Xarelto), 10 mg PO**: 24 hr (longer in renal impairment)
- **Dabigatran (Pradaxa)**: 72 hr (longer in renal impairment)
- **Dalteparin (Fragmin), 200 U/kg/day SQ or 100 U/kg SQ q12h**: 24 hr (longer in renal impairment)
- **Enoxaparin (Lovenox), 1.5 mg/kg/day SQ or 1 mg/kg SQ q12h**: 24 hr (longer in renal impairment)
- **Fondaparinux (Arixtra), 5-10 mg/day SQ**: 72 hr (longer in renal impairment)
- **Heparin unfractionated, IV continuous infusion or >5000 units SQ bid or tid**: When aPTT <40 sec
- **Rivaroxaban (Xarelto), 15-20 mg PO day**: 24 hr (longer in renal impairment)
- **Warfarin (Coumadin)**: When INR <1.5

### Agents used for full systemic anticoagulation

- **Heparin unfractionated, IV continuous infusion or >5000 units SQ bid or tid**: When aPTT <40 sec
- **Rivaroxaban (Xarelto), 15-20 mg PO day**: 24 hr (longer in renal impairment)
- **Warfarin (Coumadin)**: When INR <1.5

### Notes

- ATTENTION: When can you safely do neuraxial/peripheral nerve procedures or give anticoagulants?
  - Neuraxial routes include epidural and intrathecal infusions, implanted intrathecal pumps, and spinal injections.
  - Peripheral routes include all peripheral nerve and plexus infusions.
- NOTE: Bloody tap/procedure? Anesthesia to call pain service.

7-day-a-week call coverage, with appropriately available medical supervision. Immediate availability is important with regard to patient safety and patient satisfaction. Inadequacy of pain relief has been highlighted as a quality-of-care measure and a focus of patients’ concern. In a questionnaire survey, 57% of patients identified pain after surgery as their primary fear. The competitive health care environment mandates that hospitals share a focus on the issues that are most important to patients. Favorable reports of patient satisfaction may attract patients to partake of services in a given hospital facility and also encourage patient loyalty with return for future medical services. Furthermore, immediate postoperative patient satisfaction with care is a predictor of long-term, positively self-perceived health status according to one multicenter prospective cohort study. Indeed, data from the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) are likely to put hospital pain management, as well as patient satisfaction with that management, front and center not only with regard to comparisons between hospitals but ultimately for reimbursement of hospital services.

### DEFINITION OF THE SERVICE

Once the mission statement has been formulated in response to the perceived institutional and community needs, it is necessary to define the resources that will be required. The resources and modalities that an acute pain service may use are diverse and depend on the patient population, the skills of the personnel, and the service’s therapeutic approach. Ideally, a scientific approach to the selection of treatment modalities that specifically evaluates the efficacy and cost-effectiveness of each therapy is used. Ultimately, the resources required to implement and operate an acute pain service will represent a synthesis of characteristics of the patient population, evidence-based selection of therapeutic modalities, and consistency with the service’s mission.

The feasibility of various treatment plans based on the availability of resources has been defined by the IASP task force on the management of acute pain (Table 3.2). Again, individualized treatment of patients should ideally be chosen from a rational, evidence-based selection list, also outlined by...
the IASP task force on management of acute pain (Table 3.3). Such ideal care allows maximal improvement of patients’ outcome with the most cost-effectiveness possible. To achieve this aim, resources in the form of medications, equipment, and personnel must be anticipated and negotiated with the institution’s administrative, business, and clinical departments when one is designing the structure of the service.

After the resources are defined, it is imperative to assess the safety of the proposed plan. The principles of therapy to be implemented in the practice of pain medicine should allow one to do the following:

1. Evaluate the source and severity of the pain.
2. Understand the relationship between pain and other components of suffering (e.g., a poor prognosis creating reactive depression or anxiety).
3. Achieve and maintain adequate analgesia and incorporate it into the acute rehabilitation scheme.
4. Refine therapy based on individual needs.

Ongoing quality assurance evaluation can be managed on a service, departmental, or institutional level but should be transparent to participants and provide an opportunity for feedback and improvement for trainees, faculty, and the service itself.

FINANCING AND THE BUSINESS PLAN

The next step in the process of organizing an inpatient acute pain service is to construct the business plan. This is often the most difficult phase since the financial and business skills needed may not be innate to clinical anesthesiologists and are rarely covered in their training. Furthermore, the value analysis of this type of service is not entirely monetary.

It should be emphasized that although the cost of delivering care may be considerable, calculation of the cost analysis is a more complicated determination. The ideal measurement of utility regarding pain management is controversial. Researchers have examined outcome measures, including hospital stay, hospital readmissions, quality of
life, and productivity. However, regardless of the cost analysis, there is a cultural expectation and ethical imperative supporting the philosophy that appropriate treatment of pain is independently valuable. The JCAHO has emphasized this sentiment in their statement that appropriate pain management is "good medicine" and that "excuses for inadequate pain control will no longer be accepted because poor pain control is unethical, clinically unsound, and economically wasteful."

With that acknowledgement, the purpose of an acute pain service business plan is to describe the inner workings of the proposed service, including its organizational strategy, marketing plan, tentative schedule for implementation, and overall cost. This must occur before the first cent is spent on the project. The business plan has two components. The first arm of the plan is a narrative that includes the mission statement, its structure, and the responsibilities of the service. Here, the job descriptions of involved personnel are outlined, facility requirements are listed, and the marketing plan is presented. This document should clarify the role, responsibilities, duties, and expectations of various personnel key to a successfully operating service. Guidelines and manuals for nurses and house staff are key to this first portion of the business plan.

The second portion of the business plan is prepared as a spreadsheet that outlines the finances of the business endeavor, and these estimates must be as accurate as possible. Estimates of fixed and variable incomes, the start-up capital necessary until revenue produces profit, and a month-by-month expenditure estimate for at least the first year must be among the data provided in this document. The plan should also consider the acquisition cost of analgesic medications and other pharmacy costs.

Macario and McCoy reviewed the records of 298 patients who underwent hip or knee replacement surgery and found that pharmacy cost accounted for only 3% of the total hospital cost but that postoperative analgesia cost represented 31% of the total pharmacy cost. Other cost drivers include human resources in the form of pharmacists and nurses, as well as equipment, including PCA and epidural pumps. Medication errors are another rarely considered factor that increases the cost of postoperative analgesia. Adverse drug events, for example, have been shown to result in extending hospital stay by 4.6 days at a cost of $5857 per patient. Finally, this second section of the business plan ought to include a discussion of anticipated challenges to reimbursement either within or outside the institution.

For instance, it is necessary to examine the insurance characteristics of the patient population that the acute pain program will serve. Based on the payer mix or the percentage of the population that is served by health maintenance (HMO), preferred provider (PPO), and medical care (MCO) organizations, it may be necessary to arrange plans for preauthorization of acute pain services with the administrators of local health plans. To prepare for this step in the business plan, it is ideal to have an estimate of the anticipated monthly patient load and the minimum number of patients that will be required to support service expenses. If there is a risk that the number of postsurgical patients using the acute pain services will not suffice, expansion to include nonsurgical or cancer patients with pain may be considered.

When assessing these sources, one must be sure that reimbursement will adequately cover the expense of the additional time, energy, and personnel required to deliver and document daily care.

In construction of the business plan, total revenue minus total cost will produce a predicted financial position. This calculation begins with estimation of the approximate charge per patient for each therapeutic modality as the patient load waxes and wanes. This is best accomplished by shifting fixed cost (e.g., permanent employees) to variable cost (e.g. temporary employees) as much as possible. Remember that the result of this calculation will fluctuate over time. Financial solvency of the service will be most protected by hoping for the best while planning for the worst-case scenario.

BILLING AND COLLECTION

A well-organized structure for billing and collection for services is imperative to ensure the solvency of any medical organization. Knowledgeable personnel, the necessary hardware, and efficient software for data collection are necessities if the service’s business plan includes an internal billing and collection group. As medical coding and billing accelerate in complexity and specialty, many organizations have elected to employ outside billing and collection services that operate on a percentage-based contract.

It is crucial to be aware of current Centers for Medicare and Medicaid Services (CMS) guidelines for documentation and billing and to remain informed about modifications as they occur. Accurate documentation of services will facilitate correct and timely reimbursement, as well as represent what was actually done in the medical record. Furthermore, accurate documentation will make clear what was not done both to other health care professionals and to third party payers—thereby avoiding time-consuming changes in documentation, fines, and even criminal charges if discrepancies between CMS guidelines and physician billing are judged to be fraudulent. (Example reference guides regarding chart notation and CMS-required documentation can be found in Appendixes A through F.)

MARKETING PLAN

Once design and planning of the up-and-coming acute pain service have been completed, a marketing plan will be important to promoting its utilization. Potential referring providers and patients will need to be introduced to the concept and to the benefits that the service has to offer.

Although conventional medical education often leaves physicians naïve to the business and marketing dimensions of medicine as an industry, help can be garnered from the hospital’s public relations office or from a private marketing firm. Implementation of the marketing plan is another cost that must be considered in the service’s budget.

The marketing strategy must be designed with care. It should present a consistent image of the mission and
services offered by the budding acute pain service in a light that emphasizes the added value to patient care. The marketing strategy may also delicately make a case for the potential cost and convenience advantages of using the new service. Methods for circulating such information may include announcements and brochures, professionally prepared stationary, logo, newsletters, and websites.

Internal education is another vital part of marketing an acute pain service. Frequent positive interactions between the acute pain service and other departments and their personnel (e.g., presentations at interdepartmental case conferences) are crucial for increasing the visibility of the service and expanding its referral base. In an academic institution, this might also include the involvement of nonanesthesiology residents in the service. When residents rotating from other specialties participate, particularly from the surgical department, they can learn about the treatment modalities offered and the advantages that they provide. Finally, the importance of education and involvement of nursing colleagues cannot be overestimated since they are often in a position to suggest that a patient be referred to the acute pain service.

It is also important that the acute pain service remain attentive and responsive to changes in patient care needs. Recently, for example, some acute pain services have found utility in providing formal or informal perioperative pain clinic services as well. Such clinics can be helpful in preoperatively identifying and planning for patients who are likely to have difficult pain management problems postoperatively (e.g., patients with chronic pain or opiate tolerance), thus improving perceived service efficacy and efficiency. Moreover, a perioperative pain clinic can help surgeons wean their difficult postoperative pain patients from a complicated analgesic regimen or transition them back to their chronic pain therapies. Such outpatient services can help market more classic acute pain inpatient services to surgical colleagues, as well as provide better (and perhaps safer) continuity of care.

Finally, the marketing plan of an acute pain service should align itself with the JCAHO and its standards and expectations. Implementation and compliance with these standards should serve to propel an acute pain service toward success since both aim to make pain a top priority.

CONCLUSION

Although health care providers acknowledge that providing analgesia to acute postsurgical patients is important, this task is often easier said than done. Challenges to meeting this aim include opioid tolerance, acute-on-chronic pain scenarios, and the great variety of surgical procedures and techniques. An acute inpatient pain service can often offer insight and experience when dealing with these complex clinical issues. However, the design, planning, and implementation of an acute inpatient pain service must be performed with great care and intention. Only with thoughtful construction will a successful service emerge that is able to meet and exceed the needs of the hospital, its surgical services, and the patients whom they serve.

KEY POINTS

- Acute, postoperative pain remains widely undertreated even though it is a primary concern of patients anticipating planned surgery.
- An optimal postoperative pain management program will integrate multimodal and multidisciplinary interventions.
- Several systems for organizing an inpatient acute pain service have been described, although most use a partnership between nursing and anesthesiology.
- Detailed practice guidelines, protocols, and order sets can streamline and simplify care.
- Enlisting the support of hospital administration and defining resources are a vital first step in organizing an inpatient acute pain service.
- Treatments provided by the pain service should be individualized and evidence based.
- The business plan of the service must include a cost analysis, although delivery of pain relief is inherently valuable beyond a calculable measure.
- The business plan should be flexibly constructed by shifting fixed cost to variable cost whenever possible.
- Accuracy in documentation and billing is crucial to facilitate timely and correct reimbursement.
- A marketing plan introduces potential referring providers to the concept and benefits that the service presents.

INTRODUCTION

Chronic pain is an urgent public health concern that significantly impairs the physical, psychological, and social functioning of those experiencing it and their significant others. The Institute of Medicine (IOM) recently estimated that more than 110 million adults, over one third of the population of the United States, experience some form of chronic pain, with the symptom of pain being the most common reason for people to consult a primary care physician. Despite the magnitude of this problem, pain management is severely under-represented in the content of medical education and is delivered by many providers who feel unprepared to manage it. Consequently, treatment of pain is highly variable and often unstructured, with important decisions being based primarily on clinician intuition, personal bias, and the severe time constraints present in hurried practices.

It is estimated that chronic pain costs between $565 and $635 billion per year in health care and reduced productivity; these costs have increased fivefold in the past decade and will probably increase with the aging population. However, these increases in health care expenditures have not translated into improvements in clinical outcomes. In addition, the National Center for Health Statistics noted that 40% of people reporting chronic pain indicate moderate to severe degradation in their functioning, thereby contributing to the high direct and indirect costs of chronic pain. Poor provider self-reported pain care competency reduces clinician productivity and increases practice dissatisfaction in those managing chronic pain. Most importantly, these costs do not reflect the incalculable impact of pain on the lives of patients and their significant others.

Given that chronic pain is a complex biopsychosocial disorder, successful management of it requires a systematic multidimensional approach to assessment and strategically targeted interdisciplinary therapies. Care of complex chronic illness requires defined processes for rapid identification of problems and “stepped” systems that reliably direct services to intensified treatment strategies for challenging patients who have a limited or poor response to initial treatments. This chapter discusses a patient-centered approach to the care of chronic pain and how outcomes are improved when an interspecialty collaborative model is followed.

STEPPED CARE

The stepped care model entails a well-established primary care response to the management of chronic disease that systematically adjusts medical treatment when patients are not responding to initial interventions. Wagner and colleagues cited five components of stepped care:

1. Use of explicit plans and protocols
2. Reorganization of the practice to meet the needs of patients who require more time, a broad array of resources, and closer follow-up
3. Systematic attention to the information and behavioral change needs of patients
4. Ready access to necessary expertise
5. Supportive information systems

Von Korff and Tiemans subsequently described a model involving the stepwise introduction of targeted interventions to improve the care of patients with chronic illness; this model provides a framework for achieving cost-effective care based on patients’ observed response to treatment.

STEPPED CARE IN PAIN

The World Health Organization (WHO) cancer pain analgesic ladder is a historic example of a stepped care model, though with a sharply delineated focus on relief of the intensity of cancer pain alone. This is undoubtedly a useful and effective model for relieving acute and progressive pain from cancer and for palliative and end-of-life care of pain when reducing the intensity of pain becomes the primary and often sole goal of treatment, even, when necessary, at the expense of function. The WHO ladder continues to be useful even though it does not include pain’s other domains of biopsychosocial distress. Care of chronic noncancer pain focuses its outcome on function—not primarily comfort—in patients not at the end of life and thus needs to incorporate other of pain’s domains beyond reported pain intensity.

John Loeser from the University of Washington has depicted the individual’s experience of chronic pain as a concentric series of domains and specifically differentiated the painful nociceptive experience from the enveloping experience of suffering and maladaptive behavior that
patients with chronic pain often demonstrate. A search for the elusive nociceptive pain generator that can be numbed, burned, or otherwise removed will undoubtedly result in exclusion of care for complex pain disorders, which often require systematic multidimensional assessment of pain.

Loeser’s “onion” (Fig. 4.2) is a multilayered rather than a multisteped care model, and although he does not delineate algorithmic plans, protocols, and measures in detail, it still anticipates a stepped approach to the care of pain in patients with chronic illness.

Von Korff and Moore proposed a stepped care approach specifically for the primary care management of chronic back pain in which interventions are sequenced “so that the intensity, complexity, and costs of care are guided by each patient’s observed outcome.” Otis and coauthors also published a convincing case-based rationale for the stepwise integration of coordinated mental health services into progressively more treatment-resistant pain care coordinated within a primary care practice setting.

COLLABORATIVE CARE APPROACH

The most robust demonstration of the effectiveness of collaborative care has been described in the management of depression. Unützer and Park described a model of “measurement-based care, treatment to target, and stepped care in which treatments are systematically adjusted and ‘stepped up’ if patients are not improving as expected.” This approach has demonstrated improved patient satisfaction and health outcomes.

COLLABORATIVE CARE OF PAIN

Dobscha and others described a model and the preliminary outcomes of collaborative care for chronic musculoskeletal pain in primary care practice. A clustered randomized trial that evaluated collaborative care for chronic pain in five primary care settings within a single Veterans Administration medical center demonstrated greater improvement in pain-related disability, and in patients with baseline depression, greater improvement in the severity of depression was achieved in those receiving the intervention than in patients receiving treatment as usual. The study intervention followed the stepped care approach and included patient assessment, monitoring of symptoms, a two-session program for education of clinicians, education and activation, feedback and recommendations to clinicians, and facilitation of specialty care. Outcome measures used in this study were the Roland-Morris Disability Questionnaire and the Patient Health Questionnaire 9-item (PHQ-9) depression inventory.

EXISTING GUIDELINES

Multiple guidelines and algorithms have been published for specific painful disorders, including back pain, headache, and other chronic pain conditions commonly encountered in both specialty and primary care clinical practice. Many guidelines exist for opioid management; however, there are limited published and widely accepted clinical practice guidelines for comprehensive measurement-based, stepped care for chronic pain beyond efforts by the Department of Veterans Affairs to streamline the treatment of pain within its health care setting. This gap persists despite published evidence that such a stepped care approach leads to better overall outcomes. The following sections summarize various studies in the published literature that have evaluated the stepped care approach, as well as efforts made to date that hold promise for more standardized and widely accepted clinical practice guidelines.

PAIN CARE PROGRESSION MODEL

Dubois and colleagues proposed a pyramidal model for implementing a “population-based stepped-care approach to chronic pain” (Fig. 4.3). Their future model for management of pain in the U.S. Veterans Health Administration medical system calls for increased levels of expertise based on a patient’s level of complexity. Although it does recognize that specific degrees of expertise are necessary for effective...
CHAPTER 4 — MEASUREMENT-BASED STEPPED CARE APPROACH TO INTERDISCIPLINARY CHRONIC PAIN MANAGEMENT

Treatment outcomes, being essentially a stepped model extending up through the continuum of primary to tertiary pain care, it does not anchor these levels with measurement-based benchmarks that systematize the assessment to determine who progresses and to which type of physician or other health care professional. A proposed linkage of stepped care with a measurement-based approach is described below.

MEASUREMENT-BASED STEPPED CARE: THE PAIN TREATMENT DOMAINS

Because chronic pain is a multidimensional disorder, achieving the best outcomes requires attention to more domains than just self-reported pain intensity. The “fifth vital sign,” which is useful for the care of acute pain, is an insufficient assessment measure for achieving the best outcomes in patients with chronic pain. Measurement-based care directed toward physical and emotional function, quality of sleep, risk for chemical dependency, adherence to treatment, patient satisfaction, and self-reported quality of life is well recognized and in fact involves critical patient response domains that, when followed over time, permit useful assessment of outcomes. Adjusting pain treatment on the basis of immediate clinical outcomes follows the fundamental tenet of “stepped care.” Just as a random blood sugar measurement is not a sufficient measure of care in a diabetic patient, chronic pain in a complex chronic illness such as diabetes requires measurement and tracking of many biobehavioral and comorbid health outcomes over time. By systematizing standard metrics, measurement-based care is expected to improve assessment and facilitate adjustments in treatment to match the response of individual patients to care; improved quality and consistency of measurement will enhance the quality of care and the patient’s satisfaction with it, increase the health of the population, and probably reduce the per capita cost of care, the so-called triple aim of the Institute for Health Improvement.

A collaborative care chronic illness process for chronic pain would need assessment measures for the specific chronic pain domains frequently encountered in patients with complex chronic pain. This model would require formulating an individualized stepped care plan that matches a patient’s unique combination of active co-occurring disorders with the interspecialty domains of chronic pain. Measurement-based stepped care would systematically identify multidimensional signs and symptoms of poor physical, emotional, and sleep function and longitudinally track treatment outcomes across these specific domains. Structured multidimensional pain measurement and consistent tracking of treatment outcomes are needed to reliably and routinely prompt modifications in any care provided.

At the University of Washington, chronic pain is currently being measured with a number of specific evidence-based public domain tools. These measures are recorded in an electronic database, which can individually report the patient’s status at each visit, starting with the initial identification of chronic noncancer pain (advised to begin at day 90 of opioid therapy) and at all subsequent pain treatment follow-up visits. Different tracking versions are in place that range from pain specialty consultation to primary care practice. Unique modules are being developed for specialties commonly encountering challenges in pain management, such as orthopedics, physical medicine and rehabilitation, rheumatology, and neurology.

PROBLEM OF NONCOLLABORATIVE PAIN CARE

Many challenges confront chronic pain care as a result of gaps in policy, treatments, attitudes, education, and research,
as detailed in the 2011 report Relieving Pain in America by the IOM.\textsuperscript{2} Not only does the IOM fundamentally identify pain management as a moral imperative, but it also outlines the importance of comprehensive treatment, the need for interdisciplinary approaches, the importance of prevention, wider use of existing knowledge, recognition of the conundrum of opioid use, collaborative roles for patients and clinicians, and the value of a public health– and community-based approach.

Pain care also suffers from the frustratingly limited ability of most current chronic pain treatments, either interventional or noninterventional, to reduce the intensity of pain, with efficacy typically being less than 30%.\textsuperscript{34} These therapeutic limitations redirect attention to what else beyond pain intensity predicts success or failure in managing chronic illness. Stepped care is such a structured process for assessing and reducing the adverse impact of chronic pain on additional life measures—less of “how much does it hurt?” and more about physical function, mood, quality of life, and access to systematic care.

Current models of delivery of pain care tend to be noncollaborative, fragmented, and inconsistent. A struggling primary care provider unable to identify the cause of a patient’s disabling, severe persistent pain may recognize that the patient is doing poorly despite escalating doses of opioids without improvement in pain or function and with high levels of patient distress and problems in adherence and compliance. Referral to a wide range of specialists should follow, but to which specialist, triggered by what measures, and with what goal? Figure 4.4 illustrates the status quo in today’s common treatment approach to chronic pain. Common issues, questions, and potential problems that arise from such an inadequate model of care include the following:

- How and when does the primary care provider determine which specialist to refer to?
- How likely is it that the recommendations will be coordinated with other members of the care team?
- Are all specialists in agreement about what to measure to meet the diagnosis and treatment goals?
- Can all agree on which care guideline to use?
- How does the patient make sense of all this advice and move forward into a meaningful treatment plan?
- Who is measuring compliance and adherence to whatever treatment plan is chosen?
- Are records shared?

Given the inadequacies of current practice in the management of chronic pain, discussion of the stepped care approach provides some context toward a more collaborative and integrated management of care for patients with chronic pain.

**STEPS 1 AND 2: MEASURING PAIN INTENSITY AND PAIN INTERFERENCE**

Von Korff and others developed and validated a two-item pain intensity and interference scale that has been endorsed by the Washington State Agency Medical Directors Group (AMDG) guideline (Fig. 4.5).\textsuperscript{25} It is specifically intended for use by primary care prescribers of opioids, with the goal of assessing response to opioid treatment when given for the management of chronic pain of noncancer origin.

Other validated but more detailed tools to measure how much pain interferes with function have been used for decades, especially the Oswestry and the Roland-Morris Disability Questionnaires.\textsuperscript{35-37} These measures provide a more detailed assessment and identify specific activities of daily living directly affected by chronic pain.

**STEP 3: ASSESSMENT OF MOOD AND RISK FACTORS**

**SCREENING FOR DEPRESSION AND ANXIETY**

Given the biopsychosocial impact of chronic pain, it is imperative that the impact of chronic pain on mood be measured

---

consistently. Many studies have documented the utility of specific measures to assess and address depression, in particular, the PHQ-9 (Fig. 4.6). Pain with co-occurring psychological disorders managed in 14 rural primary care practices demonstrated improved outcomes when longitudinally measured with the Medical Outcomes Study Short-Form 36-Item (SF-36) survey and the Functional Interference Estimate at baseline, 6 months, and 12 months.

Measuring the mood of chronic pain patients at every clinical encounter is as reasonable as measuring blood pressure and weight in addition to pulse when evaluating cardiac status. Direct observation has shown that the time needed for patients to complete the nine-item PHQ-9 paper form is just 15 to 30 seconds (personal observations by D.T.). Clinicians may also adopt a shorter version for assessment of mood in place of the PHQ-9. For example, the PHQ-4 is a validated shortened combination of two measures from the PHQ-9 depression questionnaire and two measures from the Generalized Anxiety Disorder 7-item scale (GAD-7) anxiety questionnaire (Fig. 4.7). In addition, the publicly available item banks of the Patient-Reported Outcomes Measurement Information System (PROMIS) developed by the National Institutes of Health include well-developed mood and other pain-related affective disorder assessments that deploy computer adaptive testing technology to provide the shortest selection of questionnaire items needed to reliably assess the domains of interest. Other tools to measure mood are also widely available, and although the diversity of instruments will stimulate research in psychometrics, the use of diverse questionnaires in clinical effectiveness research inhibits direct comparisons between outcomes from different study populations. Therefore, a move toward the selection of standard measures holds much promise in the development and continuing advancement of the PROMIS item banks.

### Totals

Risks Associated with Chronic Opioid Therapy

Opioid dose–prescribing limits have been proposed in response to the dramatic increase in accidental overdoses of prescription opioids and deaths in most regions of the United States. The initial opioid dose limit proposed by the 2010 Washington State AMDG of 120 mg morphine equivalent dose (MED), beyond which specialty consultation is advised when pain and function are not improved or risk for poor mood, high distress, or substance abuse is present, was based on a consensus of Washington State clinicians from both community and academic practices. There is now growing evidence-based support for safety limits with escalating opioid doses for chronic noncancer pain (Fig. 4.8). Elevated risk also extends to fractures from accidental falls, sleep disordered breathing, endocrinologic disturbances, and immune dysfunction. Limited support for benefit and increasingly evident risk for escalating opioid doses in chronic pain management differentiate the comfort-directed goals for palliative and end-of-life pain from the function-directed goals for chronic noncancer pain.

### Substance Use Disorders and Pain

The value of a stepped care model when managing alcoholism has been reported by Sobell and Sobell, and many tools to assess and refer primary care patients for treatment of alcoholism are well described and have been proved effective. Measurement-based tools to assess for alcoholism include the long-familiar CAGE (cut down, annoyed by criticism, guilty about drinking, eye-opener drinks), the Alcohol Use Disorder Identification Test (AUDIT), the brief Michigan Alcoholism Screening Test (bMAST), and others. With estimates of co-occurring addiction and pain ranging from 18% to 30% and the well-established increased

complexity of care for pain patients with active or remote substance abuse disorders, it is of vital importance to care carefully to assessment and outcomes when prescribing opioids and other at-risk drugs such as benzodiazepines and other sedatives.\textsuperscript{59,63} Based on a 1-year evaluation of function in primary care patients with musculoskeletal pain and a substance abuse disorder, Morasco and associates proposed stepped-up interventions in pain patients with chemical dependency problems: “Chronic non-cancer pain patients with a history of a substance use disorder (SUD) report poorer pain-related functioning and are less likely to experience clinically significant improvements from usual pain treatment. Providers should assess for SUD status and provide more intensive interventions for these patients.”\textsuperscript{64}

Evidence that the use of opioids for pain is a risk factor for the development of substance use disorder patterns of behavior is robust.\textsuperscript{65-68} Furthermore, measurement of opioid misuse may be needed not only at the outset of chronic opioid therapy (COT) but also throughout treatment.\textsuperscript{59} Fleming and coworkers reported a ninefold increase in the likelihood of a substance abuse disorder when four or more types of aberrant drug behavior occurred (in particular, self oversedation, report of feeling intoxicated, early refill requests, self-directed dose increase) in more than 900 chronic pain patients seen in a primary care practice, with no cases of abuse being diagnosed when no aberrancies occurred.\textsuperscript{70} The challenge of uncovering or inducing frank addiction and less clear-cut addictive behavior to the many scheduled drugs used for the treatment of chronic pain complicates the management of patients who, as a result of medically prescribed and despite compliant use of long-term high-dose opioids, may proceed to develop complex persistent opioid dependency, a syndrome becoming evident to clinicians struggling to wean chronic pain patients off long-term high doses of opioids.\textsuperscript{71} Drug-dependent behavior and urine drug-monitoring aberrancies occur along a spectrum, including in many highly functioning patients, mostly those managed with long-acting and high-dose COT;\textsuperscript{72-74} many of whom may not meet addiction diagnoses by clinical or Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria (and pending DSM-V criteria).

**ADVERSE SELECTION**

There is a growing evidence base to support the high risk for psychiatric and substance use diagnoses in patients receiving the highest doses of opioids for chronic pain. The 2006 Trends and Risks of Opioid Use for Pain (TROUP) study found opioid use to be higher in individuals with mental health and substance use disorders, and in individuals with chronic pain, those with mental health and substance use disorders were more likely to receive opioids than those without these diagnoses.\textsuperscript{75} A misuse score was generated on the basis of days of short-acting opioids supplied, days of long-acting opioids supplied, number of opioid pharmacies, and number of opioid prescribers. The authors concluded that patients with chronic pain and mental health or substance use disorders are more distressed and more complicated to care for than patients who have only chronic pain. High prescriptive use of sedatives and opioids was found particularly in young depressed women receiving higher-dose COT for multiple pain problems.\textsuperscript{76} The authors noted that this “potent combination of risk factors since younger age, higher daily opioid doses, and depression have all been shown to be independently associated with worse opioid-related outcomes and, in the case of depression, higher rates of long-term COT use.” Since patients at the highest risk are being prescribed the highest opioid doses, so-called adverse selection,\textsuperscript{77} systematic measurement-based assessment of mental health will add critical structure and pain care consistency when making

clinical decisions regarding the most appropriate opioid dose for patients at the highest risk.

**STEP 4: MEASURING CHRONIC OPIOID TREATMENT RISKS**

Several widely used opioid risk scales can be used by clinicians to determine the safety of prescribing opioids long-term. As reviewed by Chou and colleagues, these scales include the Opioid Risk Tool (ORT); the Screener to Predict Opioid Misuse Among Chronic Pain Patients (SOAPP-R); the Current Opioid Misuse Measure (COMM); and the Diagnosis, Intractability, Risk, and Efficacy (DIRE) Score. Each tool offers advantages and disadvantages, although the length and total number of questions needed are a crucial determinant of applicability in the workflow of community and academic primary care practices. All are validated instruments, so selection of the optimal tool depends on clinician preference and the logistics of administration (i.e., self-report vs. clinician administered). Regardless, some measure of opioid risk must be recorded before committing to opioids for COT, and the degree of risk can also be used to systematically determine the frequency of urine drug monitoring or the frequency of accessing state prescription drug-monitoring programs, which are available in nearly all states in the United States.

The use of urine drug toxicology to monitor adherence to pain medication treatment has been extensively reviewed by Christo and colleagues. The results of urine drug toxicology are often complicated by false positives and negatives, incomplete knowledge of the expected metabolism of opiates, variable testing thresholds in different laboratories and available commercial products, and cross-reactivity of enzyme-linked dipstick assays; additional training and support by laboratory experts are often needed when unexpected results are seen in clinical practice. A clinically useful algorithm for urine testing based on risk assessment is available in Appendix D of the Washington State AMDG guidelines.

**STEP 5: CALCULATING OPIOID DOSE EQUIVALENCY**

Because high opioid doses increase risk, they need be consistently reviewed on an ongoing basis. Many different formulas are available to convert different opioids into a comparable “equianalgesic” value, typically called the “morphine equivalent dose.” To consistently record the opioid dose according to a standard equianalgesic formula, the Washington State AMDG has published a web-based calculator that is a recommended conversion tool to determine the opioid dose and hence risk. This can be accessed at the URL: www.agencymeddirectors.wa.gov/opioiddosing.asp.

**STEP 6: MEASURING THE EFFECT OF PAIN ON SLEEP**

Pain nearly always disrupts sleep, and disordered sleep or sleep deprivation increases pain intensity. Managing sleep disturbances is thus a valuable first-line approach to the care of patients with acute, chronic, or palliative pain conditions. Additionally, either isolated or combined obstructive and central sleep apnea increases in frequency with the dose of opioid. A variety of tools are available, including the STOP-Bang sleep apnea screening tool (Fig. 4.9).

**LONGITUDINAL MULTIDIMENSIONAL PAIN TRACKING**

The use of evidence-based multidimensional longitudinal data for clinical decision making has only recently been introduced into pain treatment protocols. A number of proprietary systems that combine extensive public domain questionnaires are available, and some are linked to large registry data banks, which offers the potential to improve research on the effectiveness of specialty-based pain treatments in real-time clinical practice. Less lengthy paper-based and electronic systems have been designed for primary care. One example is *PainTracker*, developed by Mark Sullivan and his group at the University of Washington. It is designed to record and graphically present several pain treatment–related domains in a format that is easily reviewed and implemented in day-to-day clinical decision making for patients taking opioids for chronic noncancer pain. Limited to 17 questions, it records pain intensity, interference of pain with function, mood, sleep, opioid risk, and treatment compliance, and it is presented graphically alongside concurrent opioid MED dosing (Fig. 4.10).
Limited access to pain specialists contributes to problems in pain care. In the United States, fewer than 3500 physicians were board-certified in pain care between 2000 and 2009. This shortage in expertise leaves more than 33,000 people with chronic pain for every specialist, and 80% of people experiencing severe pain are never referred to a specialized pain program or clinic. Solving this problem calls for a new approach to pain management, at least in the United States, if not globally. Opioid-based management of chronic pain also represents an ongoing U.S. public health problem. Pain medications are inherently dangerous, with five of the top six fatal drug outcomes in the United States attributed to this category of drug.

**ACCESS TO EXPERT PAIN CARE**

**INNOVATIVE MODELS OF PAIN CARE**

Because improved access to pain specialty care remains a major problem, is it possible to fix the problem by simply increasing the supply of highly trained pain specialists? This does not follow the progressive care model proposed earlier since it
increases the number of pain specialists without the called-for increase in collaborative and coordinated care. An alternative is to identify and train “pain champions” from the existing pool of primary care providers. This would allow more proficient non-specialty pain clinicians to be embedded in the community clinic setting, where nearly all pain is treated. This “stepped-up” clinician proficiency could add process support and technical information for a robust measurement-based stepped care approach. This kind of postgraduate educational program is now being piloted at the University of Washington and is called Pain Champions: A Look Over the Expert’s Shoulder (available at depts.washington.edu/anesth/education/forms/pain/UW-Pain-Champions-Overview.pdf).

Another solution is to deploy multidisciplinary expertise through a telehealth platform. These experts would promote measurement-based care strategies, train providers on how and which tools to use, and assist in the interpretation of poorly performing patients based on objective measures that can be tracked over time. A model of pain care delivery following a provider-to-provider educational consultation has been developed at the University of New Mexico and was further advanced for chronic pain and addiction consultation at the University of Washington (Fig. 4.11). This “Extension for Community Healthcare Outcomes” (ECHO) is designed to be an interactive learning environment or “knowledge network.” Consistent with the measurement-based stepped care approach to improve pain care outcomes, using defined measurements to assess multidimensional domains and following them over time would be expected to improve provider and patient satisfaction and clinical outcomes and reduce cost. Studies are now under way to determine how large and durable these effects will be in areas of provider knowledge, competency, and patient multidimensional outcomes.

Figure 4.12 illustrates the process and components in the systematic measurements specific to the multidisciplinary domains of chronic pain management. This then allows clinicians to quickly identify specific problem areas either at the outset of care or as pain treatment progresses. This structured approach to chronic pain care, in which treatments are systematically “stepped up” when patients are not improving as expected, follows the core principles outlined in currently effective processes of complex disease management. Attending to crucial functional and psychosocial measurements beyond pain intensity alone will facilitate consistent and rapid referral to an appropriate specialist. For instance, when a patient shows a high degree of limitation in physical function, rehabilitation medicine with physical and occupational therapy will be consistently considered. Vocational counseling can be added when pain interferes with or prevents return to work after an unexpectedly prolonged time until recovery from an injury. Evidence of a serious behavioral health problem will quickly prompt referral to a psychiatrist or clinical psychologist. Poor treatment adherence can trigger referral to a nurse care coordinator, social worker, or both. Sleep disorders can be addressed readily and treatments attempted by the treating clinician, and when tracking shows the sleep difficulty to be refractory to primary efforts, timely referral to a sleep specialist can determine whether central or obstructive sleep apnea is a factor and, if indicated, the need to step up to more expert cognitive behavioral therapies for insomnia.

When a systematic process is in place to assess and monitor for evidence of risk for a substance use disorder, there can be a consistent increase in the intensity of monitoring for adherence, such as more frequent urine drug monitoring or access to state prescription drug–monitoring programs. With systematically recorded evidence of noncompliance with a controlled substance (i.e., need for early refills, unexpected urine drug results, lost or stolen prescriptions), referral to an addiction specialist, specialized counseling, or both will be routinely triggered.

When the pain persists without a diagnosis and treatments result in no improvement in pain relief and function, especially when opioid dose escalation has occurred, timely referral to a pain specialist is indicated. This stepped care incorporates specific benchmarks to consistently and collaboratively guide the progression of pain care. Structured and systematic measurement-based care has demonstrated improved patient outcomes and satisfaction and reduces cost by treating according to prespecified care plans. Integration and coordination of mental health and primary care have
CONCLUSION

Pain is more than nociception, and chronic pain always requires a multidimensional approach to care. Stepped care is a well-established approach to chronic illness, with increased levels of treatment intensity being added when improvement is not observed in response to earlier interventions. Measuring the multidimensional disturbances that occur when pain progresses from a symptom of a disease to a disease itself increases the pain care provider’s ability to consistently identify and diagnose pain complaints and impairments related to the often accompanying biopsychosocial difficulties, including physical deconditioning unrelated to or as a sequela of the initial injury or disease, co-occurring and newly developing behavioral health disorders, abnormal sleep function, and risks relevant to the frequent occurrence of chemical dependency in this population. Finally, measurement-based care identifies the correct next step up the referral pathway for pain patients who are not doing well and prompts early referral to a specialist in pain medicine before the problem becomes intractable.

The Health-Care Policy of Pain Management

Thomas R. Vetter

INTRODUCTION

Chronic pain is a major cause of suffering, disability, lost productivity, and diminished quality of life across the entire life course. Cross-sectional studies have revealed that upward of 55% of adults experience chronic pain. Likewise, up to 45% of children experience at least one episode of chronic pain, with an attendant similar adverse effect on their daily activities and quality of life. Many pediatric patients with chronic pain eventually experience similar recurrent pain as adults.

In its 2011 report Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research, the Institute of Medicine (IOM) estimated that more than 116 million Americans struggle with chronic pain—greater than the combined prevalence of heart disease, cancer, and diabetes—which results in associated medical cost and lost productivity of US $635 billion annually. Even in a country such as Canada, with its more constrained, universal health insurance, the recently estimated (and escalating) yearly expenditure of Can $3500 per chronic pain sufferer translates into annual direct system costs of greater than Can $400 million. Acute pain also has major adverse effects on individual health and well-being, as well as a major impact on the health care delivery system. Furthermore, inadequate treatment of acute postoperative and traumatic pain in adults and children can lead to particularly severe and unremitting chronic pain.

Based on focus groups of key stakeholders, six major themes have been identified by the Pain Action Initiative: A National Strategy (PAINS) regarding chronic pain, all of which speak to its interconnected ethical, economic, and health care policy elements (Box 5.1). Pain management thus has a myriad of implications on major health care policy, several of which are discussed here. Health care policy per se is a very broad and continually evolving topic for which more comprehensive resources are available.

THE ROLE OF ECONOMIC EVALUATION IN FORMULATING CHRONIC PAIN MANAGEMENT POLICY

The individual and societal costs of pain are multifaceted and extensive, and it is essential that informed policy makers and practitioners be fully aware of them (Box 5.2). Of note, the acute and chronic pain-related cost borne by the individual, such as uninsured treatments, informal care, and intangibles related to loss of quality of life, is unquestionably substantial but difficult to estimate, and consequently it is often underappreciated.

As discussed in the current accompanying chapter on clinical trial design (Chapter 80), appraisal of a new or existing treatment involves three aspects: efficacy, effectiveness, and efficiency. Even though randomized controlled trials can rigorously assess the efficacy of a pain treatment, their findings often lack external validity (generalizability to other settings). This weakness underscores the need for more naturalistic observational studies of treatment effectiveness in real-world practice (e.g., as part of multidrug, multimodal pain therapy, in more demographically and clinically diverse patients, and for much longer periods).

There are simply not enough financial resources in the health care systems around the world—even in the most developed countries—to fund all technically feasible and potentially beneficial health care interventions. Given such inevitably constrained health care resources, difficult choices have to be made, and a formal economic evaluation offers a systematic and transparent process for informing such choices. Specifically, the comparative efficiency (incremental cost per clinical outcome) of a pain intervention can be determined. However, there is a great need for more robust, longitudinal cost-effectiveness studies on assessment and treatment of chronic pain.

Health care economic evaluation methods have matured considerably in the last 25 years, with a plethora of published resources. Nonetheless, despite widespread promotion to this audience, many physicians, health services researchers, and policy makers remain reluctant to apply economic evaluation methods in their clinical decision making and clinical trials. Much of this gap has been attributed to physicians and their inherent tendency to think more in terms of clinical effectiveness and advocacy at the individual patient level rather than about cost-effectiveness (efficiency) at the population or health policy level. This resistance to collecting, analyzing, and incorporating health economic data in the presently well-established era of both evidence-based medicine and demand for value in health care is particularly notable.
patient access to comparable health care—including pain management.\textsuperscript{18,31} Pioneered by John Bonica and Wilbert Fordyce more than 50 years ago, a multidisciplinary pain treatment program has been advocated as the optimal way to manage chronic pain.\textsuperscript{45,48} This long-standing recognition of the merit of multidisciplinary pain treatment clinics, combined with an increasing prevalence of chronic pain, has led to a growth in demand, clinic waiting list size and time, and international concerns over limited pain treatment resources—all prompting the question of how can science guide health policy regarding chronic pain.\textsuperscript{49}

Given its national health insurance program (“universal coverage” framed by the Canada Health Act of 1984), Canada presents a unique opportunity to examine the health policy and economics of pain management in a developed country. An initial survey of Canadian multidisciplinary pain treatment facilities (MPTFs) conducted by the STOP-PAIN Research Group found the median wait time for a first appointment in public MPTFs to be 6 months, approximately 12 times longer than the wait time for nonpublic MPTFs. The existing capacity of MPTFs in all of Canada could meet only 20\% of the demand.\textsuperscript{50} The authors and others concluded that current Canadian MPTFs are unable to meet the clinical needs of adult patients with chronic pain in terms of both regional accessibility and reasonable wait time for patients’ first appointment.\textsuperscript{50,51} The STOP-PAIN Research Group reported similarly inadequate access, with variable and prolonged wait times for pediatric patients suffering from chronic pain.\textsuperscript{52}

Two subsequent STOP-PAIN studies focused on the biopsychosocial and economic burden of adult patients on Canadian MPTF wait lists.\textsuperscript{53} In STOP-PAIN-1, patients on MPTF wait lists experienced severe pain (61\%), marked limitations in activity (66\%), significant depression (50\%), and frequent suicide ideation (35\%).\textsuperscript{53} These biopsychosocial findings from STOP-PAIN-1 are similar to those from large concurrent samples of pain treatment clinic patients in Australia and Germany.\textsuperscript{54,55} In STOP-PAIN-2, the median monthly cost was Can $1462 per study participant on an MPTF wait list, 95\% of which was due to lost productivity (wages) and personal out-of-pocket expenses.\textsuperscript{56}

An extensive systematic review of the literature and a survey of International Association for the Study of Pain (IASP) chapter presidents and other key stakeholders identified no established benchmarks or guidelines for acceptable wait times for the treatment of chronic pain.\textsuperscript{57} However, another systematic literature review indicated that patients with chronic pain experience a significant deterioration in health-related quality of life and psychological well-being from the time of referral to treatment.\textsuperscript{58} This consistent pattern of evidence underscores the need to improve access to appropriate care for patients with chronic pain—an escalating public health problem with major human and economic cost.\textsuperscript{58}

\textbf{Box 5.1 Current Major Themes in Chronic Pain Management}

- Reducing disparities in access to pain care in the young, elderly, and lower socioeconomic groups
- Defining quality of care in pain management
- Need to train qualified providers and offer training programs in pain medicine
- Need for evidence-based public policy regarding opioid use and diversion
- Need to raise awareness about chronic pain as a disease to prevent stigmatization and discrimination
- Promotion of multimodal therapies for pain care as a way of diverting attention from opioid abuse problem

\textbf{Box 5.2 The Multifaceted and Extensive Individual and Societal Costs of Pain}

- Cost of interventions and therapies for treating pain and securing pain relief (e.g., cost of drugs and staff)
- Cost that is incurred as a result of ineffective interventions being provided (e.g., cost of additional primary care consultations)
- Cost to health service and to patients and their families because of lack of appropriate facilities within a locality (e.g., cost of accessing alternative therapies)
- Cost resulting from inappropriate self-medication and treatment by patients (e.g., cost of treating overdoses)
- Cost of treating and preventing adverse events that arise as a result of prescribing decisions (e.g., cost of gastrointestinal bleeding)
- Cost of disability claims resulting from people’s inability to work
- Cost to the economy of reductions in productivity and absenteeism
- Cost of providing social care and support to people suffering with pain (e.g., cost of home care and respite care)
- Cost of informal care provided by families (e.g., loss of earnings)
- Cost of intangibles associated with deterioration in the quality of life of patients and their families

The World Health Organization (WHO) has estimated that more than 80\% of the world’s population is inadequately treated for moderate to severe pain and that 5 billion people live in countries with minimal to no appropriate access to controlled analgesics.\textsuperscript{59} Given this enormous worldwide burden, pain should ostensibly represent a major global public health concern.\textsuperscript{60,61} Yet pain management has been relatively neglected by national governmental agencies and international nongovernmental organizations.\textsuperscript{62,68} Acute, chronic, and cancer pain collectively represents the often unreported and hence silent dimension of many of the worldwide causes of both adult and pediatric morbidity and mortality.\textsuperscript{64} Although acute pain may reasonably be considered a symptom of disease, illness, or injury, chronic and
recurrent pain is a specific health care problem—a disease in its own right.\textsuperscript{61,69} It has been persuasively posited that this pervasive view of chronic pain as a symptom of disease rather than a disease state in itself has contributed to the paucity of public health and health policy attention (and funding) that chronic pain has received.\textsuperscript{27,60}

Consequently, the WHO, IASP, and European Federation of the IASP chapters jointly declared in 2004 that such widespread, inadequately treated chronic pain must not be tolerated and, furthermore, that relief of pain should be a universal human right.\textsuperscript{62-64,70} In 2010 the IASP issued the \textit{Declaration of Montreal: Declaration That Access to Pain Management Is a Fundamental Human Right} (Box 5.3), which, in addition to emphasizing that chronic pain is a disease entity, reaffirmed the basic human right to access effective pain management and the obligation of governments and health care institutions to establish laws, policies, and systems that help promote—not inhibit—access to pain management.\textsuperscript{69,71}

The two ultimate aims of this ongoing global pain initiative are to inform policy makers about the personal burden and economic cost of chronic pain and to educate physicians and allied health care professionals about assessment and management of pain to promote higher standards of care worldwide.\textsuperscript{65,69} Similar attention has focused on effective palliative care being a universal, international human right.\textsuperscript{67,72-74} Finally, denial of adequate pain treatment, when used as a form of punishment or torture, is a grossly egregious human rights violation.\textsuperscript{75}

### Box 5.4 Barriers to Access to Pain Treatment Globally

1. Failure of governments to put functioning drug supply systems in place
2. Failure to enact policies on pain treatment and palliative care
3. Poor training of health care workers
4. Existence of unnecessarily restrictive drug control regulations and practices
5. Fear among health care workers of legal sanctions for legitimate medical practice
6. Unnecessarily high cost of pain treatment

Even though simple, cost-effective treatments exist, a major gap exists between our increasingly sophisticated understanding of the pathophysiology of pain and its continued widespread inadequate management.\textsuperscript{64,65} Despite international human rights laws, calls for the reform of laws and policies inhibiting access to pain treatment worldwide, and the attendant obligation of sovereign states to provide their citizens access to pain relief medicine, obstacles still commonly exist in providing pain treatment and palliative care (Box 5.4).\textsuperscript{76,77} Of the 42 million grams of morphine consumed legally worldwide in 2010, 78% went to six countries—Australia, Canada, France, Germany, the United Kingdom, and the United States (Fig. 5.1A).\textsuperscript{78,79} As a result, access to even basic treatment, such as oral analgesics, including opioids (e.g., morphine), for cancer pain and antiepileptic and antidepressant drugs for neuropathic pain, is widely variable and commonly deficient (Fig. 5.1A and B).\textsuperscript{77,78,84}

Pain is a universal, multicultural experience that affects all people regardless of demographics or geography; however, inadequate treatment and the adverse effects of pain are not equally distributed worldwide.\textsuperscript{60} This gap is most apparent and problematic in the poorest and most socially dysfunctional developing nations in Africa and Asia, which are contending with widespread poverty, oppression and violence, and sometimes war and its aftermath (Fig. 5.2).\textsuperscript{64,65,79}

However, a similar disparity in pain treatment exists in Europe between the European Union member countries and the former Iron Curtain Eastern European and Balkan countries.\textsuperscript{80,85,86} Many cancer patients in Eastern Europe do not receive adequate relief of pain because of excessive regulatory restrictions on the availability and accessibility of opioids.\textsuperscript{87} According to a Human Rights Watch report, the Ukraine is one of several Eastern European and Central Asian countries that consume only enough opioids in total to treat less than 30% of their citizens with terminal cancer and human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS).\textsuperscript{86} Pain medicine and palliative care practitioners thus need to advocate for reform of governmental policy to overcome impediments to patient access to opioids.\textsuperscript{79,88} For example, a 4-year project in which health care professionals collaborated with governmental officials culminated in the Romanian Parliament passing new, more progressive legislation on the medical use of opioids and psychotropic substances, with an ensuing nationwide practitioner educational program.\textsuperscript{89}

### Increasing Worldwide Access to Analgesics

Although many in the world suffer needlessly, prescribing of opioids for chronic non–cancer-related pain has paradoxically escalated in the United States recently; yet such use has outpaced the growth of scientific evidence on the benefits
and harm of these medications.90,91 Critical research gaps exist on use of opioids for chronic non–cancer-related pain, and the need for a stronger evidence base is hence urgent.90,91 Nevertheless, a recent multidisciplinary expert panel commissioned by the American Pain Society and the American Academy of Pain Medicine concluded that based on a systematic review of the available, albeit limited evidence, chronic opioid therapy can be an effective treatment in carefully selected and monitored patients with chronic non–cancer-related pain.92

Even in countries such as the United States with its ample, if not perhaps overabundant supply of opioids, there are inconsistent prescribing patterns and thus frequently unequal and inadequate access to opioids. As with many other elements of the U.S. health care system, there are racial, socioeconomic, and age disparities in pain assessment and opioid prescribing patterns, with minorities, the poor, and the elderly less likely to have access to needed controlled substances.93-97 In many large U.S. medical centers, such marginalized patients with a legitimate need for opioids are customarily passed around from clinic to clinic. These patients thus out of necessity frequently visit emergency departments, where assessment and treatment of pain are widely variable and inadequate and where racial disparities in opioid prescribing also exist.98-102 An innovative pharmacy- and primary care–based chronic opioid management program (an “Opioid Renewal Clinic”) for such high-risk patients has been implemented successfully at the Philadelphia Veterans Affairs Medical Center.103-105 To be more widely applied, this comprehensive practice model requires close collaboration between primary care physicians and pain medicine specialists.106 However, there appears to be little support for such a labor-intensive, comparatively low-margin program among nongovernmental health care administrators and interventional pain practitioners.

Given their respective potential and historically major societal contributions, it can be cogently argued that equitable and compassionate health care of children and the elderly is a hallmark of a just, higher-order society.107-109 It is thus quite problematic that the especially vulnerable pediatric and geriatric populations remain quite prone to inadequate pain management—even in developed countries.

There is abundant published guidance on the assessment and treatment of pediatric pain, as well as robust data on its widespread prevalence and adverse effects.110-113 Thus, inadequate pediatric management can no longer be attributed to a lack of evidence-based medicine but rather to an inability to apply what is known in everyday practices.114 Clinicians, educators, administrators, and policy makers have an individual and collective responsibility to decrease pain and suffering in children and adolescents by narrowing the gap between current clinical practice and the existing research evidence and ethics supporting optimal patient care.114-117 In developed countries, including the United States, Canada, and the United Kingdom, there is a need for increased training, resources, and reimbursement for primary care physicians and pain clinicians who seek to manage pediatric chronic pain via an often indicated biopsychosocial approach.17,52,118,119 This need is especially great in smaller communities and rural settings, which are typically quite distant from formal pediatric pain medicine programs.17,52

However, the situation is even more dire throughout the developing world (in low- and middle-income countries), where access to even basic pain treatment services is largely unavailable to the vast majority of children and adolescents who suffer pain from diseases (e.g., HIV/AIDS, cancer, sickle cell disease, and severe pain from treatable injuries). Given the limited health care systems in many of these countries, the provision of simple analgesics is often beyond the capacity of health care workers to provide even basic pain management. In such cases, providing even minimal training and equipment often significantly improves pain management, but the lack of proper reimbursement for even these limited services is a significant barrier. Inadequate pain management in low-income countries is also fueling the opioid crisis, as treatment access is being limited by a severe paucity of opioid medications. As a result, patients are frequently forced to rely on unsafe and unregulated sources of opioids, which can lead to addiction and often death. Additionally, the opioid crisis is spilling into the developing world, as patients return to their home countries after seeking treatment in developed countries and are unable to access safe supplies of opioids. This further exacerbates the already severe opioid crisis in these countries, which is leading to a dramatic increase in opioid-related deaths.120-122

To address these challenges, it is essential to develop global strategies to improve pain management and ensure equitable access to pain medications. This requires collaboration between international organizations, nongovernmental organizations, and governments to promote pain education, training, and policy development. It also requires the development of sustainable solutions to address the opioid crisis and promote safe opioid use in the developing world. The development of innovative, sustainable solutions to address the opioid crisis and promote pain management in low-income countries is a critical area of research and requires significant investment in order to reduce the burden of pain and suffering in these vulnerable populations.

cell disease) and trauma (e.g., injury, burns, war, terrorism, land mines). The scope of this collective pediatric suffering and a global plan of action have been detailed by the WHO and a group of invested clinicians.

At the other end of the age spectrum, assessment and treatment of geriatric pain have also been well described. Nevertheless, chronic pain affects an estimated 25% to 50% of elderly people living in the community. Geriatric chronic pain management remains similarly suboptimal, with improvement needed in screening, clinical evaluation, follow-up, and attention to potential toxicities of therapy. In 2009 the American Geriatric Society recommend low-dose, low-potency opioids (e.g., hydrocodone) over a nonsteroidal anti-inflammatory drug (NSAID; [e.g., ibuprofen]) as the first-line drug of choice for all elderly patients with moderate to severe pain, pain-related functional impairment, or diminished quality of life because of pain. Two subsequently published, large-scale, retrospective analyses of Medicare claims data have questioned these recommendations. In a cohort of arthritis patients (mean age of 80 years, 85% female), the use of opioids was associated with a greater risk for cardiovascular events, safety events requiring hospitalization, and all-cause mortality than was the use of NSAIDs. In the same database of patients, the risk for fractures of the hip, pelvis, wrist, or humerus was lower with propoxyphene and tramadol than with codeine, hydrocodone, and oxycodone. Despite the use of propensity score matching to balance the potentially confounding covariates identified, these authors did not consider the potential dose-response gradient or account for key confounders, such as over-the-counter analgesic use and gastrointestinal bleeding, functional status and falls, and tobacco exposure and cardiovascular events.

The National Institutes of Health Pain Consortium recently sponsored an "Expert Panel Discussion on the Pharmacological Management of Chronic Pain in Older Adults" to identify research gaps and strategies to address them. This 2010 panel focused specifically on the use of opioids and NSAIDs because of these continued uncertainties regarding their risks versus benefits.

Nursing home residents are a particularly vulnerable group of elders. The Centers for Disease Control and Prevention estimated that there are currently 1.5 million nursing home residents in the United States and that 43% of Americans older than 65 years will enter a nursing home at some point in their lives, with an average 835-day length of time since initial admission. Pain is a common symptom in older residents of nursing homes and can lead to adverse effects such as a decrease in activities of daily living and quality of life. Over the last 20 years the reported multinal prevalence of pain in nursing home residents has varied from 3.7% to 79.5%. Moreover, a very large-scale U.S. cross-sectional study of nursing home residents 65 years and older revealed 17% to have substantial daily pain, but this prevalence of daily pain ranged from 0% to 54.7% by individual facility. Thus not surprisingly, regulatory agencies, health care policy makers and administrators, health services researchers, and clinicians have identified improving pain assessment and treatment in nursing homes as a high priority. However, there has been little consensus about the best strategies to optimize pain management in nursing homes. Given the unique population and care environment, clinical leadership in nursing homes needs not only proficient pain assessment and treatment skills but also working knowledge of organizational change, including quality improvement, team building, collaborative decision making, and system-level problem solving. Of note, failure to provide adequate pain control in the nursing home setting has been legally interpreted as elder abuse.

### THE REGULATORY PROCESS FOR DRUGS AND MEDICAL DEVICES

It is worthwhile to compare, contrast, and critique the regulatory processes by which new drugs and medical devices are reviewed and approved for marketing and clinical use. In the United States, the Center for Drug Evaluation and Research (CDER) of the Food and Drug Administration (FDA) is primarily responsible for assessing the safety and efficacy of a new drug. As a new drug makes its way through this federal regulatory and approval process, a series of four phases are defined by the FDA CDER (Table 5.1). Medical devices are regulated in the United States by the FDA Center for Devices and Radiological Health (CDRH). The FDA CDRH classifies a new medical device according to its perceived risk by using a three-tiered system (class I, II, or III), with escalating supporting evidence required for efficacy and safety and for postmarket surveillance (Table 5.2).

In a similar manner, the Australian Drug Evaluation Committee makes recommendations to the national Therapeutic Goods Administration. As in the United States, after a drug is initially approved, marketed, and distributed...
in Australia, it is considered eligible for phase IV trials in which new or expanded uses or populations (or both) can be approved and long-term risk versus benefits explored. In the European Union, either a state (i.e., country) level or a more centralized process is followed for drug approval. In the more centralized process, the Committee for Human Medicinal Products evaluates and makes recommendations to the European Medicines Agency (EMA), which grants community marketing authorization.\textsuperscript{152,153} In the United Kingdom, after a drug is approved and licensed by the EMA, it undergoes further review for clinical indications and cost-effectiveness by the National Institute for Health and Clinical Excellence (NICE) in England and Wales or the Scottish Medicines Consortium in Scotland, which must approve its use by the respective branch of the National Health Service.\textsuperscript{154-156}

Given this very similar drug regulatory structure and process, one might expect a similar level of evidence required (i.e., threshold) and timeline for approval; however, such is not the case.\textsuperscript{147} In the United States the threshold for regulatory approval of a pharmaceutical is much lower than in Canada, the United Kingdom, and the European Union. Under the current Code of Federal Regulations, new drug approval by the U.S. FDA is typically based on demonstration of efficacy in only two or more randomized clinical trials, often in comparison to placebo—not the currently approved competing generic drug.\textsuperscript{159} Given the perceived

Table 5.2 Food and Drug Administration and Center for Devices and Radiological Health New Medical Device Risk Classification

continued progress of medical science, governmental marketing approval of a new drug implies to clinicians and the general public that the new product represents an advance over older treatments. However, these current FDA standards for approval fail to assess whether newly approved drugs are less efficacious or less well tolerated than existing, often lower-cost alternatives. This raises the possibility that patients may be harmed by receiving a newly approved, typically more expensive, yet less efficacious treatment instead of a less costly alternative with well-established effectiveness and safety.\textsuperscript{159} Aggressive pharmaceutical industry marketing to clinicians, as well as directly to consumers in the United States, increases the likelihood of this scenario.

In contrast, health care systems in several developed countries (e.g., Australia, Canada, and Britain) are applying comparative effectiveness research methods to allow decision makers (patients, clinicians, purchasers, politicians, and policy makers) to make informed decisions on specific health practices.\textsuperscript{160} Such countries are now specifically using cost-effectiveness analysis—a form of comparative effectiveness research—to make drug approval decisions and to determine what medications will be reimbursed from the finitely available collective funding.\textsuperscript{161} Such a cost-effectiveness analysis involves a head-to-head comparison of the cost and outcomes of the proposed proprietary drug versus an existing (if available, generic) drug.\textsuperscript{162} A similar approach is used for so-called “me too” drugs.\textsuperscript{161} NICE makes such decisions in the British National Health Service.\textsuperscript{156,163,164} The cost-effectiveness–based approval process used by NICE has not been without controversy—with some clinicians and patients deriding it as being tantamount to overt rationing of health care and restricting access to potentially vital therapies.\textsuperscript{165} Supervisors of the NICE system argue that markedly higher patient co-payments for such drugs in the United States amount to barriers to access and covert rationing.\textsuperscript{166,167}

Some have contended that the introduction of a new medical device into clinical practice is typically and unnecessarily delayed between 1 and 3 years in the United States when compared with the European Union.\textsuperscript{168} This is especially so with class III high-risk devices, which to receive approval for marketing in the United States, the manufacturer must demonstrate the device to be reasonably safe and effective, typically with a prospective, randomized controlled clinical trial.\textsuperscript{168} To receive approval to market the same device in the European Union, the manufacturer must demonstrate only that it is safe and that it performs in a manner consistent with the manufacturer’s intended use.\textsuperscript{168} Nevertheless, in recent years, well-publicized device recalls and lawsuits in the United States have led to concern that the FDA does not require sufficiently well-designed and valid supporting studies and does not keep unsafe devices off the market.\textsuperscript{169,170} A recent study observed that of 78 class III (“high risk”) cardiovascular devices that were approved through the FDA full premarket approval (PMA) process between 2000 and 2007, only 27% of the devices had been subjected to a single randomized trial and only 5% had undergone two or more blinded randomized studies.\textsuperscript{171} The failure of certain medical devices such as implantable defibrillators—despite full FDA approval of the PMA—could pose deadly risks.\textsuperscript{169} Of the 113 medical devices recalled from 2005 through 2009 by the FDA for life-threatening or very serious hazards, 78% were originally approved for marketing under the less stringent Section 510(k) FDA process or were considered so low risk that they were exempt from review.\textsuperscript{172}

### MEDICAL REVERSAL: WHY WE MUST RAISE THE BAR BEFORE ADOPTING NEW MEDICATIONS AND TECHNOLOGIES

In medicine, therapies, diagnostic tests, and screening modalities decline over time in clinical popularity for two reasons. The first reason is the occurrence of replacement—when an existing practice is supplanted by one that works better.\textsuperscript{173} An example of replacement is the use of low-molecular-weight heparin (e.g., dalteparin) instead of unfractionated heparin or warfarin for the treatment and secondary prevention of deep vein thrombosis in cancer patients.\textsuperscript{174} The second reason is the occurrence of reversal—when an existing practice falls out of favor not by being surpassed by another but when it is shown to have failed to achieve its intended goal or to result in harm that outweighs its benefits.\textsuperscript{175} Although such medical reversals should be rare given the widely promulgated guidelines for study design and reporting of findings and the well-established tenets of evidence-based medicine, they are ubiquitous.\textsuperscript{176} A recent study reviewed all 212 “original articles” published during 1 year in the *New England Journal of Medicine* and found that 16 (13%) of the 124 dealing with medical practice constituted reversal of existing practice,\textsuperscript{175} thus confirming a previously observed reversal rate of 16% in highly cited original clinical research studies.\textsuperscript{176} One of the most publicized examples involved rofecoxib (Vioxx). Its manufacturer, Merck, withdrew the drug in September 2004 because of an excess risk for myocardial infarction and stroke—after more than 80 million patients had taken the drug. This represents the largest prescription drug withdrawal (medical reversal) in history.\textsuperscript{177}

Although replacement represents a logical progression in medical care, reversal reveals frequent missteps.\textsuperscript{173} Specifically, medical reversal occurs primarily when a new clinical trial that is superior to its published predecessors by virtue of more robust design, controls, sample size, or primary end points contradicts current clinical practice.\textsuperscript{173,175} For example, since first described in the mid to late 1990s, vertebroplasty quickly achieved widespread use such that in 2004 the procedure was performed more than 27,000 times in the United States—despite a lack of strong evidence in support of its efficacy.\textsuperscript{178,179} To the contrary, two eventual well-designed randomized controlled trials conclusively demonstrated that vertebroplasty was no better than placebo (sham) in treating the pain and pain-related disability associated with osteoporotic compression fractures.\textsuperscript{181,183} Unfortunately, the available evidence in support of conservative therapy (bed rest, analgesic medication, physiotherapy, and bracing) for osteoporotic compression fractures is also not strong.\textsuperscript{184}

Medical reversal is problematic for three reasons: (1) it implies that mistakes or patient harm occurred with the previous but now abandoned, ineffective practice; (2) removing a once-common practice can be difficult, and continued adherence despite the contradicted claim furthers malfeasance; and (3) it undermines trust in the medical system.\textsuperscript{173} Therefore, raising the bar for adoption of new medical practices has been proposed. The “common sense” approach that a new treatment will or should work can no longer justify
its adoption. Instead, rigorous efficacy and effectiveness studies need to be done before new modalities and technologies are adopted.

CONCLUSION

Given the widespread and substantial human and financial impact of pain, the economics and health policy of pain management are inextricably linked. As noted earlier, all health care systems—across the entire socioeconomic spectrum—are confronting the same fundamental health economic and health policy problem: how best to allocate finite resources to satisfy infinite health care demands. Ultimately, as observed by a leading health care economist, “In a world of budget constraints there are no easy solutions.” Yet clear guidance and recommendations are readily at hand. Cited at the outset of this discussion, it is fitting to conclude by revisiting the 2011 IOM report Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research. It offers a set of underlying principles (Box 5.5) and a series of 16 salient recommendations, provides a time line for implementing them, and designates the groups responsible for doing so. Though focused on the U.S. health care system, these IOM findings are universally applicable and an urgent call to action.

**Box 5.5 Underlying Principles of the Institute of Medicine’s Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research**

**A moral imperative.** Effective pain management is a moral imperative, a professional responsibility, and the duty of people in the healing professions.

**Chronic pain can be a disease in itself.** Chronic pain has a distinct pathology that causes changes throughout the nervous system that often worsen over time. It has significant psychological and cognitive correlates and can constitute a serious, separate disease entity.

**Value of comprehensive treatment.** Pain results from a combination of biologic, psychological, and social factors and often requires comprehensive approaches to prevention and management.

**Need for interdisciplinary approaches.** Given chronic pain’s diverse effects, interdisciplinary assessment and treatment may produce the best results for people with the most severe and persistent pain problems.

**Importance of prevention.** Chronic pain has such a severe impact on all aspects of the lives of its sufferers that every effort should be made to achieve both primary prevention (e.g., during surgery for a broken hip) and secondary prevention (of transition from the acute to the chronic state) through early intervention.

**Wider use of existing knowledge.** Although there is much more to be learned about pain and its treatment, even the existing knowledge is not always used effectively, and thus substantial numbers of people suffer unnecessarily.

**The conundrum of opioids.** The committee recognizes the serious problem of diversion and abuse of opioid drugs, as well as questions about their usefulness long-term, but believes that when opioids are used as prescribed and appropriately monitored, they can be safe and effective, especially for acute, postoperative, and procedural pain, as well as for patients near the end of life who desire more pain relief.

**Roles for patients and clinicians.** The effectiveness of pain treatments depends greatly on the strength of the clinician-patient relationship; pain treatment is never about the clinician’s intervention alone but about the clinician and patient (and family) working together.

**Value of a public health and community-based approach.** Many features of the problem of pain lend themselves to public health approaches—concern about the large number of people affected, disparities in occurrence and treatment, and the goal of prevention cited above. Public health education can help counter the myths, misunderstandings, stereotypes, and stigma that hinder better care.

REFERENCES

This chapter covers both quality assessment and improvement systems and patient safety issues. These are in some cases distinct and in others inextricably interrelated. They are each debated on national and international levels, and both are fundamental elements of the daily practice of pain medicine. The first section considers quality assessment and improvement programs and some practical steps to take to create a “QA/QI” program in a pain practice. The second section discusses the patient safety movement, both on a national scale and in terms of how each pain practitioner can expect to be involved.

SECTION 6.1 QUALITY ASSESSMENT AND IMPROVEMENT IN THE PAIN CLINIC

A significant factor in the deficits of our nation’s health is the broader social dysfunction of the nation: the inequities of education, income, employment, social support, and opportunity that still exist in this country. Nonetheless, we are cognizant that our health care system is also severely troubled. In the ensuing two sections we discuss the topics of quality and patient safety separately. These sections review the practical efforts that pain physicians can make to address these issues at the level that they can control: in the pain clinic.

WHAT IS “QUALITY” IN HEALTH CARE: DO WE HAVE IT?

Quality as an issue in health care is a relatively recent phenomenon. Starr’s massive and Pulitzer Prize-winning 1982 review of health care policy and its relationship to society has no entry in its index for the word “quality” (or “value” or “outcome” for that matter). Health care quality has been defined in many ways over the past several years. Since providers are not the only parties interested in defining and determining quality, many opinions are available on what constitutes health care quality.

Lohr created a definition that the National Academy of Sciences’ Institute of Medicine (IOM) has included in its discussion of quality: “Quality is the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.” This definition, with its emphasis on targeting known “desired” goals of health and its link to evidence-based medicine, is attractive to most physicians. As Donabedian wrote in his landmark paper on quality assessment in medicine in 1966: “As such, the definition of quality may be almost anything anyone wishes it to be, although it is, ordinarily, a reflection of values and goals current in the medical care system and in the larger society of which it is a part.”

A recommended addition to the “medical” definition that was offered by Lohr is one that recognizes the importance of process (delivery of an intervention), as well as the structures that support that care in determining the actual outcome of the care. This three-legged stool provides opportunity for measurement (and improvement) of more than just report cards, which leads to a more comprehensive definition of health care quality if we add what is suggested by Bowers and Kiefe: “quality being the extent to which structure and process maximize the likelihood of good outcomes.”

Again, the emphasis is on the “likelihood” of good outcomes because high-quality care and outcomes are not necessarily directly linked. As Chassin and Galvin stated, the vagaries of the human condition mean that good-quality medical care can be followed by a poor outcome and excellent outcomes can occur despite poor care.

QUALITY VERSUS VARIATION IN HEALTH CARE: MISUSE, OVERUSE, UNDERUSE, OR NONE OF THE ABOVE?

Another important definition of quality in health care is the absence of misuse, underuse, or overuse of therapy. These three embodiments of poor quality, originally cited by Donabedian in the 1960s, remain a common reference in discussions of health care quality. The process of avoiding or eliminating these three problems is inherent in the standards of evidence-based medicine and in the effort to assess and eliminate unwarranted variation in care patterns. It is
important to recognize that variation may be good or bad, or neither. It may indicate significant overuse or underuse of a therapy and thereby signal that either the science of the therapy is poor or it is being applied haphazardly.

However, before practice data can truly be defined as “variation,” it must be assayed for any underlying reasons for diverse practices (including dissimilarities in supply and demand because of geographic economics and climate, for instance). Only if these factors are similar can any variation detected be linked to quality, rather than just being associated with confounding factors unrelated to quality. For instance, an increased number of obstetricians in an area may be associated with a higher birth rate in that area, but physician supply does not cause pregnancy (or birth).9

An important example of misinterpretation of variation is found in the influential monograph “The Care of Patients with Severe Chronic Illness: A Report on the Medicare Program by the Dartmouth Atlas.”10 Here the authors counted the number of physician visits by Medicare beneficiaries with various chronic medical conditions—filtered by hospital and by geographic region—and determined that the geographic regions where there are fewer physician visits are the same locations where the Medicare beneficiaries have higher levels of patient satisfaction and quality of care. From this they extrapolated to the conclusion that we have a surplus of physicians. One example cited is the contrast between the Mayo Clinic, where there are fewer physician visits, and nonintegrated health care systems in New York City and Los Angeles.

In reality, variation in health care practitioner visits may be associated with a diversity of genetic, cultural, and social situations. These three geographic areas are markedly different in their genetic, social, and cultural homogeneity, as well as in the percentage of older adults who live below the poverty level. They vary with regard to availability of nonphysician providers and thus access to preventive care. These three areas are also quite different in their rate of uninsured, so it is unimaginable that health care would be comparable between New York City or Los Angeles and Minnesota.11

This study’s conclusion is a reminder of the critical importance of risk adjustment for dissimilitude in population types when analyzing variation in clinical processes or outcomes. The value in finding variation in care is to provide a signal that there may be “best practices” that can be emulated, but best practices can be determined only if patient and disease characteristics are similar.12 Not all variation is misuse, overuse, or underuse.

5. Acceptability of care to patients—accessibility, the practitioner-patient relationship, amenities of care, patient valuation of care outcomes, patient estimation of care’s economic worth
6. Legitimacy—consideration of the value of care by others than the patient receiving that care, the aspect of societal valuation as mentioned above
7. Equity—the balance between what individuals and what society consider appropriate distribution of care and resources

Donabedian continued, “quality cannot be judged by technical terms, by health care practitioners alone; that the preferences of individual patients and society at large have to be taken into account as well.”

This last lesson should be kept in mind when choosing any single definition of “quality” as most appropriate.

**WHAT FORCES PROPEL THE MODERN QUALITY MOVEMENT?**

The concern about quality in health care became more intense in the latter 1980s as the systems of quality research and management that grew out of the business and manufacturing world were first applied to health care.14 Despite the improved outcomes with increased economy achieved by the application of these methods in some health care organizations, quality science did not widely penetrate the national health care delivery system.

In 1998, the IOM published its first large report detailing the problems in the quality of U.S. health care: “The Urgent Need to Improve Health Care Quality.” This was followed in 1999 by To Err Is Human: Building a Safer Health System. Report from the Committee on Quality of Health Care in America, which focused on patient safety and claimed that between 40,000 and 98,000 patients die annually in hospitals because of defects in the quality of their care.15 In addition, that report stated that 5.4% of patients suffered perioperative complications, almost 50% of which were due to caregiver error.

In addition to concerns about safety, five forces are driving the resurgence of concern about quality16:

1. Cost—health care expenditures have grown well past the trillion dollar mark, and it is now the perception of many in business, government, and the public that more than one third of that sum, or almost $400 billion annually, is a waste of money. Correct or not, this impression is a huge motivator for the modern concern about quality—and value—among those who are paying the bills for health care. This concern extends to pain medicine because it is a high dollar item: in 1998, $26.3 billion was expended on the care of back pain alone. Furthermore, it has been shown that low back pain episodes are associated with increased expenditure for other health conditions.

2. Variation in the application of care—geographic variation exists in cost and care, often without linkage between more care and better quality. This situation is a red flag for those who evaluate quality and who believe that variation represents an absence of evidence of value (see Figs. 6.1 and 6.2).
3. The increase in for-profit health care delivery systems, specialty (“boutique”) hospitals, and office-based surgery is a concern for some health care policy makers, who view these as potential drivers of increased cost. In addition, there is a fear that such practice modes “skim” the most profitable segment of income from traditional hospitals, thereby leaving the larger nonprofit and public entities at risk for financial ruin. This same argument was used against ambulatory surgery centers when they were first introduced in the 1970s and is the impetus behind the Certificate of Need requirements that the American Hospital Association was able to lobby for in many states. Furthermore, there is a potential conflict of interest when the providers are stakeholders in these health care entities.

4. The increase in medical malpractice litigation, seen by some as an indicator of poor quality, is viewed by others as a driving force of the defensive overutilization of services that leads to increased spending and exposure of the patient to unnecessary risk.

5. The expanding role of government and industry in scrutinizing health care and regulating its practice is due in part to the importance of these groups as the largest purchasers/consumers of health care, coupled with the business sector’s internal history of quality innovation.
There is reasonable debate on whether a specific patient may be safe and whether a specific error contributes to real morbidity. However, the public, legislators, and payers are convinced that both patient safety and human error are significant problems in today’s health care delivery system. The health care industry is now urged to create a “culture of safety” at all levels of practice, which will put in place processes that will eliminate or decrease the impact of human error.

The majority of error committed in health care is due to system defects rather than individual mishaps, as was pointed out in the IOM’s Crossing the Quality Chasm: A New Health System for the 21st Century. This book also presented a framework for improving health care quality with six specific targets for improvement:

1. Safety
2. Effectiveness
3. Efficiency
4. Timeliness of care
5. Patient-centered care
6. Equitable care

This anxiety about safety has led the Centers for Medicare and Medicaid Services (CMS) to make contracts with Quality Improvement Organizations (QIOs) and spend in excess of $200 million per year on them, despite evidence that QIOs often pay the bill. Indeed, there is a widespread belief that business management tools can provide the solutions to the health care quality problem. Recognition of this potential industry crossover is the reason that the business community, so oddly placed as our nation’s primary provider of health care insurance, has created powerful organizations, such as the Leapfrog Group (www.leapfroggroup.org), the Bridges to Excellence program (www.btol.org), and, in league with insurers, the Integrated Health Care Association (www.iha.org). Each of these organizations aims to push health care providers to embrace specific goals and types of behavior that are likely to improve patient safety and outcome.

Among these larger forces of business, government, and society, a lesson sometimes lost is that the individual practitioner can improve the quality of health care. If practitioners identify outcomes that are desired, use the tenets of evidence-based medicine to find “best practices,” and measure both their delivery of these therapies (process) and the results of these therapies (outcomes), it is more likely that quality will improve. Adherence to evidence-based “best practice” begins with the individual practitioner and is associated with significant improvement in patient outcomes, including mortality.

Continuous quality improvement (CQI) or total quality management (TQM) is a seven-step process that consists of the identification of desired knowledge, design of appropriate measures to obtain the necessary assessments, measurement, investigation of the measurements to find trends and best practices, return of that information to those who can effect change, implementation of change in practice to increase the incidence of best practice, and then remeasurement to assess the program of change. It is an outgrowth of the “total quality control” movement that spread from the business sector to health care in the 1980s. Its origins may be traced to Walter Shewhart’s work in the 1920s, including the “plan-do-study-act” cycle that was further amplified by Deming in the 1970s. In medicine, CQI has been valuable in creating significant improvement in practice patterns, even among multiple practitioners in multiple sites across geographically large distances.

The health care quality movement has attracted significant attention from the business community, the group that often pays the bill. Indeed, there is a widespread belief that business management tools can provide the solutions to the health care quality problem. Recognition of this potential industry crossover is the reason that the business community, so oddly placed as our nation’s primary provider of health care insurance, has created powerful organizations, such as the Leapfrog Group (www.leapfroggroup.org), the Bridges to Excellence program (www.btol.org), and, in league with insurers, the Integrated Health Care Association (www.iha.org). Each of these organizations aims to push health care providers to embrace specific goals and types of behavior that are likely to improve patient safety and outcome.

These organizations have recommended financial incentives (pay for performance [P4P]), public disclosure of hospital safety rankings (“report cards”), and institutional changes in quality methodology and behavior, including the use of electronic health records (EHRs) and computerized physician order entry (CPOE). They have spawned interest in these programs within CMS and pushed along initiation of the CMS P4P programs that are growing in parallel with those being created by private payers.

Success in quality improvement as a result of employer-based initiatives has been mixed. This is in part due to the choice of quality initiatives with insufficient evidence of validity, as occurred when Leapfrog pushed for high-risk surgical procedures to be limited only to hospitals whose volume had already reached a chosen minimum level. In addition, participation has been voluntary and the financial incentives have been either paltry, easily gained, or both. Some revision of the Leapfrog criteria occurred with late recognition of the importance of risk adjustment.

One challenge is that the correlation between process measures (those most easily measured) and outcome measures (more difficult to measure) remains controversial in the most basic and oft-studied clinical circumstances (e.g., outcome of treatment of myocardial infarction by hospital). This critical aspect of the application of quality science must be certain before any real value can be attached to public reporting of hospital (or physician) performance. Moreover, evidence is growing that even when accurate, report cards alone do not induce improved performance.
There is a known means of improving quality of care: the simple act of measuring controllable clinical outcomes in a way in which they can be systematically analyzed and the information provided to the caregivers, with guidance on opportunities for change.\textsuperscript{42-44} Using specific measures to guide improvement initiatives is the key to success of the application of quality science. By contrast, monitoring of broadly defined outcome measures (such as mortality in hospital report cards) fails to effectively improve care because their causative factors are so diverse and are often independent of the practice of the caregivers under observation. The failures of a “shotgun” approach to measurement are exacerbated by a lack of risk adjustment.\textsuperscript{45}

The Department of Veterans Affairs (VA) National Surgical Quality Improvement Program (NSQIP) was created by surgeons in the VA system and in 1991 began to collect data to allow assessment of surgical outcomes and quality in the many hospitals in the system.\textsuperscript{46} Nurses hired specifically to work on the study collected the data. It included variables (e.g., preoperative serum albumin levels) to allow risk stratification of patients. Three important principles have been elucidated:

1. It is an absolute requirement that all evaluations of health care quality be amended by stratification of patient risk factors (risk adjustment). Not doing so introduces an error rate as high as 60% when comparing the unadjusted quality of programs.

2. Provider volume does not necessarily correlate with outcome. This finding disputes the Leapfrog tenet that outcomes are improved by directing surgical procedures only to hospitals with “sufficient” volumes. Instead, there is no clearly “safer volume,” but what is important is the quality of the program.\textsuperscript{47} This exemplifies the error of choosing “obvious” quality goals before gathering adequate data.

3. Regular provision to surgeons of the results of their institutions’ outcomes allows identification of “best practice” and is an effective means of improving quality of care. This approach improved patient outcome measures such as mortality and length of stay by as much as 45%.

The VA system experience has further shown that there are aspects of the Leapfrog and 100,000 Life Initiatives that are of value: the use of EHRs, CPOE, financial incentives for compliance of providers with designated performance goals, and routine comprehensive quality measurement has led to improved quality and delivery of warranted care.\textsuperscript{46}

However, there are still barriers to comprehensive CQI programs: physician-specific outcome monitoring is unlikely to be accurate because any single doctor treats too few patients for accurate statistical evaluation, in most settings there is still a lack of extant evidence-based benchmarks, and technical barriers still prevent accurate collection of data.\textsuperscript{47} In addition, the lack of good data on the appropriate management of patients with multisystem disease means that a physician who holds back from treating one disease with guideline-specific treatments because of concern about disease–disease or disease–drug interactions would be “punished” if scrutinized under the current quality assessment and improvement paradigm.\textsuperscript{48} This illustrates the difficulty of attributing specific patient outcomes to “causative” individual provider actions.

Iezzoni, a pioneer in the science of risk adjustment, noted that outcomes in health care cannot be simplistically linked directly to care but are actually part of an equation that she terms an “algebra of effectiveness.” This “algebra” is determined by three factors: the patient’s condition and inherent risk, the effectiveness of the treatment provided, and an unaccountable or uncontrolled set of random variables.\textsuperscript{49} The NSQIP has proved that collection of risk-adjusted data regarding surgery site outcomes, rather than physician-specific outcomes measurement, is a successful strategy for improving outcomes. Notably, the NSQIP data collection and analysis that were facility specific were accurate enough that it prevented the planned closure of several “poorly” performing sites once risk adjustment for patient comorbidity was invoked.\textsuperscript{42} At this point in time, concentration on evaluation of facilities rather than individual physicians is the only appropriate CQI approach in view of the current limitations of technology and evidence-based medicine.

**APPLICATION OF CONTINUOUS QUALITY IMPROVEMENT AND TOTAL QUALITY MANAGEMENT: NATIONAL SURGICAL QUALITY IMPROVEMENT PROGRAM**

Community pain practice quality is improved if a cohesive program of measurement, identification of best practice, education, and reassessment is applied.\textsuperscript{50,51} CQI programs may improve the quality of therapy simply by inducing a more extensive review of a patient’s history. For instance, inquiry about patient risk adjustors may lead to the recognition of mental health issues that could significantly affect the outcomes of any pain treatment plan.\textsuperscript{52} The use of baseline measures can both direct care and provide an understanding of the probable potential for meaningful improvement in function and pain scores by identifying risk factors for long-term treatment failure.\textsuperscript{53,54} Verhoef and colleagues made the point that the best set of outcome measures for a pain practice will include some open-ended questions and also to let patients take on part of the role of setting goals for their own therapy.\textsuperscript{55} In this way, patients can be expected to be additionally motivated to reach these goals.

An active CQI program will also allow practitioners to evaluate the effects of the introduction of new therapies or treatment algorithms into their practices and either prove or disprove their value.\textsuperscript{56} CQI provides a means to achieve accreditation for facilities and may even influence which quality measurements are adopted by regulatory agencies as sources of “grading” quality of care.\textsuperscript{57} Finally, the use of a clinical database for monitoring patient outcomes also provides a sense of participation in the process for the staff members whose work is being assessed, a key factor in their acceptance of and enthusiasm for the benefits of CQI.\textsuperscript{58} The most significant hurdle in CQI for pain medicine is a lack of apparent benchmarks or national “best practices” that providers can emulate. Using the literature to establish benchmarks is prone to error because of the significant
positive bias in the reporting of success of techniques. Overall, the evidence is not clear which, if any, interventions improve many chronic pain states.\(^59\)

Analysis of practice patterns by either partners or an unassociated local group of pain physicians is potentially an excellent source of evidence in situations in which there is a lack of randomized controlled trials in the peer-reviewed literature. Assessment programs that are under the mantle of “peer review” statutes will allow participating physicians rapid and open means of sharing their own best practices with one another in an attempt to increase the quality of the community’s pain care. Such evaluation may be accomplished with very short questionnaires. Patient interest in and compliance with such assessments are usually avid.\(^60\)

Pain medicine practitioners can find a useful template for CQI programs that can be used in their own practices in Patel and colleagues’ description of such programs in mental health\(^61\):

**Quality improvement programs are practice and system strategies that support efficiency, appropriate care, and acceptable outcome. Comprehensive approaches that support client and provider education; encourage consumers to take a more active role in their recovery; and make use of support structures, such as case management to coordinate care have been shown to improve quality, in terms of both processes and outcomes of care.**

### CONSTRUCTING A CONTINUOUS QUALITY IMPROVEMENT PROGRAM FOR A PAIN PRACTICE

There are several steps in creating a CQI program for pain:

1. **Identify the practitioners (physicians, nurses, therapists) who will be involved.**

2. **Gather these caregivers together to align their information goals and to craft a set of measures toward which all can agree that the program should be directed.** A good starting point is the list put forth by the IOM\(^28\):
   - Care should be **safe**.
   - Care should be **effective** and based on proven evidence and science.
   - Care should be **efficient** and **cost-effective with no waste**.
   - Care should be **timely**, with no waiting or delays.
   - Care should be **patient centered**—respect patient preference and give the patient control.
   - Care should be **equitable** with no unequal treatment.

3. **The most effective CQI program will start with the participants deciding what they personally believe are the most interesting (initial) questions to be answered.** For instance, four or five separate practices in a delivery area might decide to evaluate the outcomes of referral to physical and behavioral therapists in the area or the value of a particular invasive pain technique.

4. **Pick outcome measures that will allow accurate assessment of the problem.** Weinstein and Deyo recommended separation of assessment into four domains: patient health status, cost, patient expectation, and clinical status.\(^52\) Within these areas, indicators are chosen that answer the questions most important to the practitioners. Indicators are of three types\(^63\):
   - **Structure measures** assess the characteristics of the practice or a facility, such as staff-to-patient ratios or patterns of diagnosis. Such information may alert the practitioner to unforeseen aspects of practice that are causing quality issues. For instance, a growth in the number of return visits of patients with complex regional pain syndrome who demonstrate increased dysfunction after an initial period of improvement could alert the care teams to an unrealized issue of reimbursement denials for the prolonged physical and behavioral therapy required in the care of this syndrome.
   - **Process measures** assess how care is provided in the practice. For instance, the compliance audits regarding documentation by practitioners and therapists that support evaluation and management coding fit into this category. The disadvantage of process measures is primarily in determining a link with outcome, because these measures must be considered surrogates for outcome in the many situations in which direct measurement of the outcomes is impeded by difficulty in risk adjustment or other barriers. Another problem is that process measures are frequently used since they are relatively easy to measure, but they may have little connection to true clinical outcomes. An example is how long it takes for a patient to be roomed after arrival. Finally, quality assessment is best if it considers a continuum of care, but process measures tend to evaluate only small pieces of care.\(^64\)
   - **Clinical outcome measures** are those on which most practitioners focus, although an effective CQI program will monitor all three types. An example of clinical outcome measures is the use of repeated patient health status testing to determine health status longitudinally after interventions. In most practices, it would be expected that some sort of evaluation of patients in this regard would be collated and sorted by diagnosis, demographics, and intervention. This is a critical step in monitoring for overuse or underuse of medical therapies.

5. **The measures chosen should have the following characteristics**\(^65,66\):
   - **Relevance.** They should relate directly to the goals of the group, and it should be true that the interventions on the group have an effect on them.
   - **Timeliness.** The measures should be collected in a timely manner so that they can be related as closely as possible to the interventions that the practitioners wish to assess.
   - **Reliability.** The measures should be accurate and consistent no matter when or who is assessing and recording them.
   - **Validity.** A valid measure is sensitive to changes that the practitioner can effect.
   - **Precision.** The measures should be clearly defined and leave little potential for individual or erroneous interpretation.
   - **Cost-effectiveness.** A CQI program costs money, and the measures should be significant enough to your patients and your practice that they are worth the time and money expended on the process of collection and analysis.
g. **Provider control.** The variable measured must be one that the provider or organization can actually control or it is not worth measuring. For instance, measuring patient self-reported pain levels 1 year after an intervention for a chronic pain condition is unlikely to reflect a process that the provider can control because of the impact of the intervening health care and patient activity over the course of 1 year.

h. **Clear meaning.** The measure must be one that is easily understood by all concerned.

6. Terminology—once the practitioners have chosen the outcome measures, the terms must be adjusted to be in congruence with standard nomenclature. The accepted standard is a somewhat moving target, but SNOMED-CT (Systemized Nomenclature of Medicine—Clinical Terms) is produced by the College of American Pathologists (CAP) and has been designated by the National Institutes of Health (NIH) and the National Library of Medicine (NLM) for use in electronic transfer of medical information in the United States. Thus all practitioners should make sure that their own terms are “cross-walked” to SNOMED terms so that they report data that are standardized by accreditation and certification bodies and by payers in the years to come. This crosswalk process may be done in one of (at least) four ways:

a. One can download all of SNOMED at the NLM site, which has licensed SNOMED for use by any entity within the United States. This site is [www.nlm.nih.gov/research/umls](http://www.nlm.nih.gov/research/umls), but the data sets are raw and most practitioners would need help manipulating them.

b. The CAP has a complete version for sale at [www.ihtsdo.org/snomed-ct](http://www.ihtsdo.org/snomed-ct), although the price may vary depending on the nature of the entity requesting it.

c. Apelon ([www.apelon.com](http://www.apelon.com)) has two products that will take care of the translation process. One is Mycroft, which is a translator that is free via Web browser and allows the user to find the crossmatch in SNOMED for any other term. This requires a fair amount of time and may not be useful if there are a lot of terms to look up. The other option is Termworks, a translator that will automatically translate a body of terms (in a spreadsheet format). However, this product is obtained by subscription, which, as of this writing, costs $1000 per month or $10,000 per year. Another product (TermManager) allows you to upload your terms to their server, and the translation is done at that level for a subscription fee of $100 per month per user. Though expensive, in the case of a large volume of terms this may be a good way to cut down on the hunting time that would otherwise be necessary for translation of terms.

7. **Risk adjustment** must be included in the design of the monitoring system for the measurements to have any utility in identifying high quality and best practice. In the past, newly minted measures of quality have been introduced without attention to risk or to scientific investigation to ascertain that they were valid estimators of outcome. As the NSQIP proved, without accounting for the severity of patient morbidity, “significant correlation” between care processes and clinical outcomes may prove spurious when such comorbidities are later considered. Risk adjustment is a young and still potentially confounding science, and many of its controversies are yet unsolved.

---

The vagaries of risk adjustment require that practitioners use tools of measurement that are already validated. For instance, it is true to say that age and diabetes are significant comorbid conditions that should be considered when determining the probable outcome after surgery, but their relative importance can vary depending on which surgical procedure is under consideration, who is determining the severity of the comorbid condition, whether administrative or clinical determinants are used to determine the presence of disease and its severity, or which administrative coding tool is used to identify the condition. If a pain practitioner or group decides to create a completely new measure, careful attention to risk adjustment theory and its evaluation in the literature or appropriate texts is recommended. Nonetheless, it is possible for small groups of clinical experts to choose risk adjustment indices with validity if the process is done with bias controls and if there is involvement of biostatisticians and epidemiologists.

Risk adjustment in chronic pain practice poses very significant challenges in view of the wide diversity in the types of adjustors that are operant in the widely varied population known as “chronic pain patients.” The variegated nature of patients with multiple comorbid conditions ranging from physical disabilities, economic and social burdens, and mental health disorders makes it difficult to allocate risk “cohorts.” Risk adjustment in pain treatment outcome research is also a new science, and more rigorous studies than yet exist in the literature are needed before clarity and certainty exist in this area.

**SPECIFIC OUTCOME TOOLS AND MEASURES FOR YOUR PRACTICE**

Box 6.1 lists some measures and tools that might be considered for a pain CQI program. They have been used in scientific studies to measure some of the variables that would be valuable to a pain program. The reader is cautioned, however, that a great deal of variation exists in the versions of some of these instruments published in the literature.

Many organizations are still attempting to codify and make uniform the “dictionary” of terms that are used in quality databases. An excellent source of guidance in this endeavor is a document from the American Society of Anesthesiologists (ASA) titled “Guiding Principles for Management of Performance Measures by the American Society of Anesthesiologists,” available on the ASA website [www.asahq.org](http://www.asahq.org). Several organizations are involved in the effort to codify terminology in addition to the ASA, including the Anesthesia Patient Safety Foundation (APSF) and its Data Dictionary Taskforce, and international groups such as the World Health Organization (WHO). The number of societies, the importance of the task, and the lack of certainty in the area mean that any database will be mutable over the next decade. The benefit of such malleability of design, which will always cost money, is that the practitioners who use it will be better assured that they will be in compliance with the requirements of accreditation agencies (e.g., The Joint Commission [TJC], Accreditation Association for Ambulatory Health Care [AAAHC], and others), which will also be set and amended in the years to come. A review of the challenges and some tools for measuring outcomes specific to
### Basic Patient Information

Some of this information will be gleaned from the patient chart and some will require further questioning by staff.

**Demographics**
- Gender
- Age
- Ethnicity
- Residential zip code
- Referred? Y/N
- Live alone? Y/N
- Care for self without help? Y/N
- Other caregivers/providers (list)

**Disability and Litigation**
- Litigation active? Y/N
- Legally disabled? Y/N
- —percentage?
- Working? Y/N

**Mental Health**
- DSM-IV codes assigned
- Psychiatric hospitalization DRGs
- Annual psychiatric hospitalization days

**Patient Expectations**
- Expected degree of return of function
- Expected job status after treatment
- Expected changes in medication after treatment
- Expected decrease in pain level after treatment

**Costs**

**Direct Health Care Costs**
- Physician visits
- Emergency department and hospitalization costs
- Physical therapist fees
- Physical therapy modalities
- Occupational therapy
- Vocational rehabilitation therapy
- Behavioral health therapy
- Laboratory studies
- Imaging costs
- Professional home care
- Stimulator or pump and implantation fees
- Analgesic and behavioral medications
- Alternative therapy costs

**Indirect Health Care Costs**
- Litigation fees
- Lost wages
- Cost of housekeeping
- Cost of other home care
- Travel cost for care
- Time expended by family, others in care

**Tools**

Be aware that multiple versions may exist in the literature for some of these tools. When available, the most definitive source is listed below.

### Overall Quality-of-Life Status

- SF-12 or SF-36 measures: [www.qualitymetric.com](http://www.qualitymetric.com)
- U.S. National Health Interview Survey (U.S. NHIS)
- Spitzer’s Quality of Life Uniscale—a one-question set that records patient self-assessment of the past week in terms of quality of life[^78]
- Spitzer’s QOL Index—five items[^78]

### Pain- and Function-Specific Questionnaires

- TOPS (Treatment Outcomes in Pain Survey)[^79]
- PIQ-6 (Pain Impact Questionnaire): [www.qualitymetric.com](http://www.qualitymetric.com)
- PIQ-R (Revised Chronic and Acute Pain Impact): [www.qualitymetric.com](http://www.qualitymetric.com)
- Fibromyalgia Impact Questionnaire[^80]
- Roland-Morris Back Pain[^81]
- Quebec Back Pain Questionnaire
- Waddell Disability Index
- West-Haven-Yale Multidimensional Pain Inventory (MPI)

### Condition-Specific Measures

These are somewhat more specialized tools that may work in pain assessment programs.

- Pain Disability Questionnaire[^83]
- Patient Specific Index/Patient Specific Functional Scale
- Problem Elicitation Technique
- Patient Generated Index
- Canadian Occupational Performance Measure
- Schedule for the Evaluation of Individual Quality of Life
- Measure Yourself Medical Outcome Profile
- Juvenile Arthritis Quality of Life Questionnaire

### Risk Adjustment

- Functional Comorbidity Index[^84]

### Patient Satisfaction

- Picker Patient Experience Questionnaire[^85]—this is a superb assessment of how your practice measures up to the patient’s expectations. It would be worth assessing at intermittent, fixed intervals to watch for trends and administrative areas that could be improved.

### Measures Used in Health Quality and Function Studies

- Utility measures—patient assessment of the value of the overall health state
- Euroqol (EQ-5D)[^86]—highly recommended as a short and insightful look at your patient’s attitudes
- Health Utility Index[^87]
- Generic measures—these measures quantify the patient’s self-assessment of overall health
- Sickness Impact Profile[^88]—progenitor of the Roland-Morris questionnaire
- Nottingham Health Profile[^89]
- SF-12, SF-36: [www.qualitymetric.com](http://www.qualitymetric.com)

### Work and Function

- Work Limitations Questionnaire
- Oswestry Disability Index
- Simple Shoulder Test
- Neck Disability Index
- Short Musculoskeletal Functional Assessment

assessing outcomes in back pain therapy has recently been published.96

An excellent review is one by Resnik and Dobrykowski that involves outcome measurement in patients with low back pain.97 The entire December 15, 2000, issue of Spine is highly recommended reading because it contains in-depth reviews of several of the back pain measurement tools.98

Obviously, not all the measures listed will be applicable to every pain practice, and the practitioner is urged to review the references in Box 6.1 for information on how best to use the various measures.

One important issue is the significance of any change observed in the various measures over time in each patient. Some of the tools recommended were developed primarily to look at patient cohorts rather than an individual patient. This area of research is still emerging, and readers are encouraged to monitor the literature closely to assure them that their use of the tools is valid.90

THE TOOLS

The Brief Pain Inventory is adaptable to computer use, although it has not been validated for all pain conditions.99

Another valuable tool is a modification of the Medical Outcomes Study Short-Form 36-Item (SF-36) survey, the Low-Back SF-36PF18.100 This instrument is also amenable to computer use and includes aspects of the SF-36 and the Oswestry and Quebec back pain questionnaires. A newer instrument that may lend itself to prediction of outcomes is the Pain Disability Questionnaire (PDQ), which is a short list of 15 questions that uses a continuum line for responses, similar to the visual analog scales for rating pain that most chronic pain patients have seen.83 It may also be used on a computer. TOPS (Treatment Outcomes of Pain Survey) is a valuable tool that includes the SF-36 and additional questions that are specific to pain medicine.79 It has the added value of having been validated in clinical practice and as a research tool.

Over the next several years, advancement in the nomenclature of clinical outcomes monitoring will occur and lead to more specific definitions of the vocabulary of pain quality databases. This will improve the comparability of data across databases and tools, further refine the science of pain management, and increase the probability that we will be able to fix national benchmarks of quality and best practices.

### A RISK ADJUSTMENT TOOL FOR PAIN PRACTICE CONTINUOUS QUALITY IMPROVEMENT

As mentioned, it is important within a pain practice to calibrate expectations of improvement in a given patient by factoring in comorbid conditions and any evident functional disabilities and including other confounding conditions, such as ongoing litigation. One new index that allows for this is the Functional Comorbidity Index.84

### WHICH TOOL TO USE AND HOW?

Gathering data is best managed in part by using patient surveys before and after provision of services, with timing appropriate to the nature of the patient’s condition and the expected effective duration of the intervention. Several very good reviews of the relative merits of these measurement tools advocate well for certain tools in certain patients or for certain conditions.87,101,102

Brevity and speed of both information entry (either by the patient or staff) and data analysis are salutary aspects of an outcome measurement system, and these aspects should be considered when determining which instruments will be used. The use of both a short general health assessment and a specific pain evaluation tool is probably the most basic approach. Using computerized surveys (e.g., in the waiting room) improves data integrity by decreasing omitted responses and improving internal consistency.105 They should be used instead of written surveys whenever possible.

### WHAT IS THE VALUE OF CONTINUOUS QUALITY IMPROVEMENT TO A PAIN PRACTICE?

A QA/QI program can help a pain practice in several ways:

1. **Accreditation** of a pain practice facility is discussed in the section on safety. However, accreditation bodies are very interested in the nature of any CQI programs. Thus an added benefit of such a program, in addition to improved care for patients, is the approval of accreditors.
2. **Payment for quality** is the newest impetus for providers and facilities to participate in quality improvement programs.
P4P is the general term used to describe reimbursement programs that tie some portion of provider income to either process or outcome achievements. P4P will also effect changes in patient referral patterns as the information gathered on provider performance is made available to payers, employers, and patients. \(^{104}\) Therefore, investment in a CQI program will have potential benefits in terms of patient census and reimbursement rates in the coming years.

3. **Benchmarking providers** in an objective and appropriate manner is another value of a well-crafted CQI program. By evaluating practice patterns of providers at a single site or at many sites, benchmarks can be identified that allow all physicians and staff members to assess their own performances against other practitioners and thus elucidate “best practices.” Allowing practitioners to see their own process outcome data and compare it with others working in the same facility has improved efficiency with no alteration in patient satisfaction. \(^{105}\)

### WHAT WILL A QUALITY ASSURANCE AND IMPROVEMENT PROGRAM COST?

#### PERSONNEL

A busy practice will require between 0.5 and 1.0 full-time employees to manage data input. This staff person, if not completely occupied by this work, might also serve as the Health Insurance Portability and Accountability Act (HIPAA) compliance officer and oversee all policies regarding the quality initiatives of the practice. Though relatively expensive, a registered nurse is of great value in this role.

#### TECHNOLOGY

It would be convenient if each practice location were to have access to an EHR to allow automated capture of accurate data to provide evidence of quality. We may be some years away from an EHR in every procedure room and are even further away from an accurate EHR in every procedure room. Sadly, investment in changes in infrastructure that might bolster improved quality is often squelched by the nature of reimbursement in our current medical system. \(^{106}\)

In the meantime, therefore, it is appropriate to concentrate on inexpensive and already available means of capturing such data and transmitting it to practitioners. \(^{107}\) Probably the most efficacious single-site approach is to use a computer relational database (e.g., Microsoft Access) to capture information gathered by more traditional methods, such as chart assessment by clerks and patient interviews by nurses. Such databases have been valuable in determining areas of potential cost savings, improvement in efficiency, and potential error and shortfalls in quality. \(^{105}\)

If the practitioner is not a skilled programmer, it is reasonable to hire one and build his or her own database with modes of risk adjustment and automated capture of demographic and laboratory data. They can be built with a graphic user interface (GUI) that is intuitive for even the most non-technology-savvy staff member and that will allow patients to directly interface with waiting room kiosks. This can all be done with about 60 hours of programming (Fig. 6.3).

Physicians and staff will spend somewhat less time helping with design and testing. \(^{108}\) Licensing for the software and for use of the American Medical Association Current Procedural Terminology codes will be needed, and the purchase of additional computer monitors or kiosks may also be necessary, depending on the current configuration of technology at the clinic. In all, an investment of $15,000 would create a superb single-office product with automated reporting and measures very specific to the goals and practice patterns of the pain clinic whose practitioners created it.

### THE FUTURE IS NOW FOR QUALITY ASSESSMENT IN PAIN MANAGEMENT

In 2011 the IOM issued a comprehensive report that underscores the need for an extensive transformation in all aspects of our treatment of pain in America. \(^{109}\) One of the resultant findings of its work was the lack of existing data on which to support our current practice and advance our evolving field. This influential review calls for a bird’s eye view of pain management, expanded from the practitioner-patient relationship to the care of patients on a societal level.

While we are still striving to implement CQI in individual pain management practices, as detailed earlier, the Stanford Pain Registry has taken this a step further by aggregating data in the form of a National Pain Registry. \(^{110}\) This effort exemplifies the broader view that is required to improve patient care and facilitate the discovery of novel solutions for pain management. The registry is currently shared by numerous pain centers and will eventually be open to clinics nationwide. Such metadata systems already exist in primitive form online as both not-for-profit and profitable entities that collect quality assessment data on behalf of providers. The practice generally has access to its individual data and analysis, but the business essentially “owns” the collective database. This information can then be subjected to countless analyses. Thus, it is not only used by providers to assess and improve the quality of care in their private clinic but can also be pooled for research purposes. Comparative effectiveness between distant practices and longitudinal data analysis are examples of the many uses of Web-based data collection programs such as these.

Still further, the vision is coming full circle by reintroducing the patient as part of the transformation in pain management called for by the IOM. Patients are already participating in daily sampling of data, such as pain scores or accelerometer activity, via Android cell phones that remotely report to the provider and by extension to the registry. \(^{111,112}\) This information will allow the provider to track a patient’s progress, evaluate ongoing treatment, and gather data that can later contribute to evidence-based practice and document accountable care.

### CONCLUSIONS ABOUT QUALITY IMPROVEMENT IN PAIN PRACTICE

This chapter separates patient safety and quality improvement as independent sections. However, both must be considered when reviewing strategies to improve either
Figure 6.3  A, Pain clinic database: initial questions screen. This image shows a typical interface for recording the answers to an initial set of screening questions regarding the pain problem and quality of health as described by a patient on a visit to a pain clinic. Using the Microsoft Access Relational Database or similar technology, this user-friendly graphic interface allows clerical personnel to record the events and answers in a relational database that can then be used to monitor individual and collective patient outcomes for quality management in a pain practice. B, Pain clinic database: procedures screen. This image shows a typical interface for prompting and recording the events that typically occur on the day of a pain service, which allows the information to be placed into a relational database for quality management purposes. C, Pain clinic database: first callback screen. This image shows a typical interface for prompting and recording the questions and answers for phone calls to a pain patient, which allows the information to be placed into a relational database for quality management purposes. (Microsoft Access is a registered trademark of Microsoft Corporation.)
of them. The following are necessary to improve pain CQI programs:

1. CQI programs should be used at each individual clinic to discover which processes and structures beget the best clinical outcomes.
2. The data for each clinic should be linked to all the others to create national quality benchmarks that will provide a means of identifying and duplicating best practices.
3. Innovations in care systems should be welcomed, but only in settings that allow their study in comparison to the best practices that already exist.
4. Evidence-based approaches to pain medicine must be improved. Practitioners must be scrupulous in evaluating procedures and therapies with rigorous doubt and eliminate those that do not prove valuable in comparison to alternatives that may be more banal and less lucrative.

5. Access to high-quality multidisciplinary care, including mental health care, which may often be expensive and long term, must be a priority of our specialty so that we can advocate for it to payers, health care policy makers, and legislators, who too frequently ignore the benefits of such care.

Finally, pain medicine—and health care in general—needs more robust federal support for inexpensive methods to engender clinical measurement of outcomes, risk adjustment, and clinician feedback if quality improvement is to occur rapidly. Computerized systems should be made available to primary and ambulatory care facilities to allow the identification of national benchmarks of care. Only in this way can we rapidly discover best practices and decrease the waste inherent in the current care model, where individual clinicians often practice in the dark with regard to evidence and the effects of their own interventions.

SECTION 6.2 PATIENT SAFETY

TO ERR IS HUMAN AND PREVENTION OF HARM

The publication To Err Is Human: Building a Safer Health System, Report from the Committee on Quality of Health Care in America in 1999 was the Institute of Medicine’s (IOM) public alarm about patient safety and error in the health care delivery system. The authors estimated—based among others on the Harvard Medical Practice Study of 1991—that the iatrogenic injury rate was nearly 4% in U.S. hospitalized patients. They concluded that more than half of these injuries were due to errors in medical care and that two thirds of all iatrogenic injuries could be prevented. Similar results were presented in a systematic review of eight studies conducted in the United States, Canada, Australia, and the United Kingdom that encompassed nearly 75,000 in-hospital patients: 9.2% encountered adverse events and the authors concluded that 43.5% of such events could be classified as preventable. However, the rate of induced harm can be as high as 25%. The doctor’s fear of punishment for making errors, as well as the difficulty of detecting errors, makes these estimates disputable. Despite other triggered controversies, all these reports expanded the conversation considerably and focused the attention of practitioners, payers, patients, and governments on these preventable errors. Patient safety is, based on the World Health Organization (WHO) definition, “the absence of preventable harm to a patient during the process of health care.” Patient safety, with its fundamentals of collecting and analyzing events, as well as prevention of adverse events in a confidential environment, has become an indispensable discipline and element of health care quality.

A significant hurdle in the effort to improve safety is that there are insufficient data to assess health care safety or even definitively identify uniformly valid indicators of safety in health care. Therefore, which solutions, which information, and which technology will be of value in improving patient safety are still disputable.

To improve patient safety, the IOM motivated hospitals, as well as professional societies, and recommended the creation of centers and organizations for focusing on patient safety. As an effect of the efforts of the IOM, the government was one of the first to support research on safety. As a further consequence, the Patient Safety and Quality Improvement Act signed into law in 2005 also encouraged the development of a Patient Safety Organization (PSO) and defined the role of PSOs. The act called for a confidential culture of patient safety and for the establishment of a Network of Patient Safety Database (NPSD) to provide an interactive evidence-based management resource.

Based on different facets of patient safety and with varied scopes, an increasing number of agencies and organizations have emerged:

1. The Agency for Healthcare Research and Quality (AHRQ) has the federal lead in patient safety; it supports research of causes and the development of new strategies in patient safety, as well as their integration into the health care industry. This center coordinates the PSOs and distributes knowledge about effective practices. The AHRQ offers the Patient Safety Network (PSNet), a Web-based resource of news on patient safety, and the Web M&M, a morbidity and mortality round on the Web.
2. The National Quality Forum helps improve the quality of U.S. health care by building, endorsing, and promoting national consensus about priorities, measurements, and their education.
3. The Joint Commission (TJC: Joint Commission on Accreditation of Healthcare Organizations), advised by a panel of safety experts, has published its national patient safety goals since 2002. These goals are provided as clear, actionable statements, such as “use at least two patient identifiers when providing care, treatment, or services” or “mark the procedure site,” along with the rationale behind these goals, as well as the elements of
PART 1 — GENERAL CONSIDERATIONS

4. Another PSO is the National Patient Safety Foundation (NPSF), an independent not-for-profit organization that works on improving patient safety by providing knowledge and developing, as well as enhancing, the culture of safety. Lucian Leape, a contributor to *To Err is Human*, was one of the founders of the NPSF.

5. Large businesses, understanding the fundamental issue as being poor quality in the face of high prices, organized themselves via the Leapfrog Group and created programs for change while also pushing for new regulation and legislation to improve safety. The goal of the Leapfrog Group, a voluntary program, is to reward the safety efforts of health care providers and thereby trigger big leaps in health care safety. They aim to reduce preventable medical mistakes, improve the quality and affordability of health care, and encourage health care providers to publish their quality and outcomes and reward them for improving quality. This group focuses on four leaps: computerized physician order entry (CPOE), evidence-based hospital referral, intensive care unit physician staffing, and a Leapfrog safe practices score that assesses a hospital’s progress. These measures are variable in their evidentiary support for improving quality, and they are all potentially expensive. Nonetheless, Leapfrog and its proponents quickly declared that the most important next step was and is urging of the public to push for health care professionals to adopt these goals. The Leapfrog Group and its tenets have also imbued the discussion of patient safety in our health care system with an economic and political imperative that makes further objective evaluation of the true nature of health care’s safety more difficult, even as new solutions are recommended.

6. The Institute for Healthcare Improvement (IHI), another independent not-for-profit organization founded in 1991, initiated the 100,000 Lives Campaign (2004 to 2006), which was designed to save lives by introducing six safety guidelines into health care. The institute added another six guidelines and launched the 5 Million Lives Campaign in 2006 (Box 6.2). How many lives could actually have been saved is not clear, but the effect was tremendous: more than 4000 hospitals in the United States enrolled in this project committed to somehow integrate these 12 goals into their clinical routines.

7. Patient safety is not just a problem in industrialized countries, it is also a global problem. Similar to these 12 goals, in 2004 the WHO launched the World Alliance for Patient Safety in all member states to improve safety in...
Standardized and reliable definitions are needed to accurately measure harm and to evaluate the effect on patient safety. First, a medical error has to be distinguished from an adverse event. Medical errors are “the failure to complete a planned action as intended or the use of the wrong plan to achieve an aim.” Drug errors are the most common medical errors. Most often they are not directly linked to the patient’s medical condition; however, they have the potential of being harmful. An adverse event is a harmful injury resulting from a treatment and is not caused by the underlying medical problem. These events can be lethal, life-threatening, and disabling; prolong hospital stay; and require additional monitoring. They can be further classified as preventable or nonpreventable.

There is a retrospective (reactive) and a prospective (proactive) way to measure and improve safety. The retrospective way consists of a “root cause analysis” (RCA), error-reporting systems, morbidity and mortality conferences, or malpractice claims. These methods seek to answer the question of what went wrong and why. We use these techniques widely to understand the causes of harm and to improve safety. They increase the awareness of fault processes and are more likely to detect latent errors and adverse events but bear the risk of spending resources on interventions that have little chance of diminishing harm. A group of anesthesiologists from Seattle and Boston, for example, investigated conditions and patterns in malpractice claims after interventional pain treatment at the level of the cervicospine. They found that injuries leading to malpractice claims were most often caused by direct needle trauma to the spinal cord, these injuries were often severe, and they appeared more frequently in unresponsive patients.

Failure Modes and Effects Analysis (FMEA) is a proactive assessment tool. It helps anticipate and prevent adverse events based on knowledge from past failures by aiming to foresee potential failures. It involves a care team that meets on a regular basis, a serious challenge in our health care system. The advice can be scarce. Another prospective tool is based on Patient Safety Indicators (PSIs), developed by the AHRQ and revised by the University of California at San Francisco–Stanford University Evidence-based Practice Center (UCSF-Stanford EPC). They identify hospitalizations with potentially preventable patient safety events based on standardized algorithms, which are available for free. They demonstrated that the specificity was high (99.1%), sensitivity was moderate (19% to 56%), and positive predictive value was 22% to 74% for the original PSI definition when compared with the NSQIP adverse events.

In 1974, Jick introduced a prospective concept based on trigger events. Trigger tools such as the Global Trigger Tool (GTT) identify patient safety events during hospitalization. Clearly defined events (e.g., ordering of specific drugs such as antidotes, or the presence of abnormal laboratory values) serve as a trigger to activate further investigation of the case. This tool seems to be more reliable than other methods in detecting possible events. Whereas a combination of AHRQ PSIs and provider-reported events found 4% of adverse events, the GTT found 27% of adverse events.

The potential reported adverse events have a low association with documented harm, differ across organizations, and raise concern about using these patient safety measures for public reporting and comparison of organizational performance.
Box 6.3 Pronovost’s Four Points for Translation of Evidence into Practice

- Summarize evidence into checklists; identify (maximum of seven) interventions with the greatest benefit and convert them into behavior.
- Identify and reduce barriers to compliance with the checklist; “walk” through the process and observe the staff performing the intervention to recognize deficiencies, potential gains, and losses with the implementation.
- Measure and provide feedback. Be encouraging; develop and pilot-test measures that evaluate the process or the outcome and provide feedback.
- Ensure that all patients receive the interventions; recognize work, improve culture, and monitor performance.

Patient safety research developed and helped identify many solutions. There is ample evidence for the benefit of specific patient safety practices: use of prophylaxis to prevent venous thromboembolism in patients at risk, use of perioperative β-blockers to prevent perioperative morbidity and mortality, use of maximum sterile barriers while placing central intravenous catheters to prevent infections, use of antibiotic prophylaxis in surgical patients to prevent surgical site infections, asking patients to recall and restate what they have been told during the informed consent process, continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia, use of pressure-relieving bedding material to prevent pressure ulcers, use of real-time ultrasound guidance during central line insertion to prevent complications, and use of antibiotic-impregnated central venous catheters to prevent catheter-related infections.

The next step is the translation of evidence, research, or clinical guidelines into daily practice. Major difficulties can arise, but there are many different models on how to proceed. However, it is not yet clear which models are most effective and efficient. Pronovost and colleagues described one practically oriented method consisting of four key elements in an approach to integrate evidence into practice. This strategy has been used successfully to reduce bloodstream infection associated with central lines. Box 6.3 shows Pronovost’s four points for translation of evidence into practice.

SUCCESS?

The IHI declared victory on June 14, 2006, by stating that the 100,000 Lives Campaign had saved more than 122,000 lives. However, support for this contention is a retrospective calculation of a statistical probability of how many lives “would have been lost” had the statistical analysis of 2004 been applied, versus the number of lives that were actually lost between January 2005 and June 2006. Those who were skeptical of the mathematics used to calculate the original numbers of lives at risk should be just as skeptical of the methodology used to verify this success.

Safety in medicine is a very complex problem, and progress is slow. Progress may remain unknown or at least insufficient, and the main effect in the past decade instead was an increased overall sensitivity of society.

For long-term improvement in patient safety, we need a benevolent culture of safety in which health care providers can obtain an adequate education, including education on all available sources and technologies with an understanding that the costs must be monitored.

CULTURE OF SAFETY AND SAFETY CLIMATE

The IOM proposed to not only build centers and organizations but also create a culture of safety. A safety culture is crucial for improvements in safety. The concept of a patient safety culture originated from the experience in hazardous industries. It depends on attitudes, beliefs, behaviors, perceptions, values, and practices shared by employees. However, the safety culture differs considerably between hospitals and persons. Finding the commonalities may be imperative to any type of safety improvement program.

There is a difference between a culture of safety and a safety climate. A safety climate is a quantitative description or a way of measuring safety culture by taking a closer look at adverse events (outcomes measures), analyzing adherence to practices (process measures), or calibrating health care teams’ attitudes about issues relevant to safety. Nevertheless, culture and climate are positively related: a higher level of group culture correlates with higher safety climates, whereas hierarchic structures lead to lesser safety climates.

It has been suggested that engaged senior leaders are important to an organization’s successful development of a culture of safety. Improved leadership in which boards and medical staff share responsibility and focus on improvement strategies together may offer great potential. Teamwork and collaboration such as open communication have been defined as a second important behavior to support a culture of safety, especially if the increasing complexity of patients today is taken into account. Evidence-based medicine (EBM) with standardized processes leads to high reliability and, together with patient-centered medicine, has an important influence on patient safety culture. James Rogers underlined that a culture of safety can be built up through social engineering. A just culture in which providing safety-related information in a blame-free environment is rewarded and in which people have the will and the knowledge to learn from mistakes (learning culture) is essential to develop a culture of safety.

EDUCATION

In the past decade, education has altered significantly as a result of safety issues. One of the most important amendments was the work hour restriction. Because operator fatigue has been recognized as a potential source of error in
many industries, the U.S. Congress and the IOM asked for limitations on work hours to improve patient safety. However, this led to many disputes about the feasibility of education and the competency of residents. Practitioners who have completed their training tend to work longer hours with less rest than is considered appropriate in almost any other work setting. This should be particularly concerning for pain practices that use interventional therapies. All aspects of cognition are adversely affected by fatigue, although there is insufficient evidence to pinpoint a specific amount of rest as being “enough” in medicine. In general, practitioners tend to ignore or discount the potential impact of fatigue on their own error rate. Each practitioner is encouraged to create and follow personal and practice-wide policies regarding continuous time spent on clinical activity. Besides the work hour limitations, many professional societies have also adapted their curricula to focus on safety. The American College of Surgeons has already integrated six core competencies defined by the Accreditation Council for Graduate Medical Education (ACGME) and the American Board of Medical Specialties (ABMS), including listings of patient safety topics, teaching and learning strategies, and assessment methods. Guidelines for implementation and dissemination are also provided; the curriculum content underscores the need to create an organizational culture of safety and focuses on both individuals and systems. Individual residency programs may prioritize the content of the curriculum according to their specific needs.

Education is tightly linked with the introduction of new technologies. There are different ways to adopt new techniques and technologies into clinical use. Peyton’s four-step approach (1, trainer demonstrates; 2, talk the trainee through; 3, trainee talks the trainer through; and 4, trainee does) was shown to be superior to standard instructions; faster performance when learned skills were performed for the first time was seen. For physicians and other health care professionals at all levels, simulation tools in which mistakes can be made without harming the patient provide a good alternative to real patients. Simulation-based education is expensive, but it is cost-effective if used properly and has been proved to increase patient safety. Simulation-based training complements medical education in patient care settings but does not replace educational activities based on actual patient care experiences.

How effective the use of simulation is depends on informed use, providing feedback, engaging trainees in deliberate practice, integrating simulation into an overall curriculum, and instruction and competence of the faculty in its use. Bohmer and Edmondson pointed out that learning is essential to improve health care and to prevent becoming outdated. Individual learning success is linked directly to the experience of the learner. However, they could show that the slopes of learning curves for a distinct complex surgical procedure were significantly different in two groups despite equal levels of experience. They highlighted the usefulness of organizational learning consisting of managed reflection, interpretation, and repetition as a team.

Checklists have also become part of the education process. They help confirm the completion of crucial steps and appear to be particularly useful in improving performance during emergencies, as seen in the aviation industry. The WHO introduced the Surgical Safety Checklist in 2008 after preliminary research demonstrated that half of major surgical complications are preventable. Haynes and colleagues showed that implementation of the checklist lowered the rate of death from 1.5% to 0.8% and the rate of inpatient complications from 11% to 7%. The American Society of Regional Anesthesia and Pain Medicine (ASRA) showed in a randomized simulation study that checklists not only improve medical management of systemic toxicity secondary to local anesthesia but also augment nontechnical performance.

Other important sources aimed at providing evidence to improve patient safety and clinical outcomes are guidelines and practice advisories, such as those published and steadily updated for regional anesthesia and pain medicine. Based on the current literature, expert opinion, and clinical data, these systematically formulated advisories aim to improve patient safety by reducing the incidence and severity of adverse outcomes in daily practice. These recommendations usually focus on clinical topics for which treatment is as yet unclear. The recommendations may be adapted and changed to fit individual institutional and provider needs. Consensus statements based on opinions today may be rewritten and changed when overruled by new scientific facts, and readers and writers are encouraged to continuously re-evaluate these recommendations.

Information technology can reduce error and the negative impact of error by providing critical information at the point of care, improving the speed of response once an error has occurred, and tracking the occurrence of errors to allow monitoring for trends and feedback to providers. Even though an investment, today’s practitioners cannot afford to not have electronic health records, with which they can easily track and document the course of their patients’ care. It appears increasingly desirable to have a nationwide, Internet-based monitoring program, such as a prescription drug–monitoring program, to not only avoid multiple prescriptions for opioids but also improve patient safety and distribute important information about the health of patients. An example of the promise of improvement in safety through innovative technology is in patient identification. Correct patient identification and elimination of wrong-site surgery have been identified by the IOM and TJC as a significant opportunity for improved safety. The use of a bar code system can virtually eliminate the potential for patient misidentification and can also diminish medication errors. Unfortunately, high cost and slow speed of the systems have led to their adoption by only a few U.S. hospitals.

The use of technology has facilitated many steps in patient care. Calculation of medication doses, exchange of patient data between geographically or temporally separated practitioners, providing references such as guidelines for care, and monitoring of patient outcomes, adverse events, and practice patterns can all help improve patient safety. Not only is the technology itself crucial, but the organization also plays a part. Systems that support clinicians with access to guidelines and monitoring of medication errors have improved the quality of care and decreased error.
IMAGING TECHNOLOGIES

Besides the administrative technologies, more and more medical technologies are emerging into the field of health care. Imaging modalities in interventional pain medicine help identify relevant structures accurately, which intuitively appears to ensure safer interventional therapy in pain medicine. Ultrasound techniques, fluoroscopy, and computed tomography are being used. Indirect methods such as nerve stimulation can help identify nerves and increase the likelihood of success of neural blockade; however, they have limited sensitivity. There are also direct methods to differentiate the properties of the target from those of the surrounding tissue. The safe use of ultrasound techniques for performing nerve blocks has increased in past years, although this has not been proved to increase safety to date. Ultrasound is likely to substitute for the use of fluoroscopy in specific techniques, such as stellate ganglion blockade. Ultrasound can demonstrate the location of not only an intercostal nerve but also the pleura; pneumothorax can also be readily identified, which contributes to safer procedures. Fluoroscopic guidance, with or without radiographic contrast enhancement, helps ensure intravascular catheter location or detection of intravascular needle perforation, and it can be used to prevent unintentional intravascular or subarachnoid injection of local anesthetics or steroids. New techniques, such as the use of an “optical” spinal needle that provides spectrophotometric information from the tip of the needle, can safely identify the epidural space and may be complementary to fluoroscopic imaging of the epidural space. Brynolf and associates have shown that detection of nerves with optical reflectance spectroscopy is complementary to ultrasound and might replace nerve stimulation. It might also lower vascular complications while detecting intra-arterial placement of the tip of the needle. Although imaging guidance has become routine in pain medicine, there is still insufficient evidence to prove that it increases the safety of procedures.

BARRIERS: COST AND STANDARDIZATION

At this point it is not certain whether the investment in technology will be worth the cost. Cost is a primary reason that health care providers have not quickly adopted technology as a means of improving care. As a measure of federal and state governments’ belief in the IOM report on patient safety and the potential role of technology, several bills have been introduced and passed that subsidize the cost of introduction of technology at hospitals and offices. Other concerns that are holding back the widespread adoption of technology in practice include variations in software design standards that would allow different systems in different practices to directly transfer data, particularly among older “legacy” databases. In view of the cost of implementation of new systems, including education of staff and acquisition costs for software and hardware, the inability of a new system to “read” the data already on hand in the practice is a significant disincentive.

With increasing health care costs in the United States, it is essential to reduce these costs. Comparative effectiveness research (CER) offers a mean to identify feasible targets in health care. It was introduced by the Patient-Centered Outcome Research Institute, which was established by the Affordable Care Act. It helps in making informed health decisions by advancing the quality and relevance of evidence concerning the manner in which diseases can effectively and appropriately be prevented, diagnosed, treated, monitored, and managed through research, synthesis of evidence, and EBM while helping cut costs. The 2009 American Recovery and Reinvestment Act allocated about $1 billion toward CER, and the 2010 Patient Protection and Affordable Care Act established a national center to support CER. EBM and CER have been introduced as cost-cutting and rationing measures; however, EBM principles have to be implemented in a proper manner. It is important that improvement strategies be developed locally to target specific problems. Although EBM is linked to the best scientific knowledge available, it should not be disregarded that the most important improvement goal is the outcome for the patient in the real world, and direct assessment of outcomes in practice should be a basic element integrated into our routine evaluation.

NEXT STEPS FOR THE PAIN PRACTITIONER

Practitioners should work to discern practical ways to improve patient safety and the most efficient and economical means of practicing in congruence with the regulations and legislation now evolving from the public safety campaign. Whatever safety improvement programs are chosen, they should be repeatedly evaluated for efficacy and abandoned if they are not efficient and effective.

“Mistake-proofing” care will require minimizing variation in its delivery, monitoring every patient’s course of care for error and adverse outcomes, and making care delivery systems within the clinic as simple as possible to avoid the complexities that lead to variation and error. Such efforts have been effective in other industries, including aviation, nuclear power, and the military. Clinicians may believe that medical care is not amenable to the safety-monitoring systems of other industries, yet emulation of highly reliable organizations (HROs) within these other industries does lead to improvements in safety in health care. HROs succeed by making their systems as simple as possible, amenable to as little disruption as possible, and easy to understand. They combine these three characteristics with high priority on safety at the highest levels of the organization—including willingness to spend money and person-power.

Box 6.4 lists specific targets that the pain practitioner can focus on to improve patient safety. It is critical to document these efforts and their results to be sure that resources are not wasted and also to portray the diligence of the practice at times when payers and regulators inquire about safety efforts.

TREATMENT OUTCOME DATABASES: RECORDING ADVERSE EVENTS

Practitioners will best ensure their patients’ safety by recording their outcomes and all adverse events in a database. There are many ways to measure outcomes, which is
Box 6.4 Interventions That May Improve Patient Safety in the Pain Clinic

### Facility Procedures and Structure
- Routinely and repetitively conduct drills for emergency situations by assigning specific roles to personnel in the case of patient medical emergencies, facility emergencies (e.g., power outage, fire, earthquake, severe weather), and selected adverse events in patient care.
- If relocating or creating a new facility, locate it as near a hospital as possible. Arrange to create a legal transfer agreement with that hospital.
- Furnish the facility with in-wall piped oxygen and suction, as well as adequate lighting and space to allow full access to patients by sufficient personnel in the case of an emergency.
- Consider accreditation by the AAAHC, TJC, CARF, or another agency. If accreditation is not possible, consider annual inspection by one of these agencies for evaluation of your facility and practice regarding safety.
- Daily cleaning should include bactericidal cleansing of all surfaces contacted by staff, patients, or family members of patients in all parts of the facility.
- Place hand cleanser dispensers in multiple locations readily available to all clinical and nonclinical staff.
- Drawers and supply cabinets should be clearly organized and standardized in their organization between rooms.

### Medication Management
- Use and enforce contracts for opioids and controlled substances.
- Monitor and document patient response and the frequency of renewals for opioids and sedatives.
- All medications used at the facility should be labeled (including an outdate once opened) and carefully read aloud before being drawn up and before administration.
- All syringes should be labeled in a standard manner regarding label color, font, size, and information on outdate.
- The facility should be regularly inventoried (weekly or monthly) for outdated medications and other supplies.
- Use medication reconciliation techniques to confirm doses and the frequency of all medications when there is a transition in caregiver, location, or date.
- Use computer technology to monitor for potential adverse drug events.
- Contract with a clinical pharmacist for consultation services as needed.
- Use protocols for monitoring the prescription of any medication that may lead to significant morbidity with continued use, such as NSAIDs, opioids, tricyclic antidepressants, and so on. These protocols should include timely and repetitive monitoring for known risks via either laboratory or electrocardiographic studies or mandated office visits.
- Communicate prescriptions of all medications to all practitioners providing care to your patient.
- Any adverse drug events should be reported immediately and recorded in a database that is regularly reviewed for trend analysis. The patient should be notified about the adverse event. The patient’s other caregivers outside the practice should be notified about the adverse event.
- Prompt attention by staff should be focused on open discussion and adjustment of protocols and policies by the end of the day to avoid any repetition of errors that occurred either with or without an adverse drug event.

### Staff
- Establish a pattern of regular use of hand cleansing by all personnel.
- Create and enforce protocols for handoff of patients between practitioners.
- Create and enforce protocols for two-person patient identification interaction.
- Use standard teams with assigned roles for medical and invasive procedures.
- Involve all staff in discussions of quality and safety issues and invite open and nonpunitive review of adverse events and trends with freedom of each staff member to contribute ideas for improvement of the system.
- Create a plan in advance to respond to adverse events, including honest discussions with patients and family, as well as support for the staff involved.
- Do not allow employees to work beyond the limits of their education and training.
- Monitor, track, and report all practitioner work hours and do not allow them to extend beyond 80 hours per week or for more than 16 consecutive hours.
- Maintain sufficient staffing to ensure adequate care for sedated or recovering patients. These staff levels should be equivalent to or more intensive than the local standard of care as used in hospitals in the area.

### Procedures
- Use full barrier protection during invasive procedures.
- Administer appropriate prophylactic antibiotics.
- Use imaging technology when appropriate during invasive procedures.
- Use the minimum necessary contrast material.
- Develop and enforce the use of standard protocols for medical and invasive procedures, including sterile preparation and critical medication checks, such as anticoagulants.
- Use guidelines, checklists, or both.
- Develop and enforce protocols to ensure that invasive procedures are carried out at the correct site, including marking of the patient’s body area before preparation and a pause for
Box 6.4  Interventions That May Improve Patient Safety in the Pain Clinic (Continued)

- Obtain written agreement from patients that they will not drive for 8 hours following a neuraxial procedure, sedation, or any procedure that could impair their motor skills.

**Extrafacility Considerations**

- Maintain close interaction with any provider also involved in your patient’s care.
- Provide information about prescriptions of all controlled substance that you have begun, as well as any other medication or treatment interventions that you have made.
- Make direct phone contact with written confirmation regarding significant changes in condition or the treatment plan.
- Create a transfer agreement with a hospital to prepare for a patient emergency.
- Participate in exchange of regular peer review of procedures and standards with other practitioners who have no economic stake in your practice or facility.

AAAHC, Accreditation Association for Ambulatory Health Care; CARF, Commission on Accreditation of Rehabilitation Facilities; NSAID, nonsteroidal anti-inflammatory drug; TJC, The Joint Commission.

In the environment of national safety initiatives that emphasize significant investment in information technology, some of the simpler steps in improving patient safety may be overlooked. For an office that engages in interventional therapy, there are parallels to the safety features needed in offices that perform any kind of surgery. Recently, Bridenbaugh offered recommendations regarding safer office care that include: improved office emergency equipment that is routinely updated and maintained by biotechnical personnel; training and certification of personnel in delivery of medications and resuscitative techniques; use of written practice policies and procedures that are routinely reviewed with the staff, including emergency procedures; use of monitoring that conforms to the same levels as would be expected in an accredited ambulatory surgical center or hospital; guidelines for sedation and anesthesia that conform to those of the American Society of Anesthesiologists; and compliance with any local or state standards of office safety and quality standards. One cheap but creative use of technology to improve patient safety at home is the simple handheld camera phone. This may serve as a means to monitor patient wound status, a technique that could be of value to a pain practice in which patients with invasive catheters are cared for at home.

**PATIENT SAFETY AND THE IMPAIRED DRIVER: CHRONIC PAIN AND ANALGESICS**

A controversial topic is the role that a physician plays in determining the ability of patients to drive an automobile. Most state regulations require health care practitioners to report any patients who have a medical or surgical impairment that would make them unsafe if they have not voluntarily given up driving. This is a significant concern for practitioners whose practice has a large percentage of older patients, many of whom may have vision or hearing impairments that warrant concern about safety while driving a car.

Additional concerns for the pain practitioner are patients who are taking opioid medications or who undergo procedures that may impair their motor skills or mentation. The real risk of driving in the setting of long-term use of opioids is unclear, but impairment is probably present in some patients. It is also significant to consider that both opioid use and peripheral neuropathy are risk factors for impaired driving. Some evidence exists that middle-aged drivers with chronic pain, with or without treatment, are involved more often in serious accidents than are drivers who do not report...
Recently, a study raised the possibility that just the presence of chronic pain of any severity is a risk for impaired driving skills when tested on a controlled course.

PATIENTS UNDERGOING INJECTION THERAPY: SHOULD THEY HAVE A DRIVER?

Literature searches do not reveal a controlled study that provides the answer to this question. Many practitioners require all patients undergoing interventional therapy to have a driver for the following reasons:

1. Frequently, the patient’s original diagnosis entails some degree of neural dysfunction and therefore driving capability is probably already impaired.

2. Pain, which may actually increase during the initial treatment period, can cause mental distraction and muscle spasm, which could impair driver focus and function.

3. The activity of driving will very frequently exacerbate muscle spasm and is often among the activities that patients complain worsens their pain, so driving is on the list of activities that we ask our patients not to do any more than absolutely necessary during the days that treatment is in progress.

4. Theoretically, even procedures that do not intentionally block neural transmission (e.g., an epidural steroid injection with only steroid and normal saline) may cause a diminished motor response because of either volumetric compression on nerve tissue or increased pain after the injection.
5. We ask our patients to engage in therapeutic activities the day of their procedure, including the use of massage, bath, and relaxation therapy. The efficacy of these measures is opposed by the stress associated with the activity of driving.

6. In our practice, we have found that patients who are required to procure a driver for their return home are less likely to return to work immediately after the procedure or to ignore postprocedure instructions.

7. Finally, with no definitive study in the literature showing that driving after injection therapy is safe and with plausible theoretical reasons to consider that such patients might be more prone to accidents, it is a reasonable and prudent precaution.

**WHAT TO DO WHEN AN ADVERSE EVENT DOES OCCUR**

The intent of this section is to promote the use of methods to diminish the likelihood of error and avoid adverse events. Nonetheless, adverse events will happen. How should the practitioner respond? Most often the initial impulse will be to deny the event, to “cover up” any role that error played in the outcome, and to—at all costs—not implicate any practitioner as being culpable when communicating with the affected patient.

However, recent work by the APSF has emphasized the importance of open and frank communication, with open answers to even difficult questions, with the patient and family involved. An attitude of learning and correcting error rather than blaming the practitioners involved, combined with complete honesty about the events that occurred, is recommended. Above all, a strategy for dealing with patient injury should be worked out in advance among all the practice participants. The APSF has placed an “adverse event protocol” on its website at www.apsf.org that is oriented toward an anesthetic adverse event (see the drop-down list under “resource center” and click on “clinical safety tools”). It would provide guidance in the pain clinic as well.

The practice’s adverse event plan should also include discussions with malpractice carriers and practice management attorneys in advance of any events. Having a plan—and confidence in it—is the best approach to management of any breaches in patient safety. Such events should always be examined closely to find the system flaws that led to any errors.

**ACCREDITATION**

It is strongly recommended that all practitioners invite an independent agency to inspect their practice annually and provide advice about improving the quality and safety of care delivered there, even if formal accreditation does not ensue. Options include state health departments, as well as either TJC (http://www.jointcommission.org/accreditation/ambulatory_healthcare.aspx) or the AAAHC (http://www.aaahc.org/en/accreditation/). Both will certify multiple single-specialty ambulatory surgical centers, as well as physician practices and offices that practice pain medicine. If the program in question is a multidisciplinary program, another accrediting organization to consider is the Commission on Accreditation of Rehabilitation Facilities (http://www.carf.org/home/), which is willing to accredit what it terms “interdisciplinary pain rehabilitation programs.”

Certainly, full accreditation or even just a letter from an inspector describing a practice’s positive and negative attributes—assuming that the former outweigh the latter—can be valuable in contracting with third-party payers as a means of proving a salutary commitment to patient safety and practice quality. Such accreditation has been used successfully to decrease liability insurance for a facility and malpractice insurance for both a facility and the physicians who are part of its practice or ownership group. It is also probably true that such documentation would be of value in the event of any later tort action concerning a patient’s safety.

**CONCLUSIONS**

Mistakes are a fact of life. It’s the response to the error that counts.

_The only real mistake is the one from which we learn nothing._

JOHN POWELL

**SUMMARY**

- The quality movement in health care is less than 3 decades old and is still evolving. However, it is being rapidly driven by alarm among the public, payers, regulators, and the business community spurred by widespread evidence of unsafe care.
- The various stakeholders in health care define quality in different ways, and physicians must consider these alternative attitudes as they work to improve and prove the value of their practices.
- At each clinic a “culture of safety” must be established by creating new systems that will decrease the impact of human error on patient outcomes.
- Many of the current reforms aimed at improved safety and higher quality are based on as yet unproven theories and may well fall out of favor in the coming years.
- One certain way in which to improve quality is the measurement of practice to determine “best practice.” This should be done by all practitioners and all facilities and involves monitoring measures of structure, process, and clinical outcomes.
- Use continuous quality improvement (also known as total quality management) techniques to increase the number of practitioners who can replicate the best practices.
- Combining a practice that includes a comprehensive care approach and behavioral and vocational therapies with computer-based continuous quality improvement strategies will improve the quality of care in pain medicine.

The Evolution of Pain Medicine as a Subspecialty

As knowledge expands and the need for detailed skills arises, specialization ensues. This is a natural progression, and it has become impossible for any physician to become an expert in every field. There has long been discomfort with specialization despite unflagging progression in this direction. The urge to both specialize and remain unspecialized dates back to the earliest recorded history in medicine. The first specializations were between barber-surgeons and internists, and a rivalry of sorts remains to this day. Writing about Ambrose Paré, the 16th century physician who elevated the role of barber-surgeons to that of other physicians, the present-day surgeon and historian Sherwin Nuland reflected on the ongoing distinction between internist and surgeon:

Surgery is an exercise in the use of the intellect. Heckling internists, with tongues barely in check, would prefer that surgical specialists be viewed merely as dexterous craftsmen who carry out the routing errands assigned to them by their more cerebrally endowed medical overseers. I attribute this teasing raillery to a kind of good-natured fraternal envy, not so much of our celebrity status, but rather of the visibility of the cures we surgeons achieve and the particular personal gratification we have while doing it. In the United States, anesthesiology has progressed toward further specialization, first with the establishment of critical care, then pain management (now pain medicine), and more recently pediatric anesthesiology and cardiothoracic anesthesiology. The addition of pain medicine as a subspecialty of anesthesiology is just one recent example of the growth of medical specialities. With specialization comes a conscious effort to focus practice so that one becomes intricately familiar with a more limited realm. The obvious result is loss of the skills and knowledge needed to practice in the broader parent specialty. In pain medicine, many now view this as a full-time vocation. The scientific meetings and journals that keep pain medicine specialists up-to-date have little overlap with those that are designed to serve anesthesiologists practicing in the operating room. The only common thread between the technical skills needed in the pain clinic and those required for anesthesiology in the operating room is expertise in neural blockade. The pain medicine practitioner must acquire a vastly different skill set from those practicing anesthesiology, including expanding their skills as diagnosticians.

Much has been written about the origins of pain medicine as a distinct discipline, and anesthesiologists have played a primary role since the start. It really started with the introduction of effective general anesthetics in the mid-19th century, when surgical pain could be separated from surgery. Almost 100 years later, the late John Bonica, an anesthesiologist and recognized father of the specialty that we now call pain medicine, developed his career by promoting multidisciplinary pain care and formal training of specialists. From his life’s work we now have extensive ongoing efforts to recognize and treat pain effectively, to train subspecialists, and to conduct basic and clinical research to further our understanding of pain and its treatment. The International Association for the Study of Pain, founded in 1974, its U.S. chapter the American Pain Society, and the journal Pain are legacies left by Dr. Bonica for our patients.

Accredited fellowship training in pain medicine is a relatively recent development. Before 1992, training was frequently obtained in academic anesthesiology departments, including those of Bonica, Bridenbaugh, Carron, Haugen, Moore, Raj, Winnie, and others, and subsequently in programs run by their trainees. These unaccredited programs advanced the specialty, widened interest in pain medicine as a career, and propagated pain care in smaller and smaller communities across the country. Outside the United States, this type of informal training remains the rule for those seeking expertise in pain medicine. In the United States, the American Board of Anesthesiology (ABA) developed interest in certifying pain medicine specialists following their training. Through the leadership of Dr. William Owens in his roles in both the ABA and the Accreditation Council on Graduate Medical Education (ACGME) and through his representations of the subspecialty to the American Board of Medical Specialties, formal training programs were accredited and physicians were certified. Drs. Stephen Abram and John Rowlingson were both key members of the group that assisted Dr. Owens in moving the new subspecialty forward.

The first programs were accredited by the ACGME in 1992. The number of ACGME-accredited programs and trainees in accredited programs has grown steadily over the past decade, and there are now just more than 100 training programs that turn out about 300 new pain specialists each year. Working in parallel with ACGME, the ABA developed a subspecialty certification examination in pain medicine,
first named the “Certificate of Added Qualifications in Pain Management” and now titled “Subspecialty Certification in Pain Medicine.” The first examination was given in 1993. The number of candidates taking the examination has grown steadily since the initial examination.

Dr. Bonica’s original push to develop multidisciplinary pain care recently evolved into collaboration between four specialties that agreed to a single and unified set of program requirements for all ACGME-accredited pain fellowships, regardless of the sponsoring specialty. The ACGME Residency Review Committees for Anesthesiology, Neurology, Physical Medicine, and Rehabilitation and Psychiatry agreed on these requirements in late 2005, and the ACGME board approved their implementation for 2007. These requirements have standardized pain fellowship training programs. After introduction of the new training requirements in 2007, a number of programs closed because of unwillingness to adopt a multidisciplinary approach, and thus only the more comprehensive programs were left to continue the training of physician pain specialists (Fig. 7.1). Programs have begun to produce more comprehensive and multidisciplinary focused physicians from a wider range of primary disciplines (Figs. 7.2 and 7.3). Other groups are also encouraging a more comprehensive approach to pain care, with the linked American Academy of Pain Medicine and the American Board of Pain Medicine likewise devoting energy to a multidisciplinary approach.

There remain a number of experienced pain specialists who believe that eventually the ACGME-accredited fellowships will be extended to 2 years to cover an expanding knowledge base. Equally important in evolution of the discipline is the creation of academic physicians within the fellowships who undertake research programs to add new knowledge to guide clinical practice in this area of medicine.

Pain and its consequences draw on resources from all medical disciplines. Dr. Bonica’s experiences during World War II suggested that each medical specialist had unique expertise to bring to patients suffering pain—hence his consistent and effective promotion of a multidisciplinary process for pain care. Also thanks largely to Dr. Bonica, anesthesiology has led the development of formal training programs. Indeed, the majority of currently accredited programs reside within academic anesthesiology departments, and most program directors are anesthesiologists. Specialists from other disciplines have also focused their clinical and research efforts on pain. The most obvious example is neurology, from which the majority of clinical treatment and rehabilitation programs. Moreover, psychiatrists and psychologists have of course been closely involved when pain, depression, and substance abuse overlap. During the last decade, specialists from these other disciplines have been seeking subspecialty training in pain medicine with increasing regularity.

The range of practitioners declaring themselves pain medicine specialists is extraordinary, from clinics that provide largely or solely cognitive-behavioral approaches to chronic pain through functional restoration programs all the way to the type of clinic that offers nothing more than injections of various sorts. “Interventional pain medicine” is a phrase that has been coined for techniques that involve minimally invasive treatments and minor surgery as part of their application, including neural blockade and implantable analgesic devices. Despite the paucity of scientific evidence to guide pain practitioners, particularly evidence to support the use of many interventional modalities, many techniques appear to have efficacy based on limited observational data and have been adopted into widespread use. As practitioners, we are left to choose among the treatment modalities.

**Figure 7.3** Primary specialty of board certification of diplomates receiving subspecialty certification in pain medicine through a member board of the American Board of Medical Specialties (ABMS; member boards offering pain medicine subspecialty certification include the American Board of Anesthesiology [ABA], the American Board of Physical Medicine and Rehabilitation [ABPMR], and the American Board of Psychiatry and Neurology [ABPN]). (All data provided by the ABA, ABPMR, and ABPN, July 2010.)

* Diplomates receiving Pain Medicine Subspecialty Certification through an American Board of Medical Specialties (ABMS) Member Board (the American Board of Anesthesiology, American Board of Physical Medicine and Rehabilitation or the American Board of Psychiatry and Neurology)
available, often with only anecdotal and personal experience to guide us in treating a group of desperate patients with intractable pain who are willing to accept almost any treatment, even though it remains unproven. There is no single practice pattern that pain specialists can point to as being the correct way to treat patients with chronic pain. Training programs vary widely in the scope of what they train practitioners to do. The best pain medicine practitioners strike a reasonable balance between interventional and noninterventional management. This practice pattern is sustainable, and those adopting a balanced style of practice will be able to adapt to the evolving evidence that appears in support of pain treatment, regardless of the type of treatment. A balance between treatment modalities also allows practitioners to switch from one mode to another or to incorporate multiple treatment approaches simultaneously. Use of these interventional modalities is just a small part of the armamentarium of a skilled pain practitioner.

TRAINING AND CREDENTIALING IN INTERVENTIONAL PAIN MEDICINE

In our rapidly changing world of modern health care, new technologies are appearing at a dizzying rate. Many of these new treatments require physicians to acquire detailed new knowledge and technical skills. The introduction of new techniques typically extends from centers in the public or private sector, where the ideas are conceived and tested in a limited realm among innovators. From there, anecdote can often take over, and many techniques in pain medicine have blossomed into widespread use with nothing more than word of mouth to propagate their use. The use of pulsed radiofrequency treatment of pain is one such example in which clinical application has preceded detailed clinical testing.4

In the United States and Europe, industry often leads innovation by testing and initiating the introduction of new devices. When the innovation appears to have merit in limited trials, many devices are introduced to the market with approval through the Food and Drug Administration’s 510K “substantially similar device” process with little or no data regarding efficacy. Once on the market, the means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and—of great importance—the means by which practitioners gain enough expertise to introduce new techniques into their own practice are all highly variable and seemingly without any rational or consistent approach.

Interventional pain medicine is evolving as a distinct discipline that requires detailed new knowledge and expertise. Familiarity with radiographic anatomy for performing image-guided injections and the minor surgical skills needed to implant devices such as spinal cord stimulators and drug delivery systems are just a few of the techniques that practitioners must master. As we set out to introduce new interventional techniques into our own pain practices, we must be sure that we have been properly trained to perform these techniques in a manner that ensures safety and success.

Adequate exposure to these newer treatment alternatives during the fellowship training period is necessary to ensure appropriate application and optimize patient outcomes. Although we do not have scientific data that define the average minimum level of experience that will be necessary to achieve competence, especially for complex procedures associated with significant risk, logic dictates that that trainees should be exposed to a minimum number of these procedures during a fellowship. The ACGME has established requirements for the average minimum number of epidural, spinal, and peripheral nerve blocks necessary for the accreditation of anesthesiology residency programs. Other medical subspecialties also require a minimum number of specified procedures to achieve and maintain competence: subspecialty training in gastroenterology has a requirement for performing a minimum of 100 esophagastroduodenoscopy and 100 colonoscopy procedures with polyp removal8 during formal training, and subspecialty training in cardiovascular disease requires 100 cardiac catheterization procedures to demonstrate minimum proficiency.6 Indeed, the ACGME’s Residency Review Committee for Anesthesiology has accepted revised Program Requirements for Pain Medicine Training Programs that specify the minimum exposure of trainees to various procedures, including image-guided injection techniques for the cervical and lumbar spine; sympathetic blockade; neurolytic block, including radiofrequency treatment of pain; spinal cord stimulation; and placement of permanent spinal drug delivery systems. For techniques that are now widely accepted as a core element of pain practice, we must ensure that our trainees gain enough experience to conduct these procedures independently. One key element of the ACGME deliberations about unified pain training is to acknowledge that not all pain fellows will have experience in the wide variety of interventional techniques. Rather, it is hoped that these fellows will gain an understanding of all available options for patients with pain and yet demonstrate and have competence documented in only techniques for which formal training is made available during fellowship training.

It is difficult to define the techniques that are core for a pain practitioner, but it does seem that detailed knowledge of the radiographic anatomy of the spine and the minor surgical expertise required to implant spinal cord stimulators and permanent spinal drug delivery systems are among the skills that most practicing pain physicians would expect a new graduate from a pain fellowship program to have. New techniques are appearing at a staggering rate, and we cannot rely on pain fellowship programs to provide all the technical training that is needed. Stronger standards for minimum training following fellowship programs are also urgently needed. Some pain practitioners believe that too many of their colleagues find it perfectly acceptable to attend a brief weekend course and then introduce a highly technical new treatment into practice without additional study, training, or oversight.7 Practitioners themselves must take the lead in obtaining adequate training before proceeding with any new and unfamiliar technique. A weekend workshop is just a start, often a good start—the best workshops will give practitioners a detailed understanding of anatomy, pathophysiology of disease related to use of the new technique, patient selection, conduct of the procedure, outcomes, and avoidance, management, and recognition of complications. Box 7.1 is a suggested method for practitioners to introduce a new technique into clinical practice.8
The field of evidence-based medicine has emerged as a new paradigm to guide practicing physicians. This field aims to educate practitioners on how to frame specific questions based on the clinical problems that they encounter every day. They then venture to the published scientific literature with focused questions on prevention, treatment, and diagnosis of a specific clinical condition. Many evidence-based medicine centers offer concise and periodically updated summaries on specific clinical conditions. The idea is to get the best information available to practicing clinicians. They describe the best available evidence, and if there is no good evidence, they say so. In pain medicine, we are faced with an expanding array of treatment options that strike us as logical developments that should provide pain relief for our patients. However, there is a dearth of clinical evidence to guide rational choice and application of the majority of these emerging treatments. So how are we to decide when to apply them?

Nearly a decade ago, Merrill presented an analysis of the state of evidence guiding the use of interventional treatments in the field of pain medicine. He pointed out the frequent flaws in existing studies (largely the lack of valid comparators, such as no treatment) and concluded that “the practice of invasive pain medicine teeters at a particularly critical juncture...crippled by a lack of vigorous self-evaluation of its role in the treatment of chronic pain.” Merrill went on to detail the means by which we, as scientists and clinicians, can proceed to build a better body of evidence for the treatments that we are using. However, the field of pain medicine is young and early in development, and randomized clinical trials are still lacking for many treatments.

New treatments evolve slowly. Application of the scientific method in clinical medicine begins with observation, perhaps a chance observation that a certain drug typically used for another purpose provides analgesia to a given patient. If the drug is readily available, a clinician may choose to try treatment of other patients with similar conditions. If academically minded, the clinician may choose to report the limited success in a case series. Case series are a valuable beginning, the very beginning of emerging new ideas. If the problem is uniform and prevalent enough, the new treatment may gain the attention of investigators willing to assemble a randomized clinical trial. All too often, sound treatments are never tested because of lack of interest or funding. Those that are tested tend to be under patent, and the manufacturer proceeds with large trials understandably in the hope of financial return in the event that the treatment proves useful. Patients who are suffering from severe and intractable pain are desperate and can easily be convinced that desperate measures, however new or unproven, are warranted.

How then are we to proceed? Our patients are begging for us to try anything that offers a glimmer of hope in reducing their pain, and we as scientists embrace the rigor of the scientific method and want desperately to do what is best for our patients. We have treatment after treatment that makes logical sense and shows early promise in case series and observational studies, but few data that support an evidence-based approach to practice. Using acute low back pain with sciatica as an example, a number of evidence-based reports have emerged to guide clinicians. The only modalities that are rated as “beneficial” or “likely to be beneficial” are advice to stay active and use of nonsteroidal anti-inflammatory drugs, behavioral therapy, and multidisciplinary treatment programs. Opioid analgesics, acupuncture, back schools, epidural steroid injections, and spinal manipulation were all judged to be of “unknown effectiveness.” Yet in actual clinical practice in the United States, a short course of an opioid analgesic plus early intervention with epidural steroid injections is common. To complicate matters, the use of fluoroscopic guidance to direct injections to the affected level via an interlaminar or transforaminal approach has gained widespread acceptance, but with only uncontrolled case series to guide us as clinicians. Those with persistent pain and contained disk herniations now have a dizzying array of treatment options, including laser diskectomy, thermal disk decompression, and vacuum disk extraction, all using Food and Drug Administration–approved devices with only uncontrolled observational studies that suggest effectiveness. The new devices are intellectually appealing and minimally invasive, yet only open surgical diskectomy has proved superior to conservative management in patients with persistent sciatica secondary to intervertebral disk prolapse.

The evidence-based medicine movement gives little guidance to practitioners whose tools are still under development. They simply remind us that no evidence regarding many of our techniques exists. Without declaring a moratorium on all interventional pain techniques, Merrill offers the individual practitioner advice: monitor your own outcomes with valid measures, be more reflective and systematic in studying your own outcomes and patterns of care, and provide this information to your patients as part of the decision-making process. As pain practitioners we have an expanding range of treatment options available to us, few with convincing evidence of efficacy superior to that of alternative treatments.

**Box 7.1 Suggested Training and Experience When Introducing a New Technique into Clinical Practice**

1. Study the new technique and the published literature and gain detailed knowledge of all aspects of the technique.
2. Attend a workshop, preferably a hands-on cadaver-based workshop that allows introduction of the technique in as realistic a setting as can be assembled.
3. Plan adequate time for your initial procedures.
4. Get help at the bedside during the initial performance of new procedures—perhaps another experienced practitioner at your institution or an invited expert to assist or team up with a colleague in a related discipline.
5. Inform your patients that you are introducing a new technique and include this discussion as part of the informed consent process.
6. Examine your outcomes carefully in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

**FUTURE DIRECTIONS**
We must evaluate each patient and use the limited evidence available to us today to guide compassionate and rational, if not evidence-based, use of therapy for our desperate patients.

The urgent need for expanded clinical research in pain medicine, coupled with recent efforts to improve multidisciplinary training, are straining the ability of training programs to adequately provide the needed education and research experience for pain medicine fellows in the course of a 1-year fellowship. The ACGME and ABA are currently working to further restructure pain medicine training to accomplish these goals (for a recent review see Rathmell13). The idea is to provide more comprehensive and multidisciplinary training and to require meaningful research experience during fellowship training. With this approach we will create a more homogeneous group of pain medicine specialists who emerge with similar knowledge and skills, regardless of the parent discipline in which they trained. This will move us toward improving the consistency and quality of care of patients with acute, chronic, and cancer-related pain.

**KEY POINTS—cont’d**

- Detailed knowledge of the radiographic anatomy of the spine and the minor surgical expertise required to implant spinal cord stimulators and permanent spinal drug delivery systems are among the skills that a new graduate from a pain medicine fellowship program is expected to have.
- The ABA, together with the ACGME, developed a subspecialty certification examination in pain medicine, first named the “Certificate of Added Qualifications in Pain Management” and now titled “Subspecialty Certification in Pain Medicine.” The first examination was given in 1993, and the number of candidates taking the examination has steadily grown.
- Many devices have been introduced to the market with approval through the Food and Drug Administration’s 510K “substantially similar device” process with little or no data regarding efficacy. The means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and the means by which practitioners gain enough expertise to introduce new techniques into their own practices are all highly variable. Rational steps in incorporating a new interventional technique into someone’s practice are outlined in Box 7.1.
- Efforts to provide multidisciplinary training and the need for clinical research are straining the ability of training programs to provide the education and research experience for pain medicine fellows in the course of a 1-year fellowship. The ACGME and ABA are currently working to further restructure pain medicine training to accomplish these goals.

REFERENCES

The neural circuits that are responsible for pain and the reactions to pain\(^1\) can be termed the *pain system*\(^2\) or, perhaps more appropriately, the *pain systems*. The pain systems include (1) peripheral neurons with a set of peripheral receptive elements, the nociceptors; (2) numerous central neuronal relay pathways; and (3) sets of integrative neurons that impose excitatory or inhibitory influences on nociceptive information at numerous levels of the neuraxis.

The initial reception of input perceived to be painful occurs on the peripheral terminations of nociceptors transducing noxious mechanical, temperature, and chemical stimuli. Nociceptors transmit information about internal or external stimuli that are noxious, distressing, or damaging to second-order neurons located in the spinal cord or brainstem level innervated (i.e., the lumbar spinal cord for leg input, the thoracic spinal cord for stomach lining input, and the trigeminal spinal nucleus for face input). Nociceptive signals are then transmitted by projection neurons of the pain system to integration sites in the brainstem. A primary integration site for sensory information is the thalamus, but numerous other brainstem and higher brain structures are participants in the integrative neuronal circuits responding to pain.

A variety of coordinated pain reactions are generated, including protective somatic and autonomic reflexes, endocrine actions, emotional responses, learning and memory about the event, and cortical awareness of pain. In addition to pain transmission and pain reactions, the brain centers that receive nociceptive information also provide either negative or positive feedback that reduces or accentuates pain and pain reactions. Negative feedback to the spinal cord circuitry is mediated by descending pathways that are often called the “endogenous analgesia system.” The mechanism and pathways responsible for accentuation of pain and pain reactions, referred to as central sensitization or facilitation, can involve increased responsiveness at all levels of the pain system, including the peripheral nociceptors, spinal cord, brainstem, and higher centers. The net effect of the positive and negative alterations in circuitry leads to the perceptual experience of “pain.”

---

**NOCICEPTORS**

**PERIPHERAL RECEPTIVE ELEMENTS**

The initial reception of noxious input perceived to be painful occurs at the specialized endings of primary afferent sensory neurons known as nociceptors. Reception of noxious input occurs in functionally specialized free nerve endings of the skin, muscle, joints, visceral structures, and dural structures. Nociceptors, as well as \(\mu\)- and \(\delta\)-opiates, substance P (SP), somatostatin, and vanilloid receptors, have been identified immunohistochemically on the peripheral endings of cutaneous nerve fibers.\(^{12-16}\) Nociceptor subtypes respond best to either mechanical (mechanical nociceptors), mechanical and thermal (mechanothermal nociceptors), or mechanical, thermal, and chemical stimuli (polymodal nociceptors).\(^{17,18}\) Common types of cutaneous nociceptors are \(A\delta\) mechanoreceptors and \(C\) polymodal nociceptors, which relay the transduced information about potentially harmful input via \(A\delta\) and \(C\) fibers, respectively.\(^{19,20}\)

**PERIPHERAL NERVES**

The axons that relay information about noxious input from the skin and other tissues to the central nervous system (CNS) fall characteristically into the range of small, unmyelinated axonal fibers with conduction velocities lower than 2.5 m/sec for \(C\) fiber (or group IV) nociceptors\(^{21}\) (Fig. 8.2) and small fibers wrapped in a thin layer of myelin produced by Schwann cells with a conduction velocity of 4 to 30 m/sec in the case of \(A\delta\) fibers (or group III).\(^{22}\) Primary afferent \(C\) fibers are more numerous than myelinated primary afferents in peripheral nerves. For example, in the dorsal roots, the ratio of \(C\) fibers to \(A\) fibers is about 2.5:1,\(^{23}\) and in joint nerves (after sympathetic postganglionic axons are removed by sympathectomy), the ratio of \(C\) to \(A\) fibers is 2.3:1.\(^{24}\)

The peripheral nerves carry both sensory and motor axons. Regardless of whether they innervate cutaneous, deep, vascular, or visceral tissue, the primary afferent (incoming) fibers carrying sensory information separate from the motor nerve axons near the spinal cord and become the dorsal root that enters the spinal cord on the...
dorsal surface (Fig. 8.3). Motor commands are sent out to the periphery through the ventral root by large, rapidly conducting somatic efferent nerve fibers and by small, slowly conducting autonomic motor fibers. Whereas the motor neurons are located in the ventral horn of the spinal cord or intermediate regions in the case of autonomic motor neurons, the sensory afferent fibers have their cell bodies in the dorsal root ganglia (DRGs) (or cranial nerve ganglia) located outside the spinal cord or brainstem.

Noxious mechanical, temperature, and chemical (nociceptive) information is first relayed across a synapse located in the dorsal horn of the spinal cord before transmission to brainstem sites (including the ventral posterolateral [VPL] nucleus of the thalamus) (see Figs. 8.1 and 8.3). Cutaneous and visceral nociceptive input is provided to spinal

![Image of Pain Systems]

**Figure 8.1** The pain systems convey input from somatic structures, as well as from viscera and other deep tissues, via peripheral nerves. Afferent nerve fibers carrying nociceptive information have free nerve endings in peripheral tissue and terminate in the superficial spinal cord dorsal horn. Information about pain is relayed through at least one synapse to cells in the spinal cord dorsal horn. Two parallel ascending pathways provide the information to integration centers in the thalamus, which provide the information to cortical regions. Input primarily from somatic structures is relayed to spinothalamic tract cells whose axons cross the midline and ascend in the lateral and ventrolateral spinal white matter as the spinothalamic tract. As the spinothalamic tract courses through the brainstem, collateral fibers innervate a variety of brainstem centers involved in providing responses to nociceptive input on its path to the thalamus. Nociceptive input arising from visceral structures is relayed by postsynaptic dorsal column cells whose axons course in the dorsal columns. After a synaptic relay in the dorsal column nuclei and crossing to the opposite side of the brainstem, the medial lemniscus carries nociceptive information to the thalamus. Both these routes are somatotopically arranged throughout their length.
neurons in different spinal regions, has different ascending spinal projection pathways, and has different brainstem terminations.

In contrast, incoming cutaneous non-noxious input important for discerning fine, discriminative touch, pressure, and position in space is transmitted by large, myelinated peripheral nerve fibers directly through the dorsal column of the spinal cord. The first synapse of these large, uncrossed ascending primary afferent fibers is in the dorsal column nuclei of the medulla. From there, cutaneous sensory information is transmitted as the decussated medial lemniscal pathway to the contralateral VPL nucleus of the thalamus, the primary sensory integrative relay of the sensory system. Similar information is relayed to the brainstem through several tracts whose cells of origin are within the spinal cord, including the tactile component of the postsynaptic dorsal column pathway, the spinocervical tract, and the proprioceptive pathway that projects to nucleus Z in the medulla.19

Primary afferent fibers providing input to autonomic regions of the spinal cord from visceral structures and the vasculature travel along with the sympathetic efferent nerves. They pass directly through the sympathetic trunk, however, to join other afferent fibers entering the dorsal horn of the spinal cord (see Fig. 8.3).

As in most central neuronal circuits, glutamate is the primary neurotransmitter substance in primary afferent nociceptors. Its action is modulated by neuropeptides co-released at their terminal endings and by activation molecules. Calcitonin gene–related peptide (CGRP), SP, neurokinin A, galanin, and somatostatin are just a few examples of the many neuropeptides that provide neurogenic modulation and inflammation peripherally.25,26 Afferent nerve endings

---

**Figure 8.2** Peripheral nerves conveying information about pain are either small, slowly conducting fibers found unmyelinated in bundles or medium-sized axons with thin myelin, which provides a higher conduction velocity.

---

**Figure 8.3** Nociceptive afferent nerve fibers have receptive free nerve endings in the dermal papillae of skin, in muscle, in the vasculature, and in visceral structures. Nerves carrying nociceptive information travel with other somatic and autonomic motor axons, even passing through the autonomic ganglia, but have their cell bodies in the dorsal root ganglia located in the spinal vertebral column. The central axonal projection of afferent nerve fibers then passes through the dorsal root to innervate the spinal cord dorsal horn. Nociceptive information is relayed across at least one synapse in the dorsal horn to alert cells with projections to higher centers. The spinothalamic tract (STT) cells in the superficial dorsal horn send an axonal projection across the midline to travel in the lateral SST. SST cells in the deep dorsal horn send axons across the midline to ascend in the ventral white matter. SST cells bring information about both somatic and visceral pain to the thalamic levels. Postsynaptic dorsal column (PSDC) cells relay information about visceral pain through the ipsilateral dorsal column.
are also activated by inflammatory mediators, such as tumor necrosis factor-α, interleukin-1 (IL-1), and IL-6. Other activators include the small molecules adenosine, adenosine triphosphate, nitric oxide, and other reactive oxygen species. All these substances have been identified at terminal sites, in DRGs, and in the dorsal horn.

**CELL BODIES IN DORSAL ROOT GANGLIA**

The large, medium, and small neuronal cell bodies of the primary afferent nerve fibers lie just outside the spinal column clustered in DRGs, with many of the small and medium DRG cells belonging to the nociceptors. The pseudo-unipolar DRG neurons extend their axons peripherally as primary afferent fibers and centrally as dorsal roots. The modulatory neuropeptides produced in DRGs are transported quickly to terminal endings in the periphery and the spinal cord and thus may not necessarily be evident in the cell body without experimental manipulations. The small satellite glia, the other component of DRGs, provide support but are also capable of exerting modulatory influence on the neurons that promote peripheral sensitization.

**SPINAL CORD TERMINATIONS**

The primary afferent fiber type and its site of termination centrally are relevant to its function. The afferent fibers enter the gray matter of the spinal cord through the dorsal root entry zone and primarily innervate regions of the spinal cord within the same or adjacent spinal segments matching that spinal nerve. In general, large myelinated primary afferent fibers carrying discriminative sensory information (tactile, pressure, vibratory sense) enter the dorsal roots, traverse the top of the dorsal horn of the spinal cord (Lissauer’s tract), and turn to ascend uncrossed as the white matter dorsal column. The large sensory afferent nerves provide only collateral input to the dorsal horn. The smaller myelinated and unmyelinated axonal fibers entering the dorsal root carry information about temperature and nociceptive input perceived as pain in humans. The fibers enter Lissauer’s tract and then innervate the gray matter core of the spinal cord, where neuronal cell bodies and dendrites receive their arborized synaptic endings (Fig. 8.4; see also Fig. 8.3). However, these afferent fibers may also ascend rostrally or descend caudally a few spinal segments through Lissauer’s tract.

Two populations of small-diameter primary afferents carrying pain-related information to the dorsal horn are classified as (1) peptidergic, containing CGRP and SP, and (2) nonpeptidergic, containing no peptides but expressing purinoceptors for ATP (P2X3) and binding isolectin B4 (IB4).

Since the sole source of CGRP in the dorsal horn of the spinal cord is from primary afferents, this peptide serves as a convenient marker for primary afferent peptidergic terminal endings in the spinal cord (Fig. 8.5). CGRP fibers extend extensive fiber terminations up and down the superficial spinal cord dorsal horn through numerous spinal levels on entering at a particular spinal segment and can even cross the midline in small numbers. Numerous other neuropeptides have been localized in the dorsal horn. Visceral afferents are rich in vasoactive intestinal polypeptide (VIP), bombesin, CGRP, and SP and would account for some of the population of primary afferent nerve terminals innervating the dorsal horn.
the population of these peptides in the dorsal horn. Other neurotransmitters and neuromodulators are discussed more thoroughly in a subsequent chapter.

Nociceptive primary afferent endings contain small, round, clear glutamate containing vesicles\(^\text{37}\) for synaptic transmission and relay of nociceptive information. Other large, glomerular-type afferent endings typically contain large, densely cored vesicles containing peptides (Fig. 8.6). CGRP receptors have been localized on postsynaptic membranes opposite glomerular, elongated, and dome-shaped synaptic endings in the superficial dorsal horn.\(^\text{38}\) The spinal cord-specific modulatory effects of specific neuropeptides such as SP, CGRP, VIP, and cholecystokinin (CCK)\(^\text{39-41}\) contribute to enhanced nociception. In high activation states, increased release of glutamate and increased activation of dorsal horn neurons by glutamate, small-molecule activators, and cytokines occurs as in other sites of neural integration. In the spinal cord this generates enhanced nociception, referred to as central sensitization.

**SPINAL CORD AND SPINAL TRIGEMINAL NUCLEUS**

**SPINAL CORD DORSAL HORN**

The noxious input relayed by primary afferent fibers is received by neurons in the dorsal horn of the spinal cord. The dorsal horn contains both local interneurons and the projection neurons that provide the information to higher processing centers in the brain. Signals from nociceptors are relayed across at least one synapse before arriving at higher brain regions, in contrast to the input for non-noxious sensation, which is relayed directly to dorsal column nuclei in the brainstem (see Figs. 8.1 and 8.3).

The gray matter at the core of the spinal cord is a matrix of synaptic terminations and cells that form the first tier of processing and integration of sensory information. The gray matter has been subdivided topographically into 10 laminae by Rexed\(^\text{42}\) based on histologic appearance as a result of the distribution of neuronal cells and axons (Fig. 8.7; see also Fig. 8.4 and Paxinos\textsuperscript{43}). The gray matter of the dorsal horn includes laminae I to VI. Some cells in deeper laminae (VII and X) also relay nociceptive information to the brainstem.
Laminae VII to IX and lamina X are involved in somatic and autonomic motor function, respectively. The white matter encasing the gray matter is composed of ascending and descending fiber bundles traveling longitudinally and connecting the spinal cord and the brain. Many of the axons are ensheathed in myelin formed by oligodendroglia. These myelin-producing glial cells are unique to the CNS. Other glial cells in the CNS include astrocytes and microglia.

Most of the primary afferent endings carrying nociceptive information heavily innervate the superficial dorsal horn of the spinal cord (laminae I and II) (see Figs. 8.4 and 8.5). Somatic nociceptor C-fiber afferent endings are distributed rather focally in the spinal cord, mainly to laminae I and II in the same and adjacent segments, whereas visceral C-fiber afferents can extend for more than five segments before they terminate widely distributed in laminae I, II, V, and X ipsilaterally, as well as in laminae V and X contralaterally (see Fig. 8.4). Cutaneous Aδ mechanical nociceptors terminate in the ipsilateral laminae I and V, and they may also have endings in lamina X and the contralateral dorsal horn. Noxious cutaneous input is relayed by lamina I, IV, and V projection neurons as the crossed spinothalamic tract (STT) pathway traveling in the lateral and ventrolateral white matter en route to the VPL and posterior thalamus.

In addition to afferent endings, fiber terminations of the descending pathways and local interneurons also heavily innervate the superficial dorsal horn, thus adding to the dense crescent of terminal endings observed when stained immunocytochemically for many neurotransmitters and receptors. The outer marginal layer, or lamina I, contains nets of spiny dendrites of cells that are longitudinally arranged along the length of the cord. Many of the cells are interneurons, but there are also lamina I cells that send axonal projection to the brainstem, thalamus, and hypothalamus (for review see Willis and Westlund).

Lamina II, or the substantia gelatinosa, contains both excitatory and inhibitory interneurons that modulate projection neurons. Lamina II interneurons synthesize either inhibitory or excitatory neurotransmitters, such as glutamate and γ-aminobutyric acid (GABA), respectively. Typical of lamina II are large glomus-like synaptic complexes, sometimes referred to as scalloped primary afferent endings, that contact multiple dendrites of dorsal horn cells simultaneously (see Fig. 8.6). The terminals contain large dense-core vesicles, which identifies them as containing neuropeptides. The interneurons take the form of stalked (limiting) cells and islet (central) cells, with dendrites extending both dorsally into lamina I and ventrally into deeper laminae of the dorsal horn.

Laminae III and IV contain interneurons and large projection neurons of the spinocecal and postsynaptic dorsal column pathways that relay mechanotactile and visceral nociceptive information, respectively. The deeper laminae IV to VI contain interneurons and nociceptive projection neurons that distribute nociceptive input to the brainstem, thalamus, and hypothalamus. The projections of these cells form the spinothalamic, spinohypothalamic, and spinoparafascicular pathways. The dendrites of the interneurons and projection neurons in deeper laminae are oriented radially and flattened and resemble slabs stacked in the spinal cord. The dendrites of identified STT cells can extend through all laminae dorsolaterally and may extend over several millimeters in the rostrocaudal direction.

The central region of the spinal cord is a visceral nociceptive and autonomic processing area, including lamina X and adjacent parts of laminae III, IV, V, VII, and VIII. This region contains second-order projection neurons that transmit information about visceral and somatic pain in the body core, in addition to interneurons and neurons with autonomic-related functions. These cells are “silent” neurons and thus have been studied significantly less than other spinal cord neurons. In fact, the early intermediate gene product c-Fos in cells in the deeper laminae only appears after noxious visceral and prolonged pain states.

The visceral nociceptive projection cells are postsynaptic dorsal column, spinothalamic (ventromedial and ventrolateral medulla, raphe, locus coeruleus, periaqueductal gray [PAG], spinoabradachial, spinoamigdalar, spinohypothalamic (parafascicular and central lateral), and spinoparafascicular projection neurons. These are the cells of origin of the medial pain pathways that ascend to higher brain levels through routes separate and parallel to those of the lateral pain pathway originating from lamina I, IV, and V STT neurons. Their axonal projections and relay neurons innervate the brainstem core and the medial and intralaminar thalamus rather than the ventrobasal thalamus en route to the limbic and insular cortices (anterior cingulate and medial frontal cortices). The nociceptive information delivered ultimately has an impact on motivational, affective, and illness responses.

Incoming sensory information received from the head, neck, and dura arrives via afferent fibers from the trigeminal nerve. The terminal distribution in the dorsal horn of the spinal trigeminal nucleus in the caudal medulla is in a position equivalent to the spinal cord dorsal horn and appears very similar when stained for peptides. Glutamate and gluta-

SPINAL INTERNEURONS

Most of the neurons in the dorsal horn are interneurons. Neurons in the dorsal horn have been found to contain any of a large number of neuroactive substances that are presumably neurotransmitters or modulators. These substances include adenosine, choline acetyltransferase, CCK, corticotropin-releasing factor, dynorphin, enkephalin, galanin, GABA, glutamate, glycine, neotensin, neuropeptide Y, somatostatin, SP, and thyrotropin-releasing hormone. These substances are involved in excitatory or inhibitory modulation of nociceptive processing by the interneuronal circuits of the dorsal horn.

Inhibition of spinal transmission, by non-noxious mechanical stimulation, for example, can occur through activation of either the segmental or supraspinal circuitries. Events that can inhibit nociceptive transmission can occur by reducing release of neurotransmitters from nociceptor terminals at the dorsal horn. Even though physiologists have conveniently explained “surround”-type inhibition of dorsal horn synaptic transmission in terms of dorsal horn...
axo-axonic synaptic transmission, only a few anatomic figures of this type have been described for the dorsal horn. Rather, the anatomic arrangement of synapses for the gate theory of pain proposed by Melzack and Wall is mediated through axodendritic arrangements of CGRP primary afferent terminals innervating the dendrites of GABA interneurons in lamina II and reciprocal interactions. Fine myelinated and unmyelinated CGRP-labeled afferent fibers are observed synapsing with GABAergic dendritic profiles. GABA interneurons are primarily the islet cells, which are also found in laminae I and III and have been stained for another inhibitory amino acid, glycine. GABA interneurons are uniquely qualified to provide the “presynaptic” inhibition of nociceptive input either through contacts provided by their dendrites back onto CGRP primary afferent endings, through dendro-axonal contacts back onto primary afferent endings, or onto other dorsal horn neurons. Other inhibitory neurons in the dorsal horn contain dynorphin and glycine. Likewise, an interposed excitatory interneuron, such as one containing glutamate, would provide an excitatory boost to spinal nociceptive processing. Interestingly, neurons in lamina II, the substantia gelatinosa, do not respond to release of SP since they lack neurokinin 1 (NK1 or SP) receptors. SP terminal endings in the superficial dorsal horn, including lamina I cells with NK1 receptors that rapidly internalize the receptors on nociceptive stimulation.

In the case of intense or prolonged nociceptive stimulation, the same anatomic arrangement of the dorsal horn circuitry providing “presynaptic inhibition” by GABA interneurons can override the inhibition and result in sensitization. Prolonged membrane hyperpolarization evokes a secondary role of GABA receptors that changes their role from inhibition to excitation by altering the membrane conductance of central primary afferent terminals. This results in diminished presynaptic inhibition and depolarization of the afferent nerve terminal endings themselves, which generates an action potential that travels back out the afferent nerve toward the periphery. These “dorsal root reflexes” release neurotransmitters such as glutamate and peptides from the axonal terminals into the damaged tissue and allow increased release of transmitter at the central terminals in the dorsal horn. This sets up a reverberating positive feedback loop that amplifies nociceptive input and results in both peripheral and central sensitization, which can promote the establishment of chronic pain.

Thus, nociceptive information entering the spinal cord dorsal horn is modulated by both excitatory and inhibitory influences at the periphery and at the level of the spinal cord before being relayed by projection neurons to higher centers. Modulation occurs not only through influences of the primary afferent nerve on the local interneuronal circuitry but also through the input provided to projection neurons by descending input from the brainstem. This modulatory input probably also involves the spinal interneuronal circuitry.

**Projection Neurons**

Several types of projection neurons in lamina I have been described by Lima and Coimbra that send their axon rostrally to the brainstem. These cell types include fusiform (spindle-shaped), multipolar, flattened, and pyramidal neurons. Different subsets of these cells project their axons to the nucleus of the solitary tract; to the dorsal and lateral reticular nuclei in the medulla, pons, and midbrain; and to the thalamus. Neurons of the same morphologic types express SP, enkephalin, dynorphin, or GABA, although some of the cells may have been interneurons. Three morphologic types of lamina I STT cells have been described in cats and monkeys: fusiform, pyramidal, and multipolar. Evidence has been provided that the fusiform and multipolar STT cells are nociceptive whereas the pyramidal STT cells are thermoreceptive. Consistent with this finding, most fusiform and multipolar lamina I STT neurons express NK1 receptors and most pyramidal STT cells do not.

The projection cells that are found in deeper laminae of the dorsal horn are typically large, multipolar neurons with extensive dendritic arborization. The dendrites of deep projection cells tend to arborize radially in the spinal cord dorsal horn, in contrast to lamina I projection cells, whose dendrites are longitudinally distributed along the dorsal surface of the spinal cord gray matter such that in the coronal plane they are barely visible. A radial dendrite arrangement provides for the integration of convergent input encoded by STT cells in the deeper laminae, as opposed to the superficial projection neurons, which are situated to have ready access to specific incoming nociceptive and thermal input directly via the afferent nerve fibers. Some STT cells in deeper laminae do have dendrites that extend dorsally into laminae I and II (see Fig. 8.7). These STT cells receive direct synaptic connections from the terminals of nociceptors ending in the superficial dorsal horn and are particularly responsive to “high-threshold” input. Other STT cells identified as “wide-dynamic range” cells respond to a variety of mechanical, thermal, and nociceptive input. They have dendrites that extend chiefly in the ventral direction and receive convergent input from afferents supplying both deep somatic and visceral structures.

The SST and interneuronal cells in the dorsal horn have been shown to express the early intermediate gene activation marker c-Fos in many pain models. It is reported that brief nociceptive stimulation causes activation of c-Fos in laminae I, IV, and V whereas sustained nociceptive stimulation is needed to activate c-Fos in laminae III, V, VII, and X, as in models of joint and visceral inflammation. The STT neurons contain glutamate, and some also contain peptides such as SP, enkephalin, dynorphin, or VIP. Lamina X STT cells have been shown to contain CCK, bombesin, galanin, or any combination of these substances. Synapses found on the cell bodies of STT neurons in deep layers of the dorsal horn have been shown to contain glutamate, GABA, glycine, SP, CGRP, vasopressin, norepinephrine, or serotonin, thus indicating that these STT cells are affected by both excitatory and inhibitory events associated with nociceptive processing. The dorsally directed dendrites of many deep dorsal horn neurons contain NK1 (SP) receptors, and these are internalized following the presumably painful stimulation occurring during inflammation. Ultrastructural studies have revealed postsynaptic localization of the glutamate receptor subunits N-methyl-d-aspartate (NMDA) R1, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)
GluR1 and GluR2/3, and metabotropic mGluR1 and mGluR2/3 associated with terminals in contact with identified STT neurons. NMDA R1 and AMPA GluR2/3 receptors were also localized presynaptically on terminals contacting STT neurons.

CENTRAL ASCENDING PATHWAYS

Nociceptive transmission neurons in the spinal cord send axonal fiber projections to the many sensory-processing regions in the brain, including the dorsal column nuclei, dorsal and ventral medullary reticular formation, dorsolateral pontine locus coeruleus/parabrachial region, midbrain PAG, medial and lateral thalamus, anterior pretectal nucleus, hypothalamus, and amygdala (Fig. 8.8; see also Fig. 8.1). Anterograde tract tracing studies demonstrate the second-order ascending pathways crossing to the opposite side as they project through the spinal cord white matter to the brainstem as the spinothalamic tract and the medial lemniscus. Although the primary termination site for sensory integration is the thalamus, abundant collateral terminations are provided to integration sites throughout the brainstem. The ventral postero-lateral nucleus of the thalamus is the principal somatosensory relay for information provided to the sensory areas of the cerebral cortex for localization of pain sensation. The medial and intermediate portions of the thalamus project to the anterior cingulate and frontal cortex, respectively, and provide input relevant to the affective responses to pain. Autonomic adjustments occur in response to the input provided to the hypothalamus. A7, noradrenergic cell group; DR, dorsal raphe; PAG, periaqueductal gray; PSDC, postsynaptic dorsal column cell; RVM, rostral ventromedial medulla; STT, spinothalamic tract cell.

SPINOthalamic TRACT

STT neurons are the primary relay cells providing nociceptive input from the spinal cord to the thalamus, a major integration site for sensory information. Tactile information from the same body region converges to course through the brainstem as the spinothalamic tract and the medial lemniscus. Although the primary termination site for sensory integration is the thalamus, abundant collateral terminations are provided to integration sites throughout the brainstem. The ventral postero-lateral nucleus of the thalamus is the principal somatosensory relay for information provided to the sensory areas of the cerebral cortex for localization of pain sensation. The medial and intermediate portions of the thalamus project to the anterior cingulate and frontal cortex, respectively, and provide input relevant to the affective responses to pain. Autonomic adjustments occur in response to the input provided to the hypothalamus. A7, noradrenergic cell group; DR, dorsal raphe; PAG, periaqueductal gray; PSDC, postsynaptic dorsal column cell; RVM, rostral ventromedial medulla; STT, spinothalamic tract cell.

Figure 8.8 Pain systems include the spinothalamic tract and the postsynaptic dorsal column pathways. These parallel pain systems ascending from the spinal cord converge to course through the brainstem as the spinothalamic tract and the medial lemniscus. Although the primary termination site for sensory integration is the thalamus, abundant collateral terminations are provided to integration sites throughout the brainstem. The ventral postero-lateral nucleus of the thalamus is the principal somatosensory relay for information provided to the sensory areas of the cerebral cortex for localization of pain sensation. The medial and intermediate portions of the thalamus project to the anterior cingulate and frontal cortex, respectively, and provide input relevant to the affective responses to pain. Autonomic adjustments occur in response to the input provided to the hypothalamus. A7, noradrenergic cell group; DR, dorsal raphe; PAG, periaqueductal gray; PSDC, postsynaptic dorsal column cell; RVM, rostral ventromedial medulla; STT, spinothalamic tract cell.

GluR1 and GluR2/3, and metabotropic mGluR1 and mGluR2/3 associated with terminals in contact with identified STT neurons. NMDA R1 and AMPA GluR2/3 receptors were also localized presynaptically on terminals contacting STT neurons.
medially in the medial and intralaminar thalamus (subparafascicular, centrolateral [CL], and other nuclei of the thalamus). Lamina I STT neurons send their axonal projections in the middle of the lateral funiculus to terminate in the posterior part of the ventral medial nucleus of the thalamus, as well as in the ventral posterior and medial dorsal nuclei. Early electrophysiologic studies reported parallel processing of nociceptive input in the cortex arising from the ventrobasal thalamus to sensory (SI, SII), cingulate, and insular cortices, including input from the VPL and CL, and tooth pulp input from the ventromedial nuclei of the thalamus. Clear visualization of activation in cortical sites is now available with functional magnetic resonance imaging (fMRI) and is reviewed in a later chapter.

**POSTSYNAPTIC DORSAL COLUMN PATHWAY**

The spinal cord dorsal column contains ascending axons of the postsynaptic dorsal column neurons, in addition to the first-order ascending axons of primary afferent neurons relaying touch, pressure, and vibratory sensation. These second-order projection neurons are responsive to noxious visceral input. The cell bodies of many of these cells are located in laminae III and IV but have also been reported in lamina X. The postsynaptic dorsal column cell neurons may respond to noxious visceral stimulation. These cells send a direct projection uncrossed to the dorsal column nuclei in the dorsal medulla. Sacral lamina X neurons have axons traveling near the dorsal column midline septum and, from the thoracic spinal level axons, travel along the intermediate septum of the dorsal column and then travel with the crossed third-order medial lemniscal fibers to the thalamus. Cells in the sacral spinal levels terminate in the gracile nucleus, and cells in the thoracic spinal levels terminate in both the gracile and cuneate nuclei. Postsynaptic dorsal column neurons in lamina X transmit visceral nociceptive information to the thalamus and converge on some of the same thalamic cells receiving nociceptive information from the skin and other somatic structures (see Figs. 8.1 and 8.7).

**SPINORETICULAR PATHWAYS**

Many projection axons from the spinal cord also provide direct and collateral innervation to brainstem regions involved in pain-related activities, including descending modulation of pain, autonomic responsiveness, alerting response, escape response, and limbic and cortical activation. Collectively, these neurons are referred to as the spinoreticular system (see Figs. 8.1 and 8.8). These integrative regions modulate and balance excitatory and inhibitory neuronal influences on nociception through reciprocal higher brain connectivity, which ultimately determines the pain state.

A dorsal spinomedullary pathway arises from cells in lamina I, IV, and X and terminates bilaterally in the subnucleus reticulare dorsalis (SRD) of the dorsal medullary reticular formation, which is located just ventral to the cuneate and solitary nuclei of the dorsal medulla. This nucleus is a brainstem site active in balancing descending inhibition and facilitation of nociceptive processes. The diffuse noxious inhibitory controls (DNICs) inhibiting wide–dynamic range neurons in the spinal cord competing with afferent input are dependent on a supraspinal loop through the SRD and a descending pathway. Projections from this region innervate the contralateral somatosensory, motor, limbic, and insular cortices and the PAG, pons, cerebellum, trigeminal, and other brainstem nuclei. Connections to the anterior cingulate gyrus participate in descending facilitatory modulation of pain.

Major ascending axonal projections relaying information about pain pass laterally through the brainstem but have collateral terminations in the reticular formation of the ventrolateral medulla, the rostral ventromedial medulla (RVM) (nucleus giganto cellularis pars alpha and nucleus raphe magnus [NRM]). The midline raphe nuclei contain serotonergic and nonserotonergic neurons with descending projections to the spinal cord. The direct spinal projection pathway also traverses brainstem regions containing catecholaminergic neurons, including the C1, A1, A2, A5, A6, and A7 regions of both the pons and medulla. The catecholaminergic neurons of the brainstem are involved in diverse functions, including modulation of pain, stress responses, arousal, and learning. The connectivity described between the ventromedial medulla and the catecholamine cells of the pons and the anterior cingulate gyrus, as well as between brainstem catecholaminergic cells and the thalamus, assists in coordination of descending and facilitatory influences on pain perception and affective and stress responses.

Many of the spinal axonal projections terminate in the parabrachial region. Small injections of retrograde tracer into the parabrachial nucleus confirm that this nucleus receives projections primarily from lamina I nociceptive neurons and directly projects to the PAG, amygdala, and ventrobasal thalamus. Involvement in visceral nociceptive processing is reported for the parabrachial nucleus.

Ascending pathways relaying nociceptive information also terminate in the PAG and midline midbrain reticular formation. The PAG and the raphe magnus are major sources of input driving the descending inhibition and facilitation that are known to affect the perception of pain. Direct neuronal projections from the central region of the spinal cord to the midline brainstem nuclei, including the rostral ventromedial nucleus of the medulla and the midbrain PAG and raphe magnus, have been described as well.

Another termination site innervated directly by ascending pathways from the spinal cord and from the dorsal column nuclei is the anterior pretectal nucleus. The anterior pretectal nucleus is thought to be an important source of descending inhibition of nociceptive pathways. Evidence suggests that it sends axons to catecholaminergic neurons of the parabrachial region.

**SPINO-HYPOTHALAMIC, LIMBIC, AND CORTICAL CONNECTIONS**

Pain is often accompanied by motivational-affective responses, including suffering, anxiety, increased attention...
and arousal, increased heart rate and blood pressure, and changes in endocrine and autonomic responses. The neural structures that relay these changes are likely to be parallel to those relaying information localizing the source of the noxious input on the body map. An interesting hypothesis is that the medial and lateral pain pathways provide affective and epicritic (discriminative) pain sensation, respectively. The ventrolateral STT clearly provides information for specific discrimination of pain and temperature, somatotopic localization, and the quality and intensity coding of cutaneous pain. Some of the pathways in unique positions to assume a role in affective pain awareness would include the spinoamygdalar pathway, spinal pathways relaying visceral pain through the postsynaptic medial dorsal column route, and ventromedial projections to midline structures, including the RVM, PAG, hypothalamus, and CL and medial thalamus. Interestingly, some thalamic cells in the CL nucleus are activated only by noxious visceral stimulation. CL and medial thalamic projections to the anterior cingulate and frontal cortices, respectively, have been described. The thalamic connections to the somatosensory (SI, SII) cortices have not been well studied.

Spinohypothalamic and spinoamygdalar pathways have been described that may be involved in autonomic and affective responses to pain. The ascending axonal projections of these pathways arise primarily from spinal cord laminae I and X, as well as from the lateral reticulated region of the spinal cord. Synapses are made in the lateral hypothalamus and the central nucleus of the amygdala. Both these regions are also involved in antinociceptive actions, as well as in autonomic and affective responses to nociceptive input through connections with the medial thalamus and other parts of the limbic system.

The ascending axonal projections of these pathways arise primarily from spinal cord lamina I and from deep spinal laminae (VII, VIII, and X). Spinal projections to the ventrolateral medulla are conveniently located to relay to the paraventricular nucleus of the hypothalamus, amygdala, and medial preoptic region. A direct route to the medial thalamus, amygdala, and spinal-parabrachial-amygdalar pathways is clearly involved. A spinal-reticular-thalamic-cortical pathway was originally proposed as a projection to the forebrain that relays information about painful input, presumably for subjective interpretation based on known anatomic projections of the reticular formation to higher brain centers. Relays to insular cortical structures have also been described.

**DESATING PATHWAYS MODULATING PAIN**

Descending inhibition of spinal nociceptive processes was initially described in behavioral experiments in which electrical stimulation of the PAG resulted in antinociception. The antinociception was proposed, based on behavioral, electrophysiologic, and morphologic studies, to occur through a PAG relay to the RVM and then to the spinal cord (also see reviews). Subsequent findings suggest that the process is mediated through more complicated circuitry (Fig. 8.9). It is now known that both inhibitory and excitatory influences on spinal cord nociceptive processing occur after the activation of recurrent loops through the brainstem by ascending pathways from the spinal cord. Extensive behavioral and electrophysiologic studies have found that bulbospinal facilitatory projections and in particular those descending from the RVM promote tactile and thermal hyperesthesia. The RVM is responsible for the maintenance, although not the initiation, of neuropathic central and visceral

---

**Figure 8.9** Multiple integration sites in the brainstem receive nociceptive input from the ascending pain systems. Complex brainstem circuitry provides both descending inhibitory and excitatory alterations of nociceptive responses at the level of the spinal cord. Cells are situated side by side in the rostral ventromedial medulla (RVM) that impose either excitatory or inhibitory influence. Cells in the RVM are both serotonergic (5-hydroxytryptamine) and nonserotonergic. They provide both a direct descending pathway to the spinal cord and a major input to the dorsolateral pons. The A5 to A7 noradrenergic (NA) cell groups in the dorsolateral pons provide major inhibitory feedback to the spinal cord. The periaqueductal gray (PAG) and the anterior pretectal nuclei provide inhibitory input to the spinal cord through connections with descending pathways from the dorsolateral pons. Specific neurotransmitters within brainstem regions are noted, as are specific receptors having an impact on nociception in the spinal cord dorsal horn. ACh, acetylcholine; E2, estrogen receptor 2; Enk, enkephalin; GABA, y-aminobutyric acid; Glu, glutamate; SRD, subnucleus reticularis dorsalis; SP, substance P; VLM, ventrolateral medulla.
Limbic regions include the anterior cingulate gyrus, the infralimbic and prelimbic cortices medially, the precentral medial cortex, and laterally the anterior and posterior insular cortices and the perirhinal cortex.

A simplified schema of the supraspinal circuitry of the descending control systems imposing facilitatory and inhibitory modulation of nociceptive processing is shown in Figure 8.9. Current evidence has shown that descending modulation from higher centers involves the circuitry of the dorsolateral pons to the medial and intralaminar thalamic nuclei. Nociceptive insults, such as nerve damage or tissue inflammation, increase the tone of both modulatory events and shift the balance toward facilitation. Even though increased activation of pain systems and increased descending facilitation predominate during pain states, descending inhibitory systems continue to dampen the increasing nociceptive activation. Conversely, “stress-induced analgesia” would imply a shift in balance favoring activation of the descending inhibitory pathway. In truth, it is the sum of the effects of this complex polysynaptic circuitry that establishes the level of pain intensity perceived.

**CENTERS FOR HIGHER PROCESSING OF NOCICEPTION**

Specific discriminative input in response to noxious somatic stimulation is received in the VPL nucleus of the thalamus. The midline and intralaminar thalamic CL and parafascicular nuclei receive nondiscriminative visceral nociceptive input. The ventromedial nuclei of the thalamus receive face and tooth pulp input. Early electrophysiologic studies reported parallel processing of nociceptive input from the ventrobasal thalamus to the sensory (SI, SII), cingulate, and insular cortices.

Confirmation in humans of the activation of cortical sites reported in animal studies became available with the advent of positron emission tomography and fMRI. The studies confirmed brain activation in response to painful input in the human thalamus, SI and SII somatosensory cortices, anterior cingulate gyrus, insula, prefrontal cortex, lentiform nucleus, and cerebellum. The improved resolution of fMRI has made it possible to determine changes imposed by pharmacologic agents on the higher processing of pain, as has been shown for a pancreatitis model persisting 1 week in rats (see Fig. 8.8). The VPL thalamus and SI and SII cortices are known to be somatosensory-processing regions, and evidence from imaging studies is consistent with a sensory-discriminative role of these structures. The anterior cingulate cortex is presumably involved in interpretation of the emotional significance of the painful input by the limbic system, whereas the lentiform nucleus and cerebellum may be involved in the learning of reflexive motor responsiveness to painful input that is necessary to protect the individual. The insula, cerebellum, and frontal cortex may contribute to memory and learning of events related to painful stimuli, such as avoidance behavior based on previous experience. A more detailed discussion of the clinical correlation of these topics is available in other chapters.
KEY POINTS

- Nociceptive nerve endings transduce information about internal and external mechanical, thermal, and chemical stimuli that are noxious, distressing, or damaging. Sensory nerves transmit the information centrally.
- Pain is communicated from nerve endings to the spinal cord, relayed across a synapse in the spinal cord, and then transmitted to brainstem integration sites.
- Spinal cord and spinal trigeminal dorsal horn interneurons provide state-dependent signal modification that either amplifies or inhibits the pain signal before relay of the information to brainstem integration sites.
- Central ascending spinothalamic pathways carry discriminatory pain-related information coded for location, intensity, and quality of the noxious input. Axons of lamina I spinothalamic tract neurons cross the midline and ascend in the lateral spinal cord white matter on the opposite side. Spinothalamic tract neurons in deeper laminae send their axons through the ventrolateral spinal white matter on the opposite side and through the ventrolateral brainstem to the primary integrative site for discriminatory sensory information in the ventral posterolateral nucleus of the thalamus.
- Discriminative information about pain is relayed by neurons of the ventral posterolateral thalamus primarily to the primary and secondary somatosensory cortices with connectivity to the motor cortex to plan and execute appropriate escape responses.
- Collateral axons of the ascending spinothalamic tract or direct innervation of other integrative brainstem sites include the lateral medullary and pontine reticular formation, parabrachial nuclei, periaqueductal gray, hypothalamus, and amygdala. Termination sites suggest that the lateral pain-related pathways have an impact on autonomic regulation, limbic activation, and emotional response, along with the spinoamygdaloid pathway.
- Phylogenetically older axonal pathways carrying visceral pain and mechanotactile information from deep tissues arise from neurons in laminae III, VII, VIII, and X. These axons ascend in the dorsal column to innervate the caudal dorsal column nuclei in the midline of the caudal medulla or travel in the ventral white matter midline to innervate the ventral and medial brainstem sites, periaqueductal gray, hypothalamus, amygdala, substantia innominata, nucleus basalis of Meynert, globus pallidus, insular cortex, and medial and intralaminar thalamus. The termination sites suggest that the medial pain-related pathways have an impact on autonomic responses, limbic activation, fear-motivated avoidance, and emotional response, along with the spinoamygdaloid and spinothalamic pathways.
- Descending input to the spinal cord modulates the primary sensory information to either facilitate or inhibit the sensory signal.
- Descending pathways to the spinal cord that modulate pain include axons originating in the pontine locus coeruleus and medullary reticular formation. These centers are influenced by input from higher brain centers, as well as by incoming spinal sensory transmission.

KEY POINTS—cont’d

- Centers for higher processing have complex integrative connectivity among the cortical, limbic, medial thalamic, hypothalamic, and brainstem sites that has an impact on the awareness of pain, motivational responses to pain, and regulation of autonomic, emotional, and motor responses to pain.
- Functional magnetic resonance imaging provides better information about pain processing in higher brain centers.

In the early 1900s, Sir Charles Sherrington designated high-intensity stimuli that signaled a potential injury to the body as being nociceptive in character. The application of such stimuli to the body produces a syndrome that includes withdrawal of the affected body part, signs of autonomic activation, and a complex set of behavioral responses that in intact animals include agitation and vocalization. In humans, an unconditioned high-intensity stimulus evokes discrete sensations that have the assigned attribute of being painful (e.g., the sensation initiated by picking up a very hot cup of coffee). The reported sensation is referred to the site of stimulation, and the magnitude of the report or response varies with the intensity of the stimulus. Termination of the stimulus before injury results in cessation of the sensation. Accordingly, nociception is a descriptor that refers to the physiologic response generated by such high-intensity, potentially tissue-injuring stimuli, whereas pain represents the interpretation of that event as a sensation with highly aversive properties. Such stimuli have powerful motivating effects that can support the generation of escape behavior when cued by innocuous stimuli that have previously been paired with a nociceptive stimulus. Thus, a strong shock evokes the nociceptive state (e.g., hypertension). A light paired with that shock would soon become conditionally associated with the shock such that in a short time, it alone can initiate the same profile of nociception.

Should the stimulus be of sufficient magnitude to result in local injury (tissue disruption, plasma extravasation), a pain sensation will persist after removal of the stimulus, and the injury will be accompanied by increased sensitivity to subsequent stimuli applied to the injury site (primary hyperalgesia) and enhanced sensitivity to stimuli applied at sites adjacent to the injury site (e.g., secondary hyperalgesia). Again, as mentioned, these states of enhanced sensation indicate that the non–tissue-injuring stimulus now acquires an aversive property (e.g., warm water on a sunburn).

As an overview, these effects of a high-intensity, tissue-injuring stimulus reflect an initial activation of the primary afferents that project to the dorsal horn of the spinal cord, from which transmitters are released that activate a complex dorsal horn circuitry. Under normal circumstances these spinal neurons respond maximally to input arising from the root projecting to the spinal segments in which the cell lies. However, even though these afferents primarily activate these homosegmental neurons, they also send collaterals rostrally and caudally up to several spinal segments away, where they make synaptic contact with neurons in adjacent segments (heterosegmental). These distal neurons are less efficiently activated than the homosegmental cells (and may not be activated sufficiently to generate an action potential), but together these homosegmental and heterosegmental cells form the real or potential dimension of the dermatome of that spinal segment. As will be shown later, if the excitability of these higher-order spinal heterosegmental neurons is increased, cells that were not activated by a given input now become depolarized, and the size of the dermatome of a given segment will be increased. These dorsal horn neurons then project by long tracts in the ventrolateral quadrant either (1) directly to diencephalic sites (e.g., thalamus, hypothalamus) or (2) indirectly through an intermediate synapse on neurons in the medulla, pons, or mesencephalon, which then project to a variety of diencephalic and limbic forebrain sites.

The anatomic details of these pathways have previously been discussed (see Chapter 8).

In general, the processes leading to a pain state secondary to a high-intensity peripheral stimulus reflect the frequency of traffic that appears in these spinofugal pathways. Activity in the spinofugal systems is primarily dependent on the intensity of the afferent stimulus, but as will be made evident, a variety of systems serve to increase the gain of the spinal input-output function and to depress this gain. In the first case, we would anticipate that there would be an increased pain sensation associated with any given stimulus, whereas in the second case, the pain sensation produced by a given stimulus would be diminished. This dynamic property of the input-output systems represents an important characteristic of systems that process nociceptive stimuli. In the following sections we wish to consider the transmitter pharmacology that defines these synaptic linkages.

### PRIMARY AFFERENT SIGNALING

#### ACUTE STIMULATION

The systems underlying this acute psychophysical experience begin with the primary sensory neuron, the afferent fiber. It possesses several intrinsic attributes:

1. In the absence of a stimulus, most primary afferents show little if any ongoing activity.
2. Activity in these afferents is initiated by a variety of physical or chemical stimuli, which respectively activate specific populations of primary afferents.
3. The nature of the sensory information encoded by a given primary afferent is dependent on the properties of the transduction channels or receptors that are expressed on the terminals of that sensory axon.
4. The frequency of firing in these afferents generated by a particular stimulus varies in a monotonic fashion with the intensity of the stimulus (e.g., temperature for a thermal-sensitive afferent). Thus, the specific population of primary afferents activated and the frequency of discharge encode the intensity of the message.

5. Sensory afferents are morphologically described as Aβ, which are large, myelinated, fast-conducting axons that are typically activated by low-intensity mechanical stimuli; Aδ, smaller, myelinated, fast-conducting afferents with subpopulations that preferentially respond to thermal or mechanical, low- or high-threshold stimuli; and C, small, unmyelinated, very slowly conducting afferents that are activated by high-intensity thermal or mechanical stimuli (or both). A myelinated afferent axon typically displays specialized terminals that are particularly sensitive to mechanical distortion, which leads to a local increase in sodium current that depolarizes the axon. Unmyelinated afferent axons typically show “free nerve endings”; that is, they display no evident morphologic specialization. However, these terminals express a variety of specific transducer channels that are sensitive to specific stimuli and serve to increasingly depolarize the afferent terminal as stimulus intensity rises. When activated by the appropriate stimulus, these channels in turn activate voltage-sensitive sodium (Na⁺) channels that pass Na⁺ and initiate action potentials. As indicated in Figure 9.1, some of these channels that transduce a physical stimulus may also be activated by a variety of chemicals. In this case, these chemicals produce a sensation that reflects the physical stimulus that is transduced by that channel (e.g., the transient receptor potential vanilloid-1 [TRPV1] receptor is activated by capsaicin, which produces a painful burning sensation, whereas menthol activates the TRPM8 cold receptor and initiates the sensation of a low temperature).

**TISSUE-INJURING STIMULI**

High-intensity stimuli may result in local tissue injury. Such injury will lead to cellular disruption, injury to local vascular integrity and subsequent plasma extravasation, and migration of inflammatory cells such as macrophages and neutrophils. These events give rise to the release of a variety of active factors (Box 9.1). These products act through eponymous receptors that are present on the terminals of many unmyelinated axons. Activation of these receptors serves to initiate two events: (1) depolarization of the terminal leading to discharge of the afferent, with the frequency of activation being dependent on concentration, and (2) activation of intraterminal processes (phosphorylation of local membrane channels), which sensitizes the terminal such that the degree of depolarization for a given stimulus is enhanced. Such effects yield “spontaneous afferent activity” and an enhanced response to a second stimulus applied to the site of injury. These changes in the milieu of the peripheral terminal occur secondary to tissue damage and the accompanying extravasation of plasma as a result of increased permeability of the capillary wall (see Box 9.1). These events are responsible for the “triple response”: reddening at the site of the stimulus (reflecting local arterial dilation), local edema (increased capillary permeability), and a regional reduction in the magnitude of the stimulus required to elicit a pain response (i.e., hyperalgesia).

**Figure 9.1** Transducer channels on a small afferent terminal. Optimal stimulus intensities for activating channels and various chemicals that also activate these channels are indicated. Different terminals express different combinations of channels, which would define the response properties of that afferent. Channel activation leads to activation of voltage-sensitive sodium (Na⁺) channels. The Na⁺,1.8 subtype of channels is frequently present only in unmyelinated axons (C fibers). ASIC, acid-sensing ion channel; TRP, transient receptor potential.

**NERVE INJURY AS A STIMULUS**

Following nerve injury arising from a variety of insults, the organisms will frequently display the development of a variety of highly aversive “spontaneous” sensations over time. These sensations are believed to arise in part from afferent traffic. Sensory axons typically display little spontaneous activity in the absence of a stimulus. This is particularly true for small, high-threshold afferents. However, after a chemical, immune, or mechanical injury to the nerve, afferent axons exhibit (1) an initial burst of afferent firing, (2) electrical silence for an interval of hours to days, and (3) the appearance over hours to days of “spontaneous” bursting activity in both myelinated and unmyelinated axons. This ongoing activity reflects the initial dying back of the injured axon (retrograde chromatolysis) and then initiation of sprouting. Collections of these sprouts form neuromas. Recording from the afferent axon indicates that the ongoing activity originates after an interval of days to weeks from the lesioned site (neuroma) and from the dorsal root ganglion (DRG) of the injured nerve.

Several lines of evidence support the assertion that the ectopic activity in the afferent arising from the neuroma or the DRG of the injured axon is in part, responsible for the observed pain behavior: (1) the onset of ectopic activity in the neuroma or DRG and the onset of pain behavior have parallel time courses, (2) pain behavior can be blocked by the application of tetrodotoxin (TTX) or local anesthetic to the neuroma or DRG, (3) dorsal rhizotomy will transiently reverse the pain behavior, and (4) irritants applied to DRG will initiate activity and yield pain behavior. A number of changes occur that can lead to prominent alterations in ongoing afferent activity.

**ALTERED CHANNEL EXPRESSION**

A variety of channels in the sensory afferent can modulate excitability. Two major classes are the sodium channel, which carries the primary current for axonal depolarization, and a number of potassium channels. Activation of such potassium channels can reduce axon excitability. Clearly, upregulation of sodium channels or downregulation of potassium channels would have the net effect of increasing axon excitability.
**Sodium Channels**

A large increase in the expression of sodium channels in neuromas and DRGs occurs after nerve injury. Several sodium channel variants exist in primary afferent neurons, including subtypes designated as Na\(_{v}1.6\), Na\(_{v}1.7\), Na\(_{v}1.8\), and Na\(_{v}1.9\). Those designated as being resistant to the sodium channel blocker TTX, Na\(_{v}1.8\) and Na\(_{v}1.9\), are found primarily in small DRG cells (C fibers). These channels mediate slowly activating and slowly inactivating sodium currents. The importance of some of these variants in nerve injury pain states is suggested by knock-down studies wherein reduction of, for example, Na\(_{v}1.8\) has no effect on baseline pain thresholds but reverses nerve injury–evoked pain states in animal models. In humans and animal models, systemic lidocaine at plasma concentrations that block ectopic activity has the ability to attenuate the hyperpathic state observed after nerve injury, thus confirming the importance of sodium channels in the post–nerve injury pain state. In humans, mutations in one sodium channel (Na\(_{v}1.7\)) can cause extremely painful conditions. Conversely loss-of-function mutations lead to a prominent insensitivity to pain generated by tissue-injuring stimuli. Conversely, other mutations can result in a “gain of function,” and this is correlated with syndromes such as erythromelalgia, which is characterized by severe episodic pain.

**Box 9.1 Agents Released by Tissue Injury That Depolarize and Sensitize Small Primary Afferent Terminals**

The mediators listed below are released by injury from macrophages, mast cells, and blood vessels. These mediators evoke spontaneous activity in otherwise silent C fibers and lower the threshold for activation in response to a ramped thermal stimulus (right: 1 vs. 2).

1. **Amines.** Histamine (mast cells, basophils, and platelets) and serotonin (mast cells and platelets) are released by a variety of stimuli, including mechanical trauma, heat, radiation, and certain products of tissue damage.
2. **Kinin.** Bradykinin is synthesized by a cascade triggered via activation of factor XII by agents such as kallikrein and trypsin and by physical trauma. It acts through specific bradykinin receptors (B1/B2).
3. **Lipidic acids.** Tissue injury activates a variety of widely distributed phospholipases that free arachidonic acid (AA). AA is a substrate for a large family of enzymes, such as cyclooxygenase, to synthesize lipid mediators, including prostaglandin E\(_2\), prostacyclin, and thromboxane A\(_2\), all of which can facilitate the excitability of C fibers through specific membrane receptors (EP-\(_{1}\)/IPR, Tx-R, Tx-R, respectively).
4. **Cytokines.** Cytokines such as tumor necrosis factor-\(\alpha\) and interleukins such as IL-1\(\beta\) are released by inflammatory cells (macrophages) and sensitize C fibers through eponymous binding sites.
5. **Proteinases.** Thrombin or trypsin is released from inflammatory cells and activates specific receptors (proteinase-activated receptors).
6. **Neurotrophic factors.** Nerve growth factor (NGF) will activate primary afferent terminals by binding to TrkA tyrosine kinase. NGF is released from fibroblasts and mast cells by injury and inflammation.
7. \([H]/[K]\). Elevated H\(^+\) (low pH) and high K\(^+\) are found in injured tissue. A variety of channels present on C fibers (e.g., transient receptor potential vanilloid-1 [TRPV1]/acid-sensing ion channels [ASICs]) are activated by H\(^+\). Acid pH potentiates terminal activation by noxious heat and other chemical mediators.
8. **Primary afferent peptides.** Calcitonin gene–related peptide and substance P are found in and released from the peripheral terminals of C fibers. These peptides produce vasodilation, plasma extravasation, and degranulation of mast cells through their respective receptors. This leads to local reddening and swelling in skin innervated by the stimulated sensory nerve.

**Potassium Channels**

Following nerve injury, potassium currents have been shown to be reduced, thus suggesting downregulation of these channels. Potassium channel blockers increase ectopic firing after peripheral nerve injury.

**CHANGES IN THE CHEMICAL SENSITIVITY OF NEUROMAS AND DORSAL ROOT GANGLIA**

Sprouted terminals of an injured axon display sensitivity to a number of humoral factors, including prostanoids, catecholamines, and cytokines such as tumor necrosis factor (TNF). Several examples of how this sensitivity is related to the appearance of ongoing activity will be noted.

**Cytokines**

After nerve injury, release of a variety of cytokines, particularly TNF, is noted from various local inflammatory cells. These cytokines directly activate the nerve and neuroma through eponymous receptors that become expressed in the membrane after the nerve injury. The mechanisms of the TNF interaction are multiple and complicated. Acutely, TNF decreases potassium conductance in neurons, whereas longer-term effects may be initiated through activation of a variety of kinases (mitogen-activated protein kinases
[MAPKs]). Behaviorally, application of TNF to the nerve results in hyperalgesia, and systemic delivery of TNF-binding protein reduces free TNF and decreases pain behavior in animals with neuropathic pain.

**Catecholamines**

Following nerve injury, postganglionic *sympathetic efferents* sprout into the injury site. In response to the release of nerve growth factors from local Schwann cells and inflammatory cells, these postganglionic terminals locally release catecholamines. Physiologic studies have shown that following nerve injury, stimulation of postganglionic axons will excite the injured axon and the DRG of the injured axon and that such activation is blocked by α-adrenergic antagonism. After nerve injury, upregulation of the expression of α<sub>2</sub>-adrenergic receptors has been demonstrated. Accordingly, increased catecholamine concentrations in the vicinity of the DRG or the injured neuroma can translate into enhanced activity.

**Prostaglandin Receptors**

Prostanoids are released by inflammatory cells secondary to tissue injury. They can enhance the opening of TTX-insensitive sodium channels by acting through eponymous receptors on the afferent terminal. TTX-insensitive channels are typically found on small unmyelinated axons, which emphasizes the association of these observations with axons carrying information having "nociceptive" content. These events are believed to contribute to the development of "spontaneous" afferent traffic after peripheral nerve injury.

**THE FIRST-ORDER SYMPHON**

Primary afferents enter the spinal dorsal horn. As reviewed elsewhere, large afferents (Aβ) terminate deep to Rexed lamina III of the dorsal horn. Aδ afferent fibers terminate both superficially and in deeper laminae, whereas C fibers generally terminate superficially in laminae I and II (marginal layer and substantia gelatinosa).

**PRIMARY AFFERENT TRANSMITTERS**

It has classically been appreciated that primary afferent input results in a postsynaptic excitatory event, thus emphasizing that primary afferent transmitters are uniformly excitatory. As a general statement, it appears that the principal primary afferent neurotransmitter evoking acute excitation is glutamate. It is contained in the synaptic vesicles of most spinal afferent terminals, and its synthetic enzymes have been identified in virtually every primary afferent DRG cell body, regardless of size or state of myelination. These acute effects are mediated by the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamate ionophore present on the second-order neuron. This receptor produces a robust, but short-lasting depolarization of the postsynaptic membrane by increasing sodium conductance (Table 9.1).

AMPA, DL-α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; CGRP, calcitonin gene–related peptide; EAA, excitatory amino acid; NK1, neurokinin 1; NMDA, N-methyl-D-aspartate; rec., receptor; VSCC, voltage-sensitive calcium channel.
In addition to glutamate, populations of primary afferents may contain and release a number of neuropeptides, notably substance P (SP) and calcitonin gene–related peptide (CGRP), and even certain growth factors such as brain-derived neurotrophic factor. Given the complexity of the coding, it is likely that nociceptive information is processed by a variety of transmitters. The transmitters in these small high-threshold afferents display several general properties:

1. Consistent with their location in small afferent terminals, high levels of peptides are present in laminae I and II, and these levels are reduced by rhizotomy or ganglionectomy or by treatment with the small afferent neurotoxin capsaicin. The sensitivity of these afferent to capsaicin indicates that one important characteristic of many (but not all C fibers) is expression of the TRPV1 (capsaicin) receptor. A second population of C fibers that do not express TRPV1 typically express a second marker (isolecitin B4 [IB4]). These IB4-positive afferents characteristically project to the deeper layers of the dorsal horn and do not express neuropeptides.

2. Glutamate and many peptides are co-contained and co-released (e.g., glutamate, SP, and CGRP in the same C-fiber terminal).

3. Release is dependent on the opening of voltage-sensitive calcium channels, and the magnitude of release is proportional to stimulus frequency.

4. Iontophoretic application of glutamate and the peptides found in primary afferents onto the dorsal horn will produce postsynaptic excitation. Amino acids produce a rapid, short-lasting depolarization, whereas the peptides produce a delayed and long-lasting discharge (see Table 9.1).

**REGULATION OF DORSAL HORN EXCITABILITY**

As noted in the introduction, the intensity of the painful stimulus is encoded in the projection to higher centers by the frequency of the output function. Accordingly, factors that enhance the excitability of spinal afferent terminals (leading to increased release of transmitter) or the excitability of the dorsal horn projection neuron will increase the apparent magnitude of a given stimulus, whereas factors that diminish the excitability of the primary afferent or the projection neuron will lead to a reduction in the apparent stimulus intensity. In the following section we will consider substrates that respectively enhance and diminish the response of the dorsal horn to a given stimulus.

**FACILITATION OF DORSAL HORN EXCITABILITY**

Persistent small (C fiber), but not large (A fiber) afferent activation of lamina I (marginal cell) and lamina V (wide dynamic range [WDR]), as occurs with tissue injury and inflammation, has been shown to (1) enhance the response to subsequent dorsal horn input and (2) increase the receptive field of the activated neurons. Thus, the conditioning afferent input increases the receptive field size of the neurons such that afferent input from dermatomal areas that previously did not activate the given neuron now evokes a prominent response. Moreover, low-threshold tactile stimulation also becomes increasingly effective in driving these neurons. This phenomenon, first described by Lorne Mendell and Patrick Wall in the mid-1960s, is broadly referred to as “wind-up.” These physiologic effects reflect events that are referred to as central or, more specifically, spinal sensitization and are believed to underlie the psychophysical correlates of tissue injury wherein tissue injury leads to hyperalgesia and secondary hyperpathia (e.g., increased sensitivity to stimuli applied outside the area of injury). The relevance of this small-afferent-evoked facilitation in humans has been emphasized by psychophysical studies in human subjects. Here, local activation of C fibers by the intradermal injection of capsaicin leads to an initial pain report followed for an extended period by a surrounding region showing enhanced mechanical and thermal sensitivity. This effect is blocked by a transient local anesthetic block of the nerves innervating the capsaicin-injected area. These observations emphasize that ongoing small-afferent input can initiate central sensitization of pain processing.

Based on the above commentary, a decrease in C-fiber-evoked excitation in the dorsal horn produced by a reduction in the release of small-afferent transmitter or block of the postsynaptic receptor (e.g., AMPA for glutamate) will diminish the magnitude of the afferent drive and, accordingly, diminish the facilitated processing evoked by protracted small-afferent input. The facilitated state, however, reflects more than the repetitive activation of a simple excitatory system.

**GLUTAMATE RECEPTORS AND SPINAL FACILITATION**

The first real demonstration of the unique pharmacology of the facilitated state was achieved by showing that spinal wind-up was prevented by the spinal delivery of antagonists of the N-methyl-D-aspartate (NMDA) receptor, a glutamate ionophore composed of a number of subunits that is potently excitatory. When activated, it passes large amounts of Ca2+ and Na+ current. An important observation is that NMDA antagonists have no effect on acute evoked activity but reduce the wind-up induced by repetitive C-fiber stimulation. Correspondingly, behavioral studies have revealed that such drugs have no effect on behavior evoked by an acute noxious stimulus (e.g., acute thermal escape) but do reduce the hyperalgesia observed after tissue injury and inflammation.

The absence of an effect of NMDA antagonism on acute afferent-evoked activation or the pain state reflects an important property of this receptor. At resting membrane potential the NMDA receptor displays a block of the channel by Mg2+. Occupancy of the NMDA receptor by glutamate will not activate the ionophore in the presence of Mg2+. With ongoing depolarization of the membrane (as produced during repetitive stimulation) secondary to the activation of AMPA and SP receptors, the Mg2+ block is removed. If several allosteric binding sites on the NMDA ionophore are occupied (glycine/polyamine sites), glutamate may now activate the NMDA channel and permit passage of Ca2+ and Na+ current. This opening thus serves to further depolarize the membrane and, importantly, to increase intracellular Ca2+, which serves to initiate downstream components of the excitatory and facilitatory cascade (see below).

It has become increasingly apparent that although AMPA mediates an acute depolarization reflecting an increase in Na+ influx, in the presence of repetitive stimulation, Ca2+ permeability develops in the AMPA channels (e.g., calcium-permeable AMPA channels with a distinct antagonist pharmacology).

**Downstream Cascades**

Primary afferent C fibers release peptides (e.g., SP, CGRP), purines (adenosine triphosphate [ATP]), and excitatory
amino acid (glutamate) products. These peptides and excitatory amino acids induce excitation in second-order neurons. As noted for glutamate, direct monosynaptic excitation is mediated by AMPA receptors (i.e., acute primary afferent excitation of WDR neurons is not mediated by the NMDA or neurokinin 1 [NK1] receptor). This initial activation leads to enablement of the NMDA ionophore (and the generation of Ca\(^{2+}\)-permeable AMPA channels), which in turn initiates a number of complex cascades that reflect processes that serve to "sensitize" the postsynaptic dorsal horn neuron. Several primary examples of such facilitatory cascades initiated by repetitive small-afferent input are presented in the following text.

### Local Neuronal Circuits

**NMDA Receptors.** The best example of a cascade initiated by small-afferent input is activation of the NMDA receptor. As noted above, with ongoing membrane depolarization, the NMDA ionophore loses its Mg\(^{2+}\) block, which allows the large increase in intracellular Ca\(^{2+}\).

**AMPA Receptors.** Although the AMPA receptor is largely considered to be an acutely activated ionophore that allows the primary passage of sodium, there are structural variants on the AMPA receptor that allow it to pass calcium. These “calcium-permeable” AMPA receptors are believed to participate along with the NMDA receptor in various aspects of spinal facilitation.

**Neurokinin 1 Receptors.** NK1 receptors are G protein–coupled receptors that are activated by the SP released from small primary afferents. Activation of this receptor leads to prolonged depolarization and mobilization of intracellular calcium. Spinal delivery of agents that block the NK1 site for SP can diminish wind-up and significantly reduce the second-phase response to intradermal formalin injection.

### Prostaglandin Cascade

The increase in intracellular calcium serves to promote the transmigration of a variety of phospholipases to the membrane, where they then serve to cleave arachidonic acid. Arachidonic acid serves as a substrate for cyclooxygenase (COX) to produce a number of prostanoids. All these enzymes have been found to be constitutively expressed in spinal neurons and non-neuronal cells. This cascade leads to the release of a number of prostaglandins that act on a number of eponymous receptors that are located presynaptically on the primary afferent terminal and postsynaptically on second-order neurons. The presynaptic effect has been shown to enhance the opening of voltage-sensitive calcium channels, which serves to mediate vesicular mobilization and release of transmitter. A postsynaptic action that attenuates the activation of inhibitory glycine receptors has been demonstrated. This leads to loss of the regulatory inhibition that otherwise limits postsynaptic activation. In turn, this results in an enhanced response of the second-order (projection) neuron to a given afferent input (Fig. 9.2).

---

**Figure 9.2** Small-afferent input activates second-order neurons and thereby leads to increased intracellular calcium, which initiates several intracellular cascades. (1) Activation of phospholipase A\(_2\) (PLA\(_2\)) increases free arachidonic acid (AA). This serves as a substrate for cyclooxygenase (COX-1 and COX-2), which leads to the release of a number of prostaglandins (PG) that act on a variety of eponymous prostanoid receptors that are located presynaptically on the primary afferent terminal and postsynaptically on the higher-order neurons. See text for further comment. (2) Activation of nitric oxide synthase (NOS) in the presence of arginine leads to release of nitric oxide (NO), which diffuses to enhance the release of transmitter (e.g., glutamate). These events can serve to increase terminal release and increase postsynaptic excitability. cGMP, cyclic guanine monophosphate; Gly, glycine; NMDA, N-methyl-D-aspartate; p38 MAPK, p38 mitogen-activated protein kinase; rec., receptor; VSCC, voltage-sensitive calcium channel.
Nitric Oxide Synthase. Small-afferent input also leads to the activation of nitric oxide synthase (NOS). Both neuronal NOS and inducible NOS are present in neurons and other cells. In the presence of arginine, nitric oxide forms and diffuses to act presynaptically (retrograde transmission) through cyclic guanosine monophosphate to enhance release of transmitter (e.g., glutamate). These events can serve to increase terminal release and increase postsynaptic excitation (see Fig. 9.2).

Phosphorylation. As reviewed, small-afferent input serves to increase intracellular Ca\(^{2+}\) in second-order neurons. This leads to the activation of a number of protein kinases such as PKC and PKA or MAPK (Fig. 9.3). There are many isoforms of these kinases. All serve to phosphorylate consensus sites on various proteins. PKC has been shown to phosphorylate amino acids sites on NMDA and AMPA receptors. This phosphorylation tends to lower the threshold for activation, which leads to greater membrane permeability. In the case of the NMDA ionophore, it serves to lower the threshold for removal of the Mg\(^{2+}\) block that otherwise prevents channel activation. p38 MAPK, when activated, phosphorylates phospholipase A\(_2\), thereby leading to its activation (see Fig. 9.2), and it activates various transcription factors, such as the nuclear factor NF-kB, which serves to increase the synthesis of various proteins, such as COX, and a variety of channels (Na\(_v\), Ca\(_v\)), receptors (TRPV1), and transcription factors (activation transcription factor 3 [ATF-3]).

Bulbospinal Pathways. Of particular interest has been the growing appreciation that small-afferent input can initiate facilitated activation through spinobulbospinal linkages (Fig. 9.4). Thus, it has been shown that C fibers make synaptic contact with superficial dorsal horn neurons (lamina I neurons). These neurons project into the brainstem and make synaptic contact with medullary midline raphe spinal neurons that are serotnergic. These cells in turn project into the spinal dorsal horn and make synaptic contact with a number of neuronal populations but, importantly, those with cell bodies in the deep dorsal horn (lamina V). The serotnergic projections act through excitatory 5-HT\(_3\) receptors to enhance the firing of these lamina V neurons. As stated, these cells are noted for their ability to display a facilitated state called “wind-up.” Block of this bulbospinal linkage or the use of 5-HT\(_3\) inhibitors has been reported to reduce this facilitated state.

Non-neuronal Cells

The central nervous system has a wide variety of non-neuronal cells. Among these are astrocytes and microglia. These astrocytes, microglia, and neurons form a complex network in which each can influence the excitability of the others (Fig. 9.5).

Transmitter Mediators of Non-neuronal Cell Activation.

Primary afferents and intrinsic neuron transmitters (glutamate, ATP, SP) can overflow from the synaptic cleft to these adjacent non-neuronal cells and lead to their activation. Activation of neurons can result in the release of chemokines such as fractalkine. Astrocytes may communicate with microglia by the release of a number of products, including glutamate/cytokines and “S-100” protein. These products have eponymous receptors, which can lead to changes in the biology of astrocytes and microglia and result in the extracellular movement of a variety of neuroactive products, such as free radicals, cytokines (interleukin-1β [IL-1β] and TNF), and a host of lipid mediators, including arachidonic acid, platelet-activating factor, prostaglandins, and leukotrienes. Astrocytes have the well-known ability to regulate extracellular glutamate through an active uptake system. Conversely, during certain activation or stress, these intracellular glutamate stores can be released and result in significant increases in the extracellular glutamate concentration.

Gap Junctions. Astrocytes may communicate over a distance by the spread of excitation through local nonsynaptic contacts referred to as “gap” junctions. These junctions represent specialized proteins (hexagonal multimers made up of connexin macromolecules) that serve to link the adjacent membranes of two cells. Through such linkages, local excitation in one astrocyte can lead to increased Ca\(^{2+}\) reversal.
of a glutamate transporter and increased extracellular ATP, which can depolarize local neuronal processes and produce local cerebrovascular constriction. Though classically limited to astrocytes, it is currently evident that such linkages may also occur between astrocytes and neurons and microglia. The gap junction thus represents a mechanism whereby a syncytium of excitability can be created.

Circulating Factors. Finally, after tissue injury and inflammation, circulating cytokines (such as IL-1β/TNF-α) can activate perivascular astrocytes and microglia. As noted, microglia are in fact brain-resident macrophages. Such mechanisms provide an important linkage for the somatic sensations associated with systemic infection (e.g., such as in the course of a common cold or the “flu”).

The relevance of the non-neuronal cell population to the facilitation process in pain processing after peripheral injury is supported by a variety of observations. First, peripheral injury and inflammation will lead to the acute and chronic activation of microglia and astrocytes. Thus, p38 MAPK-β is present in microglia and shows activation in minutes after a peripherally injuring stimulus. Over longer periods, other markers of microglia (OX42) and astrocytes (glial fibrillary acidic protein [GFAP]) show a significant increase in expression. Drugs such as minocycline (a second-generation tetracycline) and pentoxifylline have been reported to

---

**Figure 9.4** Small-afferent-evoked activation of lamina I neurons that project into the medullary raphe nuclei and serve to excite bulbospinal serotonin (5-hydroxytryptamine [5-HT]) pathways that activate excitatory 5-HT3 receptors on lamina V neurons. This projection serves to facilitate the firing of these lamina V projection neurons and may underlie the phenomenon of “wind-up.” rec., receptor; WDR, wide dynamic range.

**Figure 9.5** Schematic showing the complex assemblage in the dorsal horn with respect to astrocytes, microglia, and neurons. Products released from neurons can activate the release of a variety of active products from astrocytes and microglia. Astrocytes can activate other astrocytes through gap junctions, as well as activate microglia, and can induce the excitability of neurons by releasing a variety of active factors. As indicated, postsynaptic neuronal activation can lead to the release of chemokines such as fractalkine, which can act on eponymous receptors on microglia. See text for further details. ATP, adenosine triphosphate; Glu, glutamate; NO, nitric oxide; SP, substance P; TLR, toll-like receptor.
block microglial activation and diminish hyperalgesic states. Similar metabolic inhibitors that block astrocyte activation (fluorocitrate) can likewise diminish hyperalgesia after nerve and tissue injury. These agents, though not clinically implemented, suggest important directions in drug therapy development.

**Innate Immune Systems.** It has become increasingly appreciated that components of the innate immune response systems may also play a role in the development of ongoing pain after injury. One component is the toll-like receptors (TLRs). The TLRs recognize molecules derived from damage and infectious products and are expressed in cells involved in immune function (e.g., macrophages, neutrophils). They are also found in spinal cord neurons, glial cells, and DRGs. Several TLRs have been implicated in pain processing through the use of mutant mice. These receptors signal via a complex series of downstream cascades that can lead to signaling mediated by a wide variety of cytokines. As an example, in DRG neurons, consistent with expression of TLR message, TLR4 agonists increase intracellular calcium and thereby lead to release of neurotransmitters. Importantly, it has been increasingly appreciated that many ligands, such as tenascin C, which can activate various TLRs, are generated in neuraxial tissue after peripheral injury and inflammation.

**IMPORTANCE OF FACILITATORY SYSTEMS TO INJURY-EVOKED PAIN**

The preceding section reviewed a number of systems that serve to increase the gain of the spinal transmission system. This facilitation serves two interrelated functions. First, it explains in part the mechanisms whereby a peripheral injury that leads to repetitive small-afferent input can result in a potent hyperalgesic state (i.e., the response to any subsequent afferent stimulus is enhanced). Second, as was noted, following local injury there is frequently the development of enlarged receptive fields that extend beyond the territory of original injury. As discussed earlier, the dermatome for any given root is represented in part by spinal collaterals of afferents that project to neurons in adjacent segments. When these cells undergo facilitation, the input from distal dermatomes becomes sufficient to drive activity in these cells. Accordingly, the receptive field of that cell now incorporates this distal body surface. Given this perspective, it is not surprising that agents targeted at these facilitatory mechanisms can have profound effects on injury-induced pain states. Agents such as COX inhibitors are an important example for emphasizing the role of the facilitated state in the pain experience. COX inhibitors act to diminish hyperesthesia secondary to tissue injury. This reaction reflects the important role of prostaglandins released not only in the periphery but also in the spinal cord, where they can act to facilitate the release of C-fiber transmitters such as SP. Current evidence suggests that both COX-1 and COX-2 are important constitutive enzymes in the spinal systems. However, spinal COX-2 inhibitors appear to be particularly important in regulating injury-induced spinal facilitation. Nonetheless, work also points to other facilitatory mechanisms that may likewise be useful targets in the development of future agents. The potency of NOS inhibitors on behavior suggests the importance of spinal release of nitric oxide in facilitatory processes leading to hyperalgesia. Agents that inhibit microglial and astrocyte activation can also diminish hyperalgesic states. These agents, though not clinically useful or defined as safe after spinal delivery, suggest important directions in drug therapy development.

As a final caveat to this discussion of neuraxial facilitation, it is important to note that central facilitation studies examining the effects of repetitive C-fiber stimulation on dorsal horn neurons (described earlier) are carried out in animals that are under 1 MAC (minimum alveolar concentration) anesthesia (typically isoflurane or halothane). It has indeed been demonstrated that behavioral models of facilitation wherein the injury is induced under the effect of a systemic anesthetic (barbiturate, volatile agent, etc.) show that the hyperalgesic state may be initiated despite the fact that the injury is produced under anesthesia. The relevance of this observation to the performance of surgery on patients “anesthetized” with volatile anesthetics or with barbiturates alone is clear. Though preventing the ascending pain message, these anesthetics surprisingly do not appear to block the facilitatory processes that are initiated by small-afferent input, probably at the level of transmitter release at the first spinal synapse. This lack of effect of anesthetic on primary afferent release is believed to represent the basis of the consideration for the concept of “preemptive analgesics” via such therapeutic approaches as regional anesthesia.

**PHARMACOLOGY OF SPINAL INHIBITION**

Second-order dorsal horn neurons (WDR neurons) receive excitatory input from large afferents, as well as from excitatory interneurons. This input is typically mediated by glutamate. The output from the spinal dorsal horn evoked by such excitation is subject to upregulation of excitability, but it has long been appreciated that these cells are also subject to mechanisms that downregulate local excitability. In the following sections we will consider the pharmacology of such processes.

**LOCAL INHIBITORY CIRCUITS**

This section considers systems that are local to the dorsal horn and regulate local excitability.

**INHIBITORY AMINO ACIDS**

Based on the effects of various inhibitory amino acid antagonists, it appears that the excitatory effect of primary afferents, both small and large but particularly large (Aβ) ones, are subject to potent inhibition that is expressed by inhibitory γ-aminobutyric acid (GABA) and glycine receptors, which are both presynaptic on the primary afferent and postsynaptic on the second-order neuron. This relationship is indicated in Figure 9.6. Release of GABA and glycine from local interneurons will act on GABA<sub>A</sub> and glycine receptors and glycine receptors, respectively. The GABA<sub>A</sub> receptor and glycine receptors are ionophores that when activated, serve to increase Cl⁻ conductance. Based on resting transmembrane Cl⁻ gradients, such an increase in permeability leads to modest membrane hyperpolarization and an increase in shunting current. These effects reduce the ability of an excitatory
GABAB receptors are G protein-coupled receptors that are also inhibitory. The relevance of this ongoing inhibitory organization to ongoing sensation is substantiated by the fact that local application of GABA_A (bicuculline) or glycine (strychnine) receptor inhibitors will lead to powerful augmentation of the discharge of dorsal horn neurons evoked by large (Aβ)-afferent input.

**OPIOIDS**

The potent analgesic effect of opiates reveals the efficient role played by opiate receptors in regulating pain transmission. Systematic study has shown that opiate receptors that regulate the pain response are located both at the spinal level and in several brain loci.

**Spinal Opiate Action**

Intrathecal delivery of opiate agonists will potently inhibit the injury-evoked discharge of superficial and deep dorsal horn neurons induced by small high-threshold afferents (C fiber). The deep dorsal horn neurons also receive input from low-threshold large (Aβ) afferents, but this evoked component is not typically blocked by opiates. These effects are mediated by an action on opioid receptors (typically characterized as µ-opioid based on agonist and antagonist pharmacology). Localization of these µ receptors has revealed them to be largely on C-fiber primary afferents that terminate in the superficial dorsal horn and on the dendrites and cell bodies of deeper dorsal horn neurons (Fig. 9.7).

Intrathecal administration will reliably attenuate the response of the animal to a variety of unconditioned somatic and visceral stimuli that would otherwise evoke organized escape behavior in all species. Confirmation of the presynaptic action is provided by the observation that opiates reduce the release of primary afferent peptide transmitters, such as the SP contained in small afferents. The presynaptic action corresponds to the ability of opiates to prevent the opening of voltage-sensitive Ca^2+ channels, thereby preventing mobilization and release of transmitter. A postsynaptic action is demonstrated by the ability of opiates to block the excitation of dorsal horn neurons evoked by glutamate, a process reflecting direct activation of the dorsal horn. The activation of potassium channels leading to membrane hyperpolarization is consistent with direct postsynaptic inhibition.

**Supraspinal Opiate Action**

Direct injection of opiates into the brain has shown that opioid receptors that modulate pain behavior are found in several restricted brain regions, including the amygdala and the midline medulla, but the best characterized of these supraspinal sites so identified is the mesencephalic periaqueuductal gray (PAG). Microinjection of opiates into this region will block the nociceptive response in a naloxone-reversible fashion. Several mechanisms exist whereby opiates acting in the PAG may alter nociceptive transmission:

1. **Activation of bulbospinal projection.** In the PAG, opiate receptors are presynaptic on GABAergic terminals that inhibit projection to the medulla. Morphine acts to block the release of GABA, which terminates the inhibitory control over PAG outflow. The PAG has excitatory projections into the medulla, which then activates bulbospinal noradrenergic and serotonergic pathways. The noradrenergic projection acts through spinal α2-receptors to reduce dorsal horn excitation.
2. Opiate binding within the PAG. Such binding may be preterminal on the ascending spinofugal projection. This preterminal action would inhibit input into the medullary core and mesencephalic core.

3. Outflow from the PAG. PAG outflow can increase excitability of the dorsal raphe and locus coeruleus/lateral tegmental nuclei from which ascending serotonergic and noradrenergic projections, respectively, originate and project to limbic forebrain. These projections are thought to modulate emotionality (see later).

These three mechanisms are summarized in Figure 9.8.

**Endogenous Opiates**

Opiate receptors are presumed to be targeted by endogenous compounds released from local interneurons. A number of such functionally qualified families of agents have been identified according to the family of prohormones from which they are derived: proenkephalin (enkephalins), prodynorphins (dynorphins), and proopiomelanocortins (β-endorphin). Other endogenous opioids have also been described, such as the endomorphins. These are all peptides that have been shown to have significant affinity for one or more of the several identified opioid receptors. Enkephalins have been found in dorsal horn interneurons and in bulbospinal pathways. Such interneuronal systems are present throughout the brain. β-Endorphin is present in long projection pathways that largely originate in the hypothalamus. Even though opiate receptors can regulate spinal nociceptive processing, there is surprisingly limited data to suggest that the endogenous systems have a robust effect on pain processing. Naloxone, an opioid antagonist, has modest effects on ongoing pain processing. Enkephalins are rapidly metabolized by a variety of peptidases, and changes in the pain threshold in animal models have been shown to alter pain thresholds in a number of experimental pain states.

**Bulbospinal Projection Systems**

A number of transmitters are known to be contained in and released from bulbospinal projecting pathways; however, those best characterized are the monoamines norepinephrine and serotonin.

**Bulbospinal Norepinephrine**

Norepinephrine projections to the spinal cord arise from lateral medullary sites and the locus coeruleus, whereas norepinephrine projections to the forebrain arise from the locus coeruleus (see Fig. 9.8). The rostral projections are believed to play the primary role in altering the affective components of behavior. The caudal adrenergic projections play a principal role in regulating spinal nociceptive processing through an action on spinal dorsal horn α2-adrenergic receptors that are located presynaptic and postsynaptic to the primary afferent. Spinal delivery of α2-adrenoceptor agonists such as clonidine and dexmedetomidine produces significant analgesia. This spinal action of an α2-agonist is mediated by a mechanism similar to that used by spinal opiates, but the receptor is distinct: (1) α2 binding is presynaptic on C fibers and postsynaptic on dorsal horn neurons, (2) α2-receptors can depress the release of C-fiber transmitters, and (3) α2-agonists can hyperpolarize dorsal horn neurons through a G_{i}-coupled potassium channel.

**Bulbospinal Serotonin**

Serotonin (5-hydroxytryptamine [5-HT]) arises from the nucleus raphe magnus, which projects spinaly, and from the raphe dorsalis, which provides the principal source of forebrain 5-HT. As reviewed earlier, spinoptetal 5-HT projections can have multiple effects, including excitation and
inhibition. These complex effects suggest that under certain conditions, increasing spinal 5-HT tone may facilitate nociceptive processing.

**Altering Terminal Monoamine Concentrations**

Importantly, agents that regulate the extracellular concentrations of these monoamines can have pronounced effects on emotional tone and nociceptive transmission. Because extracellular levels depend not only on release but also on their reuptake, agents that block the reuptake transporter, such as the tricyclic antidepressants, can have analgesic properties. Current evidence suggests that the analgesic actions are largely mediated through an effect on norepinephrine and not serotonin. This difference in their relative contributions to analgesic efficacy may reflect the several opposing effects that are associated with the action of serotonin.

**PHARMACOLOGY OF FACILITATORY STATES THAT OCCUR SECONDARY TO NERVE INJURY**

From the preceding sections it was evident that the events that take place following peripheral tissue injury can lead to potent facilitation of neuraxial processing that results in large part from the persistent small-afferent traffic that occurs with injury and inflammation. These changes reflect events that occur in the injured nerve (as reviewed in a preceding section): alteration of protein expression leading to upregulation of some proteins and downregulation of others. The increased spontaneous activity arising from neuromas and DRGs provides a tentative explanation for the ongoing dysesthesias that are associated with a variety of nerve injury conditions. The prominent finding that low-threshold tactile stimulation acquires an averse component appears to present a more complex set of events. Current thinking is that it is mediated by low-threshold mechanosensitive (Aβ) afferents. The precise mechanism of this involvement of low-threshold afferents in initiation of pain is not known, although several possibilities have been considered credible.

**CROSSTALK BETWEEN LARGE AND SMALL AFFERENTS**

Following nerve injury, “crosstalk” mediated by ephaptic contacts may develop between afferents in DRGs and neuromas. Here, depolarizing currents in one axon would generate a depolarizing voltage in an adjacent quiescent axon. In this manner, a large low-threshold afferent would drive activity in an adjacent high-threshold afferent.

**LARGE-AFFERENT SPROUTING**

As reviewed previously, large myelinated (Aβ) afferents project into the spinal Rexed lamina III and deeper. Small afferents (C fibers) tend to project into spinal laminae I and II, a region populated by neurons responding to this high-threshold input. Following peripheral nerve injury, it has been argued that the central terminals of myelinated afferents (A fibers) sprout into lamina II of the spinal cord. With this synaptic reorganization, stimulation of low-threshold mechanoreceptors (Aβ fibers) could produce excitation of these neurons and be perceived as painful. The degree to which this sprouting occurs is a point of current discussion, and even though it does appear to occur, it is considerably less prominent than originally reported.

**LOSS OF INTRINSIC INHIBITORY CONTROL**

A large number of small interneurons lie in the superficial dorsal horn; these interneurons contain and release GABA and glycine. As reviewed earlier, these terminals are presynaptic to the large central afferent terminal complexes and form reciprocal synapses, and GABAergic axosomatic connections have been identified on second-order and projection neurons (see Fig. 9.6). Accordingly, these transmitters exert powerful inhibitory control over the activity of Aβ primary afferent terminals and second-order neurons in the spinal dorsal horn. As discussed earlier, the importance of this local inhibitory circuitry is indicated by the observation that intrathecal delivery of a GABA_α (bicuculline) receptor or glycine (strychnine) receptor antagonist evokes a powerful tactile allodynia. Such observations led to the hypothesis that nerve injury may induce a loss of GABAergic/glycinergic neurons. Although some data do support a loss of such neurons, this loss appears to be minimal. Recent observations now support a second alternative. After nerve injury, spinal neurons are altered in such a fashion that GABA_α and glycine receptor activation becomes excitatory. As noted previously, these receptors are chloride ionophores. When these ionophores are activated, chloride moves according to its transmembrane gradient. The transmembrane gradient is maintained by transporters that export chloride. After nerve injury the activity of the chloride transporter is reduced, which leads to an increase in intracellular chloride, and increasing membrane Cl⁻ conductance, as occurs with GABA_α receptor activation, now results in membrane depolarization. Thus, paradoxically, afferent input that activates GABA_α/glycine channels may actually serve to facilitate membrane depolarization and lead to a much enhanced response to the Aβ drive.

**ENHANCED EXCITATORY DRIVE**

**GLUTAMATE RELEASE**

Spinal glutamate release plays an important role in post-nerve injury pain states. There is a significant enhancement in resting spinal glutamate secretion after nerve injury. Such release is in accord with (1) increased spontaneous activity in the primary afferent and (2) loss of the intrinsic inhibition that may serve to modulate resting glutamate secretion (see below). The significance of this release is emphasized by several observations: (1) Intrathecally delivered glutamate will evoke a powerful tactile alldynia and thermal hyperalgesia through the activation of spinal NMDA and non-NMDA receptors. (2) Spinal delivery of NMDA antagonists has been shown to attenuate the hyperpathic states arising in animal models of nerve injury. NMDA receptor activation mediates an important facilitation in neuronal excitability. In addition, the NMDA receptor is a calcium ionophore, which when activated, leads to prominent increases in intracellular calcium. The increase in intracellular Ca²⁺ initiates a cascade of events that includes the activation of a variety of
enriches (kinases), some of which phosphorylate membrane proteins (e.g., calcium channels and the NMDA receptors) and others such as the MAPKs serve to mediate intracellular signaling, thereby leading to the altered expression of a variety of proteins and peptides (e.g., COX and dynorphin). A number of factors have been shown to enhance release of glutamate. Two examples will be discussed further.

**Spinal Dynorphin**

Nerve injury leads to a prominent increase in spinal dynorphin expression. Intrathecal delivery of dynorphin can initiate the concurrent release of spinal glutamate and a potent tactile allodynia; NMDA antagonists reverse the latter effect. Even though dynorphin is an endogenous opioid peptide, these effects appear to be independent of any action on an opiate receptor.

**Altered Channel Expression**

As reviewed previously, nerve injury leads to the upregulation of a variety of sodium channels and downregulation of potassium channels. This altered expression is referred to as the *neonatal phenotype*. This assertion belies the enormous changes in channel expression that are associated with nerve injury. As an example, it has been shown that after nerve injury there is a significant increase in expression of the α_2δ_1 subunit. This subunit is found in the structures of several members of the voltage-sensitive calcium channel family. At the spinal level, this binding site is densely present in the substantia gelatinosa of the superficial dorsal horn and in the DRG. The relevance of this increased expression is suggested by the potent anti-allodynic effects associated with the actions of the agent gabapentin. This molecule appears to exert its effects by highly selective binding to the α_2δ_1 subunit. N-type voltage-sensitive calcium channels also show an increase in expression, and spinal delivery of N-type calcium channel blockers such as ziconotide also produces potent anti-allodynic effects.

**NON-NEURONAL CELLS AND NERVE INJURY**

As reviewed in preceding sections, astrocytes and microglia have been shown to play a powerful constitutive role in increasing synaptic excitability through the release of a variety of active factors (see Fig. 9.5). After nerve injury, significant activation of spinal microglia and astrocytes takes place in the spinal segments receiving input from the injured nerves. Work with TLRs suggests that products released centrally by nerve injury can activate these cells through the constitutively expressed TLRs. This activation is manifested by morphologic changes in these cells, as well as by increased expression of cellular markers for microglia (e.g., OX42/αβ2 MAPK) and astrocytes (GFAP). Of particular interest is that in the presence of pathology such as bone cancer, extravagant activation of these non-neuronal cells has been shown. Although the origin of this activation is not clear, increased afferent traffic and release of excitatory transmitters, as well as products that appear to be increased secondary to nerve injury, such as growth factors, appear to be involved. This activation of intracellular transcription factors serves to increase the spinal expression of COX, NOS, glutamate transporters, and proteinases and to downregulate other systems such as the chloride transporters discussed in the preceding section. Such biochemical components have previously been shown to play an important role in the facilitated state. In addition to the role played by glia, there is also the appreciation that after injury, a variety of cell surface markers are expressed in the DRG that promote the migration of macrophages and neutrophils into the DRG. These cells are believed to contribute to the inflammatory milieu.

In summary, the post–tissue injury pain state reflects sensitization of the peripheral terminal in response to the local release of a variety of factors that initiate spontaneous activity and sensitization of the peripheral terminal. There is also a potent central (spinal) sensitization that leads to enhanced responsiveness of dorsal horn neurons that receive ongoing small-afferent traffic. This condition results in an enhanced response to input from the injured receptive field and enlargement of the peripheral fields, which can now activate these neurons through originally ineffective subliminal input. The augmentation reflects not only the local synaptic circuitry (glutamate/SP) but also spinobulbospinal linkages (5-HT) and by-products released from local non-neuronal cells. The afferent activation and sensitization are subject to regulation by a variety of systems, including those that regulate release of transmitter from the primary afferent and activation of the second-order or projection neuron.

Regarding the events that occur after nerve injury, it is evident that there are two principal elements, those that account for the spontaneous pain and those that lead to an alteration in the encoding of normally innocuous low-threshold mechanical stimuli. The spontaneous activity is probably a reflection of the complex events that arise from channel expression and the inflammatory factors that appear after nerve injury and lead to ectopic activity. The alterations related to the facilitated response represent evident changes in dorsal horn function. The net effect appears to be enhanced excitability secondary to the increased expression of excitatory elements and reduced inhibitory contribution. The increased excitation probably arises from a number of sources, including the activation of non-neuronal cells.

Finally, peripheral nerve injury, such as that caused by compression or trauma and chemotherapy, leads to a persistent pain state. In contrast, local tissue injury or inflammation results in hyperpathic states, with the time course paralleling the onset and resolution of the injury state. However, as reported in humans, the pain state originating from prolonged inflammation may persist even when the inflammatory state resolves (loss of neutrophils/macrophages and cytokines). Comparable pain states have been identified in preclinical models. Recognition of this propensity of an acute injury to transition to a persistent or chronic pain condition raises important issues about the convergence of mechanisms that underlie the inflammatory and nerve injury conditions. For example, it is noteworthy that trophic and persistent changes in the DRG have been identified after long intervals (days to weeks) in animal models. In this case, transcription factors (e.g., ATF-3) are activated that show little tendency to reverse even over extended intervals. This suggests the possibility that in populations of patients
and in certain preclinical models, peripheral inflammation may lead to persistent changes in afferent neuraxial coupling. In studies involving TLR mutants, these changes in persistent pain and upregulation of transcription factors have been prevented. Other persistent changes will probably also be identified.

**KEY POINTS—cont’d**

- Though preventing the ascending pain message, anesthetics surprisingly do not appear to block the facilitatory processes that are initiated by small-afferent input, probably at the level of transmitter release at the first spinal synapse.
- Prostaglandins act on a number of eponymous receptors that are located presynaptically on the primary afferent terminal and postsynaptically on second-order neurons.
- Following peripheral nerve injury, ongoing pain appears to represent ectopic activity in the neura and the DRG, a phenomena reflecting upregulation of sodium channels and the expression of receptors activated by changes in the local milieu. The enhanced response to low threshold stimulation may reflect loss of intrinsic GABA and glycnergic inhibition and activation of non-neuronal cells.

**SUGGESTED READINGS**

The comments in this chapter related to the pharmacology of the substrates activated after tissue injury and nerve injury must be considered as a broad overview. More detailed considerations and citations can be found in a several detailed reviews and texts listed above.
Change, alternatively referred to as reorganization or plasticity, is a fundamental property of the brain that enables it to adapt and thus enhance survival of the organism. It has been documented and studied across all the scales of the brain. The smallest unit of neural processing is the individual channel and its related receptor. Its efficacy can be modulated by various mechanisms, for example, changes in the availability or concentration of various chemicals within the intracellular or extracellular environment. Such a change can lead to an increase either in local resting membrane potential or, when it influences the excitability of the neuron, in an increased or decreased rate of firing. A change in either resting membrane potential or individual neuronal firing rate can in turn modulate individual synapse strength, which can be demonstrated experimentally as phenomena called long-term potentiation and long-term depression. Cumulative changes across these microscopic scales would in turn lead to reorganization of whole territories of the cortex, in which one functional specialization may be abandoned and replaced by another. Several review articles highlight the recent excitement in the topic across multiple brain functional systems, from the single synapse to large-scale reorganization. We now know that all of this happens in the human brain, perhaps more subtly in the adult than in the developing brain, and we also know that such events are fundamental for understanding the brain mechanisms of pain. We will revisit each of these mechanisms specifically in the context of pain perception.

Regarding pain, there has been a fundamental shift in our concept of the functional role of the brain. Until about 15 years ago, most basic research on pain involved charting the “telephone lines” and the “code” for these lines. Basically, most work in the field was an attempt to establish pain as a sensory modality with its unique pathways and presentation within the peripheral nervous system (PNS) and central nervous system (CNS). Chapter 8, which discusses the anatomy of pain systems, nicely demonstrates this knowledge and shows the distinct PNS and CNS components that participate in coding pain. This work has been highly successful in showing that unique receptors in the skin are involved in responding to mechanical, thermal, and chemical noxious stimuli. This information is transmitted through specialized myelinated and unmyelinated fibers to the spinal cord, where the nociceptive input converges on specific populations of cells, which in turn transmit the signal cephalad through multiple ascending pathways to give rise to the perception of pain. Descending modulatory pathways converge back on nociceptive neurons in the spinal cord and control their level of excitability based on environmental conditions. This is the “telephone line” view of pain perception, also known as the specificity theory of pain, which some researchers criticized for years as being too limited and simplistic in scope. Its basic underlying assumption is a unidirectional flow of information from the environment to the cortex through specific pathways, disruption of any parts of which would break the telephones lines of communication and relieve the pain. Within this viewpoint there is little space to accommodate some of the most debilitating clinical pain conditions, namely, chronic pain, and in fact even the existence of these conditions was highly controversial for large portions of the past century. There remain hardcore scientists who still adhere to this notion, however, the brunt of scientific evidence generated recently shows that the plasticity of the brain and peripheral nerves is a fundamental component of pain, especially for clinical pain in general and even more specifically for chronic pain. Recent studies have repeatedly uncovered the fact that disruption of any of the PNS or CNS components of the network underlying pain perception results, in most cases, in exacerbation of pain behavior rather than its diminution and that the specific site and extent of injury result in mimicking, at least in part, various clinical pain conditions. Plasticity of the PNS and CNS seems to be a universal consequence of persistent pain, the details of which depend on the type and extent of injury giving rise to the persistent pain. Accordingly, Woolf and Salter concluded, “All living organisms need to be able to react to noxious stimuli, and a major evolutionary drive for the development of a plastic nervous system might have been the acquisition of the capacity to detect and remember pain.” This suggests the possibility that the ability of the brain to change was driven by its need to adapt to coping with pain rather than the other way around.

**ACUTE NOCICEPTION IN CONTRAST TO PERSISTENT PAIN**

Activation of the nociceptive system in the absence of changes in the PNS or CNS is supposed to happen only when short-lasting stimuli (on the scale of a few seconds and not persisting for more than minutes) are applied that can evoke pain but do not cause inflammation or injury. Under such restricted conditions, one expects to observe a primarily neuroelectric response in which, depending on the stimulus, nerve endings of unmyelinated and small myelinated nociceptors are excited and, in turn, activate second-order spinal cord cells that project to multiple supraspinal sites. The best known and best characterized of these is the spinothalamic pathway, which has all the characteristics necessary for coding stimulus properties such as its location, intensity, and modality. The spinothalamic pathway has also been classically attributed with conveying the emotional properties of
noxious stimuli, although recent brain-imaging studies are beginning to question this notion, at least in humans. As soon as noxious stimuli increase in duration or intensity, they are accompanied by inflammation or injury, which in turn results in a long list of PNS and CNS changes.

**DEFINITIONS OF GENERAL PAIN TYPES**

- **Nociceptive pain** refers to normal, acute pain perception evoked by short-lasting noxious stimuli in intact tissue in the absence of peripheral or central sensitization.
- **Inflammatory pain** refers to pain following tissue injury but with no neural injury. Some group this under nociceptive, others under pathophysiologic pain. There is ample evidence of peripheral and central reorganization in such conditions; thus, it cannot be regarded as normal pain.
- **Neuropathic pain** refers to pain after neural injury. It is generally accepted as a pathophysiologic state accompanied by peripheral and central reorganization.

**DEFINITIONS OF ABNORMAL PAIN**

- **Allodynia** is the perception of pain from a stimulus that in a healthy organism is not painful.
- **Hyperalgesia** is an enhanced perception of pain from a stimulus that does evoke pain in a healthy organism but to a lesser extent.
- **Primary sensitization** is an enhanced sensation and related enhanced neuronal transmission within and around the site of injury, which suggests that the effect is a consequence of reorganization of neuronal signaling directly from the injury.
- **Secondary sensitization** is an enhanced sensation and neural transmission at body sites removed from the site of injury. It is usually attributed to changes in neuronal properties in the spinal cord where the end product of various changes leads to increased excitability of neurons involved in transmitting nociceptive input cephalad. The process is assumed to be a result of reorganization of the spinal cord nociceptive circuitry.
- **Supraspinal sensitization** is the term used to distinguish between spinal and supraspinal changes in nociceptive coding. Such processes are assumed to change the cortical elements involved in pain perception. These in turn would modulate the spinal cord processing of afferent nociceptive input through descending modulatory pathways.

**INFLAMMATION AND CHANGES IN RESPONSE IN FREE NERVE ENDINGS**

Free nerve endings terminating in the skin and viscera are the machinery for signaling local mechanical, thermal, and chemical changes as well as for modulating this local environment (Fig. 10.1). Thus, even at the level of the afferent receptor, nociceptive afferents are involved in two-way communication. Moreover, these receptors undergo changes in their response properties that affect the trafficking of chemicals, as well as the sensitivity to local events. Free nerve endings possess a long list of receptors (proteins that span the lipid bilayer membrane that separates the extracellular and intracellular spaces) specialized for detecting the presence of specific chemicals or stimuli (Fig. 10.2) that act as agonists and, by binding to the receptor, either activate intracellular second-messenger events or directly open the channel. To provide inflow of Na+ ions, for example, the VR1 cation channel is activated at around 43°C and is also sensitive to capsaicin and acidity. This process initiates a current, which then generates an action potential that by propagating centrally into the spinal cord may in turn activate second-order neurons that transmit this information farther centrally. Injury or inflammation results in local release of the “inflammatory soup,” which includes peptides (bradykinin), neurotransmitters (serotonin), and neurotrophins (nerve growth factor). These factors interact with
cell surface receptors (see Fig. 10.2) to activate the nociceptor. Besides transmitting the information centrally, this process also initiates neurogenic inflammation by locally releasing various neurotransmitters such as substance P and calcitonin gene–related peptide (CGRP). Release of these substances by terminals on the free endings of nociceptors induces local vasodilation and plasma extravasation, as well as activation of non-neuronal cells such as mast cells and neutrophils, all of which contribute to the inflammatory soup (Fig. 10.5) and further sensitize these peripheral nociceptors by binding to their respective receptors, thus enhancing intracellular processes.11,19

NEUROPATHIC PAIN AND PERIPHERAL CHANGES

Neuropathic pain is distinct from nociceptive and inflammatory pain conditions in that the injury is itself neuronal whereas inflammatory injuries are caused by disease of non-neural tissue. Osteoarthritis is the prime example of a persistent (or chronic) non-neuropathic condition, whereas clinical conditions such as post-herpetic neuralgia (PHN) and diabetic neuropathy are classic examples of neuropathic pain following metabolic disease or infection. When the neuropathic pain is of central origin (e.g., after autoimmune disease, stroke, trauma, or cancer), it has been proposed that it occurs only if the central insult directly involves the nociceptive pathways.20 The opposite does not seem to be true. That is, an injury to the nociceptive system does not imply the necessity of having pain. A partial lesion of a peripheral nerve commonly induces neuropathic pain.21 However, severing of dorsal roots seems to have little chance of creating lasting pain.22 Generally, neuropathic pain conditions are associated with abnormal neuronal activity at the site of the injury, as well as with central sensitization.23 Thus, neuropathic pain is generally viewed as paradoxical because it involves severing portions of the nociceptive system and thereby usually causing various types of sensory deficits, which rather than decreasing pain transmission results in long sustained increased pain because of reorganization of the peripheral and central neural elements participating in pain perception.

When neuropathic pain is a consequence of injury to the PNS, the extent to which it depends on peripheral as opposed to central sensitization continues to be debated, with strong evidence provided for both views. The mechanisms underlying such conditions have been studied extensively, and peripheral and central changes have been well characterized, primarily because of a number of animal models that have been advanced over the past 15 years. In contrast, pain induced by central neural injury remains less well characterized and is best studied following spinal cord injury (SCI).24 Neuropathic as well as inflammatory pain conditions are commonly accompanied by tactile allodynia, heat or cold hyperalgesia, and spontaneous pain. The extent of the contribution of each of these abnormalities to specific clinical conditions varies with the type of clinical

Figure 10.2 A variety of receptors spanning the nociceptive free nerve ending interact intracellularly to either enhance or diminish excitability as a function of the extracellular milieu. If the nociceptor’s environment changes as a result of inflammation or injury, its excitability is altered. The effect of such changes on the vanilloid receptor (VR1) and voltage-gated sodium channels (Nav 1.8 and 1.9) is illustrated. An extracellular increase in the concentration of bradykinin (Bk) and nerve growth factor, acting through its own receptor (TrkA), shifts the excitability of VR1 to heat and acidity through intracellular pathways. Similarly, inflammatory products such as prostaglandin (PG) increase the excitability of sodium channels through intracellular messengers, whereas cannabinoids (CB) or opioids counteract this effect. AC, adenylyl cyclase; AEA, arachidonyl ethanolamide; PGE2, prostaglandin E2; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; TTX, tetrodotoxin. (Adapted from Julius D, Basbaum AI. Molecular mechanisms of nociception. Nature. 2001;413:203-210, with permission.)
condition; for example, PHN is associated with a very high incidence of tactile allodynia, whereas chronic back pain (CBP) is dominated by spontaneous pain. Consistent with this clinical picture, animal models of inflammatory pain that persists for different durations show distinct peripheral and central reorganization. Similarly, different animal models of neuropathic pain, in which the differences sometimes seem trivial (for example, different approaches used to induce partial sciatic nerve injury), also show various differences in reorganization.

In intact healthy organisms, nociceptive input is transmitted through Aβ and C nociceptors. However, there is now very good evidence that following central sensitization caused by inflammation or neuropathic injury, peripheral input to the CNS through non-nociceptive, thickly myelinated Aβ touch afferents may evoke pain.25,26 The latter is clear evidence that the functional roles of afferent fibers can be disturbed, again providing evidence that notions regarding specificity of the pain pathway are tenuous.

Nerve injury provides a new source of afferent activity as a result of ectopic discharges from the injured axons, in contrast to normal tissue, in which electrogenesis is limited to excitation of free nerve endings through transduction of noxious stimuli.27 When an axon is severed, its proximal stump seals off and forms a terminal swelling, or end-bulb. In adults, axotomized cells survive and begin to regenerate from the proximal cut end. Many of these cells grow back and reinnervate peripheral target tissue. When growth is blocked, as commonly occurs with most injury conditions, the terminal end-bulbs persist, turn back on themselves, and form a tangled mass termed a neuroma. There is good evidence that neuromas generate spontaneous ectopic activity

---

**Figure 10.3** The inflammatory response at the skin is more complex than presented in text. This figure illustrates the main components that influence local inflammatory responses in the skin. The skin is regarded as a neuroimmunoendocrine organ and is associated with the peripheral nervous system, central nervous system, and autonomic nervous system. Stressors activate the hypothalamus/hypophysis in the central nervous system, thereby releasing neuromediators such as adrenocorticotropic hormone (ACTH), as well as macrophage migration inhibitory factor (MIF) and pituitary adenylate cyclase-activating polypeptide (PACAP). They may either stimulate the release of norepinephrine and cortisol from the adrenal glands or directly stimulate leukocytes in the blood via corticotropin-releasing hormone, melanocortin, or pituitary adenylate cyclase receptors and thereby modulate the immune responses during inflammation. Norepinephrine and cortisol affect several immune cells, including lymphocytes, granulocytes, and macrophages. Immune cells release cytokines, chemokines, and neuropeptides that modulate inflammatory responses in the skin. On stimulation, sensory nerves release neuromediators that modulate cutaneous inflammation and pain. Skin inflammation affects the activation of immune cells via cytokines, chemokines, prostaglandins, leukotrienes, nitric oxide, and melanocyte-stimulating hormone, which may have a proinflammatory effect (e.g., substance P) or an anti-inflammatory effect (e.g., calcitonin gene-related peptide), as well as PACAP by upregulating or downregulating inflammatory mediators such as cytokines. Autonomic nerves in the skin, mainly sympathetic cholinergic and rarely parasympathetic cholinergic nerves (ACH), innervate several cells in the skin, thereby maintaining skin homeostasis and regulating inflammation as well as host defense. (From Roosterman D, Goerge T, Schneider SW, et al. Neuronal control of skin function: the skin as a neuroimmunoendocrine organ. *Physiol Rev*. 2006;86:1309-1379.)
that directly contributes to the perception of spontaneous pain. Neuromas are also sensitive to mechanical and chemical stimuli; their activity is exacerbated by temperature. Both A fibers and C fibers show ectopic activity, although the latter persist longer after injury, and sympathetic-sensory coupling may occur at the neuroma through noradrenergic sensitization. Overall, these changes, which are a consequence of damage to peripheral nerves, are triggered by metabolic and functional responses of the sensory cell that render it hyperexcitable, thereby contributing to the positive sensory symptoms of neuropathic pain, as well as triggering and maintaining central sensitization. Nerve injury induces alterations at multiple sites along the neural axis. Abnormalities occur in the injured and uninjured afferents, accompanied by central sensitization at the spinal cord level coupled with cell death. Additionally, there are changes in the descending control system, and immune responses in the periphery and the spinal cord are observed. As described later, such changes are also accompanied by reorganization of the cortical-subcortical circuitry involved in pain perception, in which immune responses as well as signs of cell death have also been observed. Generally, the literature on central sensitization simply refers to the fact that spinal cord transmission of nociceptive information is enhanced. Here, I argue that there is a specific cortical-subcortical reorganization that accompanies neuropathic pain and perhaps persistent inflammatory pain states as well. I label the latter “supraspinal sensitization.”

The following is a summary of the evidence regarding the roles of various sources of afferent input in neuropathic pain. (1) Systemic administration of a selective CB2 cannabinoid receptor agonist reverses the mechanical and thermal hyperalgesia–related behavior in an animal model of peripheral neuropathy. Because CB2 is expressed only in the periphery, the result is strong evidence of the role of peripheral afferents. (2) Similarly, reducing the efficacy of specific sodium channel subtypes in the periphery can decrease signs of mechanical hyperalgesia. (3) In addition to the hyperexcitable injured afferents, there is also good evidence that neuropathic pain can develop in the absence of activity from the injured nerve. (4) Spontaneous activity develops in uninjured, unmyelinated nociceptive afferents that innervate the same territory as the injured afferents, similar spontaneous activity develops following inflammatory injury, and in both the rate of this activity relates to spontaneous pain as assessed by the frequency of lifting the injured limb. (5) There is also evidence for sensitization of intact afferents that develop adrenergic sensitivity and increased responsiveness to thermal and mechanical stimuli. (6) Messenger RNA for a variety of receptors is upregulated in the cell bodies of dorsal root ganglion (DRG) neurons of both injured and uninjured afferents, which are regulated by trophic factors transported from the site of injury to these cell bodies. These processes contribute to changes in sensitivity to heat, cold, and mechanical stimuli in intact and injured afferents, as well as their responses to various modulatory input.

**CENTRAL SENSITIZATION FOLLOWING INFLAMMATORY, NEUROPATHIC, OR CANCER PAIN**

Glutamate is the dominant excitatory neurotransmitter in all nociceptors, and all primary nociceptors terminate and make synaptic contact with second-order neurons in the dorsal horn gray matter of the spinal cord. Unlike the rest of the CNS, nociceptive afferents also contain a long list of neuropeptides that are co-released from afferents and can modulate neurotransmission at longer distances than just at the synapse. Substance P is a peptide neurotransmitter that binds preferentially to the neurokinin-1 (NK1) receptor in the spinal cord. Changes in NK1 receptor expression and internalization can be used to identify the spatial and temporal effects of peripheral nociceptive input on individual spinal cord neurons (Fig. 10.4). In animal models of both inflammatory and neuropathic injury there is ample evidence that second-order synaptic transmission becomes sensitized, though with distinct properties for each general type of injury. Moreover, newer evidence shows that in animal models of cancer pain there is yet another set of distinct cellular and molecular signs of reorganization regarding the state of second-order neurons within the spinal cord. 

Inflammatory pain involves the sensitization of both primary afferent and spinal cord neurons. The neurochemical changes that contribute to inflammatory pain have been examined via expression and internalization of the NK1 receptor in the spinal cord (see Fig. 10.4) in acute, short-term, and long-term inflammatory pain states. With acute inflammatory pain there is ongoing release of substance P as measured by NK1 internalization in layer 1 neurons (neurons located at the marginal zone; these neurons send supraspinal projections to a variety of targets). Although there is no tonic release of substance P with short-term inflammatory pain, 3 hours after injury, both noxious and
non-noxious somatosensory stimulation induces NK1 internalization in neurons located in layers 1, 3, and 4. This is significant because neurons in layers 3 and 4 are classically responsive only to innocuous stimuli and in intact, healthy organisms do not show NK1 internalization. In longer-term inflammatory pain models (3 weeks after the initial injury), the same pattern of substance P release and NK1 activation occurs as in short-term inflammation, with the addition of significant upregulation of NK1 in layer 1 neurons. These changes suggest that there are unique neurochemical signatures for acute, short-term, and long-term inflammatory pain, and given that NK1 internalization is associated with potentiation of glutamatergic neurotransmission, it is clear that the longer that inflammatory conditions persist, the more spinal cord circuitry is recruited and associated with the behavior.

With inflammation there is significant upregulation of substance P and other neuropeptides, such as CGRP, in the dorsal horn, whereas these same primary afferent neurotransmitters are downregulated with neuropathic pain. In contrast, in a bone cancer pain model, no change in these peptidergic neurotransmitters takes place. Likewise, galanin and neuropeptide Y are markedly upregulated in sensory neurons with neuropathic pain, but no change is observed in these neurotransmitters with cancer pain. Even more marked are the different biochemical changes induced by each pain state in the spinal cord. Whereas inflammation induces an increase in substance P and CGRP in layers I and 2 of the spinal cord, nerve injury induces downregulation of these same markers in this area of the spinal cord with an additional upregulation of galanin and neuropeptide Y. In contrast, with cancer pain, the concentrations of these molecules or markers are not significantly changed. However, the greatest change observed in the spinal cord in response to metastatic bone cancer pain is the activation of astrocytes. These results imply that with inflammatory, neuropathic, or cancer pain, a unique and highly distinct set of neurochemical changes occur in the spinal cord and DRG.

Central sensitization occurs following inflammation or neuropathic injury and involves homosynaptic and heterosynaptic mechanisms. Homosynaptic mechanisms involve changes in the response properties of second-order neurons with direct afferent input from the site of injury, whereas heterosynaptic mechanisms underlie the spread of hyperexcitability to neurons with input from intact afferents. The latter accounts for the mechanisms of allodynia. In this case, nociceptive input alters synaptic efficacy such that Aβ mechanoreceptors acquire the capacity to activate second-order nociceptors. Additionally, uninjured nociceptors can acquire spontaneous activity after neuropathic injury, and this leads to enhanced excitability of the spinal cord nociceptors supplied by this input. Sensitization, both homosynaptic and heterosynaptic, involves the increased release of excitatory neurotransmitters, such as glutamate and substance P, or enhanced synaptic efficacy, all of which result in a reduction in the threshold for activation, increased responsiveness as measured by the number of action potentials generated for a given stimulus, and expansion of the receptive fields of dorsal horn neurons. There is a long list of mechanisms that can contribute to different extents to this outcome, including

1. Regarding presynaptic effects, the best evidence is for opioid receptors, which are downregulated with neuropathic pain and upregulated with inflammatory pain. Because opioid receptors control presynaptic and postsynaptic neural transmission from nociceptive afferents, these changes in expression result in modulation of central nociceptive transmission by both mechanisms.

2. There is ample evidence for involvement of postsynaptic mechanisms in central sensitization. Primarily, release of substance P and other peptides opens the N-methyl-D-aspartate (NMDA) glutamate-gated channel, thereby leading to increased calcium entry, which in turn may also potentiate glutamate transmission through α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors.

3. Inhibitory γ-aminobutyric acid (GABAergic) interneurons control the overall excitability of neuronal transmission throughout the CNS and play an important role in governing the sensitivity of dorsal horn–projecting neurons. The reduced expression of inhibitory receptors observed following nerve injury decreases the inhibitory control on afferent input. Also, nerve injury is accompanied by downregulation of the potassium chloride (KCl) transporter, which reverses the effects of GABA release in that opening of the CI channel now leads to excitation rather than inhibition.

4. Descending modulatory pathways seem to reorganize with neuropathic pain and play a critical role in associated behavior. The rostral ventromedial (RVM) medulla receives input from the periaqueductal gray (PAG), which in turn receives convergent input from cortical, basal ganglia, and amygdala input. The RVM medulla projects to the spinal cord and has excitatory and inhibitory innervations within the dorsal horn. Many of the RVM cells express opioid receptors, ablation of which either before or after induction of neuropathic behavior eliminates hyperalgesic behavior. This evidence is important from two viewpoints: first, the descending modulation must be substantially reorganized with neuropathic pain, and second, the supraspinial, including cortical, input interacts with the spinal cord processing of nociceptive afferent input and plays an important role in hyperalgesic behavior. Again, this provides the view that pain behavior is the integrated output of ascending and descending signals throughout the CNS and casts grave doubt on the unidirectional, dedicated telephone line model of pain perception.

5. Involvement of the immune system in peripheral inflammation is well established (see Fig. 10.3). There is now also good evidence for its role in neuropathic conditions. Peripheral nerve damage evokes a cascade of peripheral immune responses that lead to macrophage infiltration and increased expression of proinflammatory cytokines. Knockout of the proinflammatory interleukin-1 (IL-1) receptor along with overexpression
of the IL-1 receptor antagonist decreases hyperalgesia and results in reduced spontaneous activity as recorded from dorsal root fibers. Therefore, peripheral IL-1 clearly participates in neuropathic pain. There is recent evidence that central immune mechanisms, mediated through activation of microglia, are also essential in neuropathic pain (Fig. 10.5).

6. Cell death has now been repeatedly documented to occur in the spinal cord following peripheral nerve injury. It seems to have a limited time course, underlies apoptosis, and affects primarily GABAergic inhibitory interneurons (Fig. 10.6).

This summary of peripheral and spinal cord changes with persistent pain of various types highlights the main components involved. It also ignores or skims over much of the detail. In fact, the literature on the subject is vast and growing rapidly. Here I have attempted to identify cellular, molecular, and structural changes that accompany persistent or chronic pain. This overview also sets the stage so that one can examine the literature regarding human brain activity with respect to pain and its relationship to the expected equivalences between supraspinal sensitization and peripheral and central sensitization.

There is a long list of pathways that convey nociceptive information from the spinal cord to higher brain centers (see Chapter 8). These pathways can generally be subdivided into two groupings: pathways accessing the cortex through the thalamus, which is the spinothalamic pathway, and pathways that access the cortex more indirectly through synapses at the brainstem, amygdala, and basal ganglia, as well as direct projections from the spinal cord to the prefrontal cortex. The relative size of these projections and the response properties of spinal cord neurons that participate in the different pathways have been studied relatively well in mammals, but such information is mostly lacking in humans. It is quite possible that some of these pathways may be preferentially enhanced in humans as compared with other mammals. The spinothalamic pathway has been studied most extensively, and the supraspinal circuitry regarding pain is usually cast within the anatomic framework of this pathway while ignoring the contribution of the others.

Conscious perception of external stimuli requires encoding by sensory organs, processing within the respective sensory system, and activation of the appropriate sensory cortical areas. Based on a small case series of infratentorial and supratentorial brain lesions in 1911, Head and Holmes postulated that the sensation of pain is an exception to this rule and that its conscious perception occurs in the “essential organ of the thalamus.” Despite evidence to the contrary from clinical reports, single-unit recordings in animals, and neuroanatomic tracings, it was maintained for a long time that the cortical representation of pain was negligible.

This situation changed when modern neuroimaging techniques (positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]) demonstrated systematic changes in metabolism and perfusion in a large number of cortical areas following the application of painful stimuli. These findings were supported by invasive and noninvasive electrophysiologic studies in humans using magnetoencephalography (MEG), electroencephalography (EEG), and subdural and depth recordings. Meanwhile, it has been recognized that painful stimuli activate a vast network of cortical (and subcortical) areas, including the primary and secondary somatosensory (SI, SII) cortices, insula, posterior parietal cortex, anterior and midcingulate cortex, and parts of the prefrontal cortex (Fig. 10.7). These areas are now presumed to be involved in the generation of pain perception, as well as in the descending control of pain. A recent meta-analysis examined the incidence of statistically significant activity across all brain-imaging studies of pain in healthy subjects over the past 15 years and indicated that in 68 studies the incidence of activity across these regions was 55% to 94%, with the lowest incidence seen for the prefrontal cortex (55%) and the highest for the insula (94%). Hence the nociceptive system converges with other systems for generation of the conscious percept of pain. In this sense the nociceptive system is not different from, for example, the visual system. However, to what extent any cortical regions can be considered nociceptive specific is still an open question.
Over the past 15 years or so, activation of the cortical and subcortical areas (including the thalamus, basal ganglia, amygdala, and brainstem) by pain in healthy subjects has been examined in terms of the specific dimensions of pain that can be mapped within this network, as well as its modifications with various cognitive and pharmacologic manipulations. Traditionally, pain perception has been conceived to consist of sensory-discriminative, affective-motivational, and cognitive-evaluative dimensions. The sensory-discriminative dimension includes intensity discrimination, pain quality, stimulus localization, and timing discrimination; this dimension is traditionally thought to involve the lateral thalamic nuclei and the SI and SII cortices. The affective-motivational dimension includes perception of the negative hedonic quality of pain, autonomic nervous system manifestations of emotions, and motivated behavioral responses; this dimension is traditionally thought to involve the medial thalamic nuclei and the limbic anterior and medial cingulate cortices (ACC and MCC, respectively). The insula has an intermediate position in this concept and receives input from the lateral thalamus but projects into the limbic system. The cognitive-evaluative dimension includes interaction with previous experience, cognitive influence on perceived pain intensity, and an overall evaluation of its salience; this dimension is traditionally thought to involve the prefrontal cortex. However, numerous neuroimaging studies have assessed various experimental paradigms derived from several psychological concepts that do not easily fit into the traditional three dimensions of pain. Therefore, I discuss the evidence for involvement of cortical areas in specific functions instead of the dimensions of pain.

**LOCATION AND QUALITY OF PHASIC PAIN**

Neuroimaging studies have examined brain regions activated by many types of painful stimulation, including noxious heat and cold, muscle stimulation, topical and intradermal capsaicin, colonic distention, rectal distention, gastric distention, esophageal distention, ischemia, cutaneous electric shock, ascorbic acid, laser heat, and the illusion of pain evoked by combinations of innocuous temperatures. Despite the differences in sensation, emotion, and behavioral responses provoked by these different types of pain, individuals can easily identify each as being painful. Thus, there appears to be a common construct of “pain” with an underlying network of brain activity in the areas described. Nevertheless, despite the similarities in pain experiences and similarities in neural activation patterns, each pain experience is unique. Subjects can usually differentiate noxious heat from noxious cold and from noxious pressure. Given that there is ubiquitous convergence of information from cutaneous, visceral, and muscle tissue...
throughout the afferent nociceptive system, differentiation of types of pain must be achieved by feature extraction via interactions between neurons in the cortical-subcortical circuitry (Fig. 10.8). Although this has not yet been demonstrated, somatotopic organization for noxious stimuli has been shown in human brain imaging, at least for the SI and SII cortices and the basal ganglia, and electrophysiologically in nonhuman primates in the thalamus. Thus these regions can all play a part in localization of pain. Strigo and colleagues directly compared the brain activation produced by esophageal distention and by cutaneous heat on the chest that were matched for pain intensity. They found that the two qualitatively different pain types produced different primary loci of activation within the insula, SI cortex, and motor and prefrontal cortices. Such local differences in response within the “nociceptive network” might subserve our ability to distinguish visceral and cutaneous pain, as well as the differential emotional, autonomic, and motor responses associated with these different sensations.

REPRESENTATION IN THE TIME DOMAIN

The dual pain sensation elicited by a single brief painful stimulus is caused by the different conduction times in nociceptive A and C fibers (about 1-sec difference) and is reflected in two sequential brain activations on EEG and MEG recordings from the SI and SII cortices and the MCC. Intracranial recordings show that the earliest pain-induced brain activity originates in the vicinity of the SII cortex. These observations support the suggestion derived from anatomic studies that the SII region and adjacent insula are primary receiving areas for nociceptive input to the brain.

ATTENTION AND DISTRACTION EFFECTS

Early human brain-imaging studies examining the effects of attention and distraction showed modulation of pain-evoked activity in a number of cortical regions, including
the sensory and limbic structures, as well as the prefrontal areas.\textsuperscript{69-71} Other studies extended these notions by showing that during distraction there is a functional interaction between the pregenual ACC and the frontal cortex that exerts a top-down modulation on the PAG and thalamus to reduce activity in cortical sensory regions and correspondingly decrease the perception of pain.\textsuperscript{72-74}

\textbf{ANTICIPATION AND EXPECTATION}

Anticipation or expectation of pain can activate many of the cortical areas related to perception of pain in the absence of a physical pain stimulus.\textsuperscript{75-78} Two studies have attempted to identify the circuitry for modulation of pain expectation.\textsuperscript{79,80} The results indicated that the expectation of pain intensity is necessary for maximal activation of the afferent pain circuitry and maximal perceived pain intensity, thus suggesting that cortical modulation by expectancy changes the gain for afferent input to the cortex. Generally, there remains a strong need for systematic studies to identify brain elements that modulate pain responses as a result of expectation.

\textbf{EMPATHY}

A provocative study in which the authors defined empathy as the ability to have an experience of another’s pain opened the field regarding the interaction between pain and empathy. Using this definition and comparing brain activity when experiencing pain or knowing that a loved one, present in the same room, was experiencing the same pain, the authors showed that many cortical regions were similarly activated for both conditions.\textsuperscript{81} These results were interpreted as evidence that the affective component of pain is active in both empathy and pain, and they thus concluded that empathy for pain involves the affective component but not the sensory component of pain. The study induced a flurry of activity in attempting to understand the relationship between empathy and pain. Multiple groups have replicated the main finding and proposed different underlying mechanisms.\textsuperscript{82-84} Even though these results are internally consistent, their interpretation remains problematic. Simple introspection casts doubt on the notion that empathy means actually experiencing another person’s pain. Instead, what is called empathy may be assessment of the magnitude of negative emotion that the other person may be experiencing, that is, a cognitive function of interpersonal communication. According to this concept, empathy may be conceived of as a psychological process involving cognitive-evaluative and affective mechanisms that allows us to understand the personal experience of another person. A study in patients with congenital insensitivity to pain\textsuperscript{85} reported a deficit in rating pain-inducing events, but normal inference of pain from facial expressions (“empathy”), thus indicating that empathy for pain does not require an intact pain percept.

\textbf{MOOD AND EMOTIONAL STATES}

Studies show that experimental procedures that improve mood generally reduce pain whereas those that have a negative effect on mood increase pain. One study showed that looking at fearful faces increases the level of anxiety and discomfort, which also resulted in enhanced esophageal stimulation and evoked activity in limbic regions such as the ACC and insula.\textsuperscript{86}

\textbf{PLACEBO}

Placebo is a potent modulator of pain; it affects all clinical studies of pain pharmacology. Placebo effects have also
been seen in depression and Parkinson’s disease, and recent brain-imaging studies have shown robust involvement of the brain and subcortical reward circuitry in these conditions.87 The first neurochemical evidence for opioid involvement in placebo was demonstrated about 35 years ago by showing that placebo analgesia can be blocked by naloxone.88 Consistent with this notion, changes in endogenous opioid release have been shown to be involved in placebo-induced analgesia, in which the prefrontal cortex (medial and lateral), as well as the insula and ventral striatum, seem to be involved, and in high placebo responders, increased opioid release in the ventral striatum is positively correlated with pain ratings.89 Results generally consistent with this brain response pattern have been demonstrated by a number of other groups,80-82; the medial prefrontal/rostral ACC responses to placebo seem to recruit the PAG and amygdala,92 and involvement of the PAG in placebo-induced analgesia is experimentally observed as well, which links opioid descending modulation with prefrontal cortical control of placebo analgesia. The correspondence between placebo analgesia and reward was studied directly, and the results showed a strong correspondence between the brain regions involved in each.93

**PHARMACOLOGIC MODULATION OF PAIN**

**OPIOIDS**

The literature is vast regarding opioid descending modulation through the PAG and its effects on inhibitory interneurons in the spinal cord. The presence of large concentrations of opioid receptors at the cortical and subcortical levels has also been known for decades, yet little effort has been devoted to understanding the role of the latter in pain. Recent studies of opioid responses in the brain have used two approaches: examination of metabolic function in response to pharmacologic agents and direct measurement of receptors. The effect of the µ-opioid agonist fentanyl on brain responses to painful stimuli has been explored, and it was found that most cortical responses to pain are reduced or eliminated, thus confirming the analgesic effects of the opioid.94,95 Changes in the endogenous opioid system are studied with a selective µ-opioid radiotracer, which shows activation of opioid neurotransmission in the ACC, prefrontal cortex, insular cortex, and subcortical areas during tonic muscle pain.96-98

**DOPAMINE**

Dopamine is best known for its role in motor, motivation, and pleasure control; accumulating evidence suggests that dopamine, primarily acting at the level of the subcortical basal ganglia, may also be involved in pain modulation. Human brain-imaging studies have documented increased pain sensitivity associated with lower levels of endogenous dopamine,99-101 and sustained experimental pain has been shown to result in the release of dopamine in the basal ganglia.101 Moreover, abnormal levels of dopamine in the basal ganglia have been associated with chronic pain in burning mouth syndrome, atypical facial pain,102-104 and perhaps fibromyalgia.105

**ESTROGEN**

Women far outnumber men in susceptibility to many autoimmune disorders, fibromyalgia, and chronic pain. Differences in physiologic responses to stress may be an important risk factor for these disorders inasmuch as physiologic responses to stress seem to differ according to sex, phase of the menstrual cycle, menopausal status, and pregnancy status.106 Some studies have documented that the threshold for and tolerance of pain is lower in women.107,108 The association of sex hormones with pain perception and pain memory was studied by Zubieta and colleagues.97 Their studies showed that more µ-opioid receptors were available in the presence of high estrogen levels and that women reported less pain in response to acute painful stimuli than when their estrogen levels were low. Moreover, estrogen-associated variations in the activity of µ-opioid neurotransmission correlated with individual ratings of the sensory and affective perceptions of pain and the subsequent recall of that experience. These data demonstrate a significant role of estrogen in modulating endogenous opioid neurotransmission and the associated psychophysical responses to an acute pain stressor in humans.

**OVERVIEW OF THE ROLE OF THE CORTEX IN ACUTE PAIN PERCEPTION**

The preceding section describes the contribution of modern imaging studies to our understanding of the involvement of the cortex in pain perception. Cortical activity has been demonstrated to possess the properties necessary for involvement in pain perception, such as somatotopic representation of painful stimuli, correlation with stimulus intensity, modulation with attention, modulation with expectation and other psychological variables, and distinct brain regions showing differential activity for the sensory and affective dimensions of pain, as well as attenuation of responses with analgesic drugs. Thus human brain-imaging studies have asserted the role of the cortex in acute pain.

However, because imaging studies identify brain responses in a correlative manner, they may all reflect secondary processes. Perception of pain automatically directs attention to the source of the pain and results in autonomic responses, motor reflexes to escape from the pain, and other emotional and cognitive responses that are undoubtedly at least partially mediated through cortical processes. Therefore, the role of the cortex in pain perception, in contrast to its activity as a consequence of these secondary responses, remains unclear and needs to be properly addressed in future studies.109 In fact, unpublished data from the author’s laboratory suggest that a large proportion of the brain network activated by acute pain may be responses that are commonly involved in estimation of general magnitude for any sensory modality and, as a result, are not specific for nociception, thus suggesting that the majority of cortical activity for acute pain is instead sensory, cognitive, emotional, and attentional responses to nociceptive input. Therefore, the extent to which any given cortical region is necessary for acute pain needs further studies using multiple technological approaches. For most parts of the nociceptive cortical network, as illustrated earlier, it is likely that they participate
only partly in pain perception (by providing certain feature extraction functions) and also participate in other functions in different contexts.

**CLINICAL PAIN**

It should be emphasized that although the subjective phenomenon of being in pain can be considered an emergent phenomenon of cortical activity, there is currently no measure of brain activity that would objectively show whether a person is in pain. Therefore, neither electrical studies (EEG or MEG) nor imaging with fMRI or PET can be used to verify the presence of ongoing spontaneous pain in an individual. Neither fMRI nor PET allows clinical assessment of nociceptive pathways in individual cases because thus far no activation paradigm has been developed that would reliably induce a particular cortical activation pattern in each and every healthy subject. Consequently, negative findings with these techniques are inconclusive.

For the study of pathologic nociceptive processing at the group level, however, fMRI and PET techniques are extremely powerful. These techniques have broadened our understanding of the pathophysiology of conditions involving decreased pain perception, such as afferent pathway lesions or borderline personality disorder, as well as conditions involving increased pain perception, such as neuropathic pain or fibromyalgia. Nevertheless, there are also large gaps in our current knowledge regarding general clinical pain states. For example, we have yet to begin to understand how the duration of pain in simple clinical states affects the brain’s processing of pain. Do patients suffering from tooth pain for 24 hours versus others suffering for a week have similar or distinct brain responses? Clearly, animal data on spinal cord processing of inflammatory pain suggest that the two conditions should engage and excite a greater number of projection neurons, but clinical data are missing. Similarly, we have little knowledge on inflammatory clinical pain states in general. However, chronic pain conditions have been studied more extensively, which is appropriate because these are the conditions that we understand the least and this knowledge may translate into new avenues for therapy.

**CHRONIC PAIN**

**STUDYING BRAIN ACTIVITY IN CHRONIC PAIN WITH NONSPECIFIC PAINFUL STIMULI**

Chronic pain might result from cortical processing of chronic nociceptive input according to the same mechanisms as for acute pain, or there might be specific changes in the cortical processing of nociceptive input in patients with chronic pain. Such changes could then be either a causal factor for or a consequence of the chronicity of the pain condition. The primary expectation from animal model studies of persistent pain, whether inflammatory or neuropathic, is enhanced excitability of spinal cord nociceptive neurons, which would translate into generally larger cortical activity throughout the brain regions activated by acute pain. This is exactly what has not been observed for a long list of chronic pain conditions. Pointing to an important disconnect between the animal models and human studies, it is unclear whether the mismatch is a result of inadequate animal models or inappropriate explanation of the results seen in animal models.

A recent meta-analysis has in fact shown that across some 100 studies one can establish statistically significant differences in the incidence of different brain areas activated by experimental painful stimuli between acute and chronic pain conditions: the prefrontal cortex shows stronger activation in patients with chronic pain, whereas other nociceptive cortical areas and the thalamus show a weaker response. A simple interpretation of these findings is that nociceptive signal processing of experimental painful stimuli in chronic pain patients involves a reduced sensory-discriminative component and an increased affective-motivational or cognitive-evaluative component. This interpretation is also consistent with the stronger affective component of clinical pain than of experimental pain. However, there are further implications: Is the result a consequence of some trivial confounding factors, or does it signify changes in the physiology of pain? One could construct a long list of confounders that may underlie the observation, from shifts in attention to coping mechanisms to the effects of drug use to heightened anxiety and depression.

The standard approach for studying brain activity in subjects with acute pain is to induce pain with a mechanical or thermal stimulus and determine the brain regions modulated with the stimulus period and even with the various intensities used. Therefore, it is natural to carry the same technology to the clinical arena and apply it to patients with chronic pain. An example is one study that attempted to identify brain activity in patients with chronic regional pain syndrome (CRPS) via fMRI. The design of the study was to examine brain activity when thermal stimuli were applied to the body part where CRPS pain was present and compare brain responses to this stimulus in CRPS and healthy subjects. Moreover, because the pain in CRPS patients with sympathetically maintained pain may be modulated by a sympathetic block, it was reasoned that one could decrease the patients’ ongoing pain and then re-examine brain activity responses to the same stimulus. The study was done in a small group of patients, and this by itself is an important weakness, endemic throughout clinical pain brain-imaging studies. The main observation was that thermal stimuli in patients with CRPS evoked more prefrontal cortical activity than usually seen in healthy subjects, and this was reversed (became more similar in pattern to normal subjects’ brain activity in response to thermal stimuli) following sympathetic blocks. The introduction of sympathetic blocks necessitated use of the same procedure in healthy subjects as well, and its effects were minimal. The study also observed that when a placebo block resulted in decreased pain perception, the cortical response pattern changed similarly to that of an effective block. These results show that brain activity with thermal stimuli may be distinct between CRPS and healthy subjects, but they raised a number of unanswered questions, many of which challenge the validity of the approach. For example, the simple assumption that sympathetic blocks were only or mainly affecting the CRPS pain without interfering with afferent sensory transmission was unclear. The analysis was based on the idea that spontaneous pain per se would not affect subjects’ ability to assess stimulus pain,
which may not be true, and that contrasting the effects of sympathetic blocks in CRPS and healthy subjects is valid.

**CLINICAL PAIN CONDITIONS STUDIED BY STIMULATION AND THE ROLE OF THE CORTEX**

A direct approach to studying clinical pain states is to provoke them and examine brain activity. This is feasible with the use of drugs that induce headache and cardiac pain. As a result, there is a growing literature in both fields. There is also now good evidence that migraine with aura is accompanied by decreased blood flow and reduced activity in the occipital cortex and that migraine with or without aura is associated with increased cortical thickness in the visual cortical regions involved in motion detection. 117

**MIGRAINE**

Migraine attacks are characterized by unilateral severe headache often accompanied by nausea, phonophobia, and photophobia. Activation of the trigeminovascular system is thought to be responsible for the pain itself, and cortical spreading depression (CSD) seems to underlie the aura symptoms. This view has been greatly advanced and substantiated by brain-imaging studies. fMRI studies show the typical cerebrovascular changes of CSD in the cortex of migraineurs while experiencing a visual aura. 118 The subsequent decrease in fMRI signal is temporally correlated with the scotoma that follows the scintillations. These changes in fMRI signal develop first in the extrastriate cortex, contralateral to the visual changes. It then slowly migrates toward more anterior regions of the visual cortex, which represent the peripheral visual fields, in agreement with progressive movement of the scintillations and scotoma from the center of vision toward the periphery. A recent study that analyzed visually triggered attacks showed hyperemia in the occipital cortex independent of whether the headache was preceded by visual symptoms. 119 An alternative view considers migraine aura and headache as being parallel rather than sequential processes and proposes that the primary cause of migraine headache is an episodic dysfunction in brainstem nuclei involved in the central control of nociception. 120

**CLUSTER HEADACHE**

The pathophysiology of cluster headache is thought to involve multiple brain regions. Brain-imaging studies imply that the associated, excruciatingly severe unilateral pain is probably mediated by activation of the first (ophthalmic) division of the trigeminal nerve whereas the autonomic symptoms are caused by activation of cranial parasympathetic outflow from the seventh cranial nerve.

Using PET in patients with cluster headaches, significant activations ascribable to the acute cluster headaches were observed in the ipsilateral hypothalamic gray matter and in multiple cortical areas, including the cingulate and prefrontal cortices. When compared with the headache-free state, only hypothalamic activity was distinct. 121 This highly significant activation was observed in patients only while they were experiencing an acute cluster headache attack. Newer magnetic resonance spectroscopy (MRS) results further substantiate this idea by showing reduced metabolites within the hypothalamus of patients with cluster headache in contrast to healthy or migraine headache controls. 122 These data suggest that although primary headaches such as migraine and cluster headache may share a common pain pathway (the trigeminovascular innervation) and activate similar cortical regions, the underlying pathogenesis may be quite different.

**CARDIAC PAIN**

Cardiac pain and its variants have been studied by brain imaging and the use of various drugs that induce these symptoms. 123-125 Overall, these studies imply that differences between different cardiac pain conditions are a result of central processing. Syndrome X, for example, is interpreted as a cortical pain syndrome, a “top-down” process, in contrast to the “bottom-up” generation of a pain percept caused by myocardial ischemia in coronary artery disease.

**IRRITABLE BOWEL SYNDROME**

Irritable bowel syndrome (IBS) is a disorder of abdominal pain or discomfort associated with bowel dysfunction. Hyper-sensitivity to visceral but not somatic stimuli has been demonstrated in IBS. A number of groups have examined brain activity in this condition, mainly by monitoring responses to painful and nonpainful rectal distention, as well as responses to the anticipation of painful distention. Two studies are interesting in that both show a significant positive correlation between cingulate cortex activity and subjective ratings of rectal distention pain in normal subjects, and in both studies this relationship completely disappeared in IBS patients. 126, 127

More recent studies show a hint of sensitization in IBS patients inasmuch as the use of subliminal and supraliminal rectal distention seems to indicate small differences between IBS and healthy controls in the total cortical volume activated or in regional activity as a function of distention volume. 128, 129 A study of IBS versus healthy subjects examined thermal and visceral hyperalgesia and related brain activity. 130 This seems to be the only study in which, besides pain intensity and unpleasantness measures, the authors also documented fear and anxiety and showed that all are rated higher by patients with IBS undergoing both heat and rectal distention and that, not surprisingly, these increased sensations and emotions give rise to larger cortical activations in IBS patients. The latter is most likely a reflection of a mismatch in perceptual magnitude between the groups and says little regarding abnormalities in cortical activity in IBS patients. Such mismatches, at least for fear and anxiety, are most likely common in the majority of IBS studies. One assumes that the simple introduction of a rectal balloon in IBS patients would result in increased anxiety, which undoubtedly affects cortical activity in response to visceral and somatic pain, yet its specific contribution has remained unexplored.

In an elegant study, perception-related ratings were used during rectal distention to evoke either the urge to defecate or pain, and brain activity related to the ratings was compared in IBS patients and healthy subjects. 131 The approach is similar to the technique used for mapping brain activity in response to spontaneous pain in patients with CBP and PHN. 132, 133 The results showed large differences between the two groups contrasted, with far more extensive brain activation in the healthy subjects. The results are complicated by the fact that the authors did not take into consideration the
influence of spontaneous pain. Still, this is perhaps one of the best-controlled IBS studies and indicates distinct cortical areas involved in the urge and pain perceptions in each group.

**SPONTANEOUS PAIN AS A CONFOUNDER IN ASSESSING BRAIN ACTIVITY**

A person who has lived for years with pain must have developed some coping mechanisms that aid in pursuing everyday life interests. How does this affect the brain? Can one consider the brain of a patient in chronic pain as being a brain signaling pain together with a brain undertaking other tasks as in healthy subjects? Or does the presence of ongoing pain interact with and affect other processes as well? There is now direct evidence of the modulation that ongoing pain imposes on brain activity in general.

A recent study reported brain activity in patients with spontaneous pain and PHN before and after topical lidocaine treatment. The PHN patients were imaged with fMRI before treatment, after 6 hours, and then again after 2 weeks’ treatment with lidocaine. Behaviorally and based on questionnaires, most participants showed a modest but significant decrease in their ongoing pain. The patients were scanned while they were either rating their pain or rating a visual bar that varied in time in a pattern that mimicked their ratings of pain. Thus, the latter is a control task that captures the motor and cognitive parts of the task, but of course it does not reflect the pain. Brain activity with both tasks increased from the first to the third session. This observation is similar to earlier reports in which a decrease in clinical pain in many instances resulted in increased brain activity. In this case, however, the internal control was also changing in a manner parallel to the pain condition, thus hinting that the effects of decreased pain were modulating more than just the pain-related circuitry.

To identify the role of spontaneous pain on brain activity in general, a correlation analysis was performed for both tasks with mean spontaneous pain. The result showed that brain activity for both tasks was influenced by the level of spontaneous pain, which implies that pain intensity in general influences task performance. This is in line with previous studies showing that ongoing pain may interfere with cognitive function. The finding indicates that the intensity of spontaneous pain affects brain activity for any task that the subject attempts to perform, with some aspects being enhanced and others inhibited. Therefore, the decreased brain activity reported for pain tasks in many clinical pain conditions is most likely a reflection of the presence of the spontaneous pain and is not specific to the task being investigated. The fact that pain intensity seems to modulate brain activity in general has another powerful consequence. It suggests that by simply studying brain activity in tasks unrelated to pain, one should be able to identify the presence of pain and study its effects on sensory, cognitive, motor, and attentional processing, an exciting prospect that remains to be pursued.

**FUNCTIONAL MAGNETIC RESONANCE IMAGING OF SPONTANEOUS PAIN**

Spontaneous pain is highly prevalent in clinical pain conditions and is usually the primary drive for patients to seek medical care. Thus, understanding its related brain circuitry is scientifically as well as therapeutically imperative. Cortical responses to standard mechanical or thermal stimulation are of limited value for understanding these clinical pain conditions. Spontaneous pain fluctuates unpredictably on the time scale of seconds to minutes, and these fluctuations have characteristic properties that differentiate between different chronic pain conditions such as PHN and CBP. This variability can also be observed in fMRI signals when such patients rate their spontaneous pain. Therefore, this technique was applied to study brain activity in patients with CBP and PHN with respect to their subjective report of fluctuations of spontaneous pain.

The combination of relating brain activity to spontaneous pain and correcting for confounders by subtracting the brain activity for visual bar lengths provides a robust approach with which clinical pain may be studied directly. Note that in this case the brain activity is related to exactly the event about which the patient complains. With this approach it was shown in CBP patients that the brain regions activated when the pain was increasing corresponded to the brain regions activated with acute pain in normal subjects. In contrast, at times when the pain was high and sustained, brain activity was limited mainly to the medial prefrontal cortex, a region not usually activated with acute pain (Fig. 10.9). The resultant brain activity was strongly correlated with the patients’ reported pain intensity at the time of the scan, specifically with medial prefrontal activity. Also, the duration or chronicity of the pain was captured in the insular activity, a region activated only during increases in spontaneous pain. Thus, two fundamental properties of CBP—its intensity and duration—were directly reflected in the brain activity identified in these patients (Fig. 10.10). By applying a painful thermal stimulus in the same patients (as well as in healthy subjects), the same study showed that brain regions reflecting the intensity of the stimulus were not related to that reflecting the intensity of the spontaneous pain. In turn, the brain region that reflected spontaneous pain intensity was activated only for the latter and did not reflect painful thermal stimulus intensity. Therefore, at least in the patient group studied, spontaneous pain involved a different brain activity pattern than acute pain did.

**NEUROPATHIC PAIN**

An MRS study showed that level of N-acetylaspartate (NAA), a neuronal marker, was decreased in the thalamus of patients with chronic neuropathic pain after SCI but not in patients with SCI and no pain. Thus, neurochemical brain imaging provides evidence for the occurrence of long-term changes in the brain chemistry and morphology of patients with chronic neuropathic pain. Thalamic activity in neuropathic patients was also reported to increase after pain relief and to be significantly negatively correlated with the duration of the condition in patients with CRPS. Thus, the reduced activation of the thalamus may also be an altered functional state rather than an irreversible degeneration. Patients with neuropathic pain in addition show reduced availability of opioid receptor binding sites. This reduction was symmetrical in those with peripheral neuropathic pain, which suggests possible release of endogenous opioids, but lateralized to the hemisphere contralateral to
the pain in patients with central pain, consistent with a loss of receptors.\textsuperscript{140}

Differences in brain activity between healthy subjects and patients in activation paradigms are difficult to interpret because they do not distinguish between brain activity specifically related to the clinical condition and abnormalities in sensory processing secondarily associated with the clinical state. Particularly in neuropathic pain, the accompanying sensory deficit may be reflected in the imaging results and not the pain. Reduced relevance of the acute stimulus in subjects who are already in pain may also account for much of the decreased regional brain activity in those with neuropathic pain. To overcome such nonspecific differences in brain activity, one needs to compare brain activity in response to stimuli for which perceptual evaluation has been equated between patients and healthy subjects.

A number of studies\textsuperscript{76,116,133,137} have looked at the regions of the brain modulated by relief of chronic neuropathic pain. The brain regions modulated by these procedures were quite disparate. This heterogeneity is not surprising because the pattern of brain activity may be specific to each neuropathic pain condition. The most recent study\textsuperscript{133} illustrates how such therapeutic procedures can be used to functionally subdivide brain responses to areas related to acute changes as a result of therapy and those that respond with longer-term treatment: regions involved in sensory coding such as the thalamus seem to be associated with the former, whereas areas involved in emotions and hedonics, such as the ventral striatum and amygdala, seem to respond to the longer-term treatment.
LOW BACK PAIN AND FIBROMYALGIA

As mentioned, the brain activity in healthy subjects and patients with increased pain sensitivity should be compared in such a way that the perceived intensity has been matched across the two groups. A recent study used such a design and showed generally heightened brain activity in response to painful mechanical stimuli of equivalent perceptual intensity in both patients with fibromyalgia and patients with CBP versus healthy subjects. Morphometric and neurochemical brain-imaging studies provide evidence for the occurrence of long-term changes in the brain chemistry and morphology of patients with chronic pain. The level of NAA, a neuronal marker, was decreased in the medial and lateral prefrontal cortex of patients with CBP in comparison to an age- and gender-matched control group. A morphometric study of patients with CBP also showed a decrease in gray matter density in the dorsolateral prefrontal cortex and thalamus when compared with matched controls. Furthermore, these long-term chemical and morphologic changes are significantly correlated with different characteristics of pain such as pain duration, pain intensity, and sensory-affective components. The morphometric and neurochemical studies imply an active role of the CNS in chronic pain and suggest that supraspinal reorganization may be critical for chronic pain.

EVIDENCE FOR SUPRASPINAL NEURODEGENERATION IN CHRONIC PAIN

Neurodegeneration in the spinal cord, which changes the topography as well as the gain for transmission of nociceptive signal, probably provokes parallel reorganizations in the supraspinal pathways. Human brain-imaging studies are beginning to address this question in relation to specific chronic pain conditions.

THALAMIC ACTIVITY IN CHRONIC PAIN

In contrast to experimentally induced pain in normal subjects, chronic clinical pain conditions are consistently associated with decreased baseline activity or decreased stimulus-related activity in the thalamus. Interpretation of these results, though, is hampered by inadequate controls. The most elegant study on the topic thus far has been a single-photon emission computed tomography (SPECT) blood flow experiment, which showed a strong relationship between the time of onset of CRPS and thalamic activity, thus suggesting that thalamic activity undergoes adaptive changes in the course of CRPS and indicating a transition from an acute to a chronic state. Unfortunately, there are no biologic markers for pain that would define standard time lines for the transition from acute to chronic pain. This ambiguity complicates interpreting the thalamic adaptive changes seen in CRPS. Early hyperperfusion in the thalamus might be a consequence of central sensitization or spinal disinhibition as a result of apoptosis of interneurons. Increased polysynaptic excitation after the removal of GABAergic inhibitory control may prompt a vicious circle that causes the degeneration of more dorsal horn neurons, including nociceptive transmission neurons, which would explain the long-term thalamic hypoperfusion.

Regional brain activation with experimental pain in humans is usually interpreted in relation to the spinothalamic pathway. The decreased thalamic signaling in chronic pain poses a puzzling dilemma from this viewpoint and suggests that nociceptive pathways outside this projection may be more important in chronic pain. Given the changes in thalamic activity seen with CRPS, one possible explanation is early activation of the spinothalamic pathway, which at longer periods becomes hypoactive and is compensated by enhanced activity in other nociceptive pathways, such as the spinal-parabrachial-amygdala, spinal–basal ganglia, spinal-prefrontal, and spinal-hypothalamic pathways.

DECREASED METABOLISM IN THE THALAMUS AND CORTEX

In most human neurodegenerative conditions, such as Alzheimer’s disease (AD) or Parkinson’s disease, proton MRS shows decreased levels of brain metabolites, primarily NAA, either in absolute terms or in relation to internal markers such as creatine, phosphocreatine, inositol, or choline. Because NAA is found mainly in neuronal cell bodies, it has become accepted as a parameter for neuronal density and a tool with which neurodegeneration can be studied noninvasively. Recent studies indicate that NAA levels discriminate between patients with amyotrophic lateral sclerosis and healthy controls with 71% sensitivity and 95% specificity and predict survival outcomes in this population. In AD, higher parietal lobe NAA levels are reported to be predictive of a positive treatment outcome, and lower levels correlate with AD progression as strongly as the rate of ventricular expansion does.

With chronic pain, NAA decreases in the dorsolateral prefrontal cortex (DLPFC) of patients with CBP. The concentration of NAA in the DLPFC correlated with pain intensity, as well as with the affective dimensions of back pain. In contrast, NAA in the orbitofrontal cortex was not associated with particular pain descriptors but correlated with state and trait anxiety parameters. The association of decreased thalamic NAA levels and pain intensity has also been observed in patients with central pain after SCI and in patients with CRPS or PHN. Decreased concentrations of metabolites such as glucose or inositol have been found in the cerebrospinal fluid of patients with back pain caused by disk herniation or spinal stenosis.

REDUCTION OF CEREBRAL GRAY MATTER

Given the baseline activity pattern and metabolic changes in the brain that have been found in functional imaging studies, one would expect a decrease in neocortical gray matter volume and regional gray matter density in the thalamus and DLPFC. Such changes were in fact the main observation of the first morphometric study in which the morphology of CBP patients was contrasted with that of sex- and age-matched healthy control subjects (Fig. 10.11). Total neocortical gray matter volume was negatively correlated with the duration of chronic pain. Every year of living with the condition decreased cortical volume by an additional 1.5 cm³ beyond the decrease in volume attributable to normal
aging. The specificity of the outcome is corroborated by the fact that the magnitude of DLPFC gray matter changes in patients with spinal nerve root injury differed from that in patients with non-neuropathic back pain. Furthermore, gray matter variability correlated with the sensory and affective dimensions of back pain. A recent independent study replicated most of these results. Specific changes in regional gray matter density have also been found in patients with tension headache and recently in those with fibromyalgia. Details of the morphologic changes may be specific to particular chronic pain states, thus potentially providing biologic parameters that allow differentiation of chronic pain conditions.

The results imply that chronic pain is accompanied by cerebral atrophy. Yet the mechanisms underlying this atrophy remain to be elucidated. Cortical neurodegeneration may occur secondary to spinal cord neurodegeneration or reflect stress impinging on neurons that are trying to cope with increased afferent input. Genetic factors may render subjects vulnerable to chronic pain either because they have genetically determined lower gray matter density in brain regions such as the DLPFC or because neurons in brain regions at risk for chronic pain–related degeneration are more susceptible to stress, such as increased excitatory input. The brain atrophy in patients with chronic pain may be caused by an irreversible loss of neurons or by changes in volume, which could recover when the chronic pain is treated properly. The extent of reversibility of the brain atrophy in those with chronic pain is a crucial issue, and its relationship to successful therapy deserves to be investigated.

INCREASED AMYGDALA EXCITABILITY IN PERSISTENT PAIN

As part of the limbic system, the amygdala plays a key role in attaching emotional significance to sensory stimuli, emotional learning and memory, and affective states and disorders. The amygdala also mediates conditioned and environmentally and morphine-induced analgesia, thus suggesting coupling to descending inhibition. The amygdala is one of the higher brain centers with direct links to brainstem centers that are important for pain inhibition and facilitation. Only recently, however, was a systematic analysis of pain processing and pain modulation in the amygdala performed. In these studies an arthritis model was used to show pain-related sensitization and synaptic plasticity of amygdala neurons and, as a consequence, increased nociceptive and affective pain behavior.

Neuroimaging pain studies using PET and fMRI have produced mixed results regarding pain-related amygdala function in humans. Some studies identified pain-related changes in signal in the human amygdala. The experimental conditions included the application of brief noxious heat stimuli to the skin of humans, and recently in the human amygdala and spontaneous pain in patients with CBP, with an absence of activity in the amygdala in response to acute thermal pain in patients with CBP.

CYTOKINES IN THE BRAIN AND THALAMUS

The role of proinflammatory cytokines has been extensively studied in the periphery, spinal cord, and hypothalamus following peripheral inflammation. Recent results indicate that mice with a deficiency in the IL-1 gene have reduced responses to inflammatory and neuropathic injury. The authors concluded that IL-1 modulates both the generation and maintenance of inflammatory and neuropathic pain. Another study in rats with neuropathic pain indicated increased endogenous levels of the proinflammatory cytokine IL-1β only in the animals in which there were clear behavioral signs of the presence of pain. The latter is proposed as a marker for brain regions undergoing synaptic plasticity because changes in neuronal activity can result in cytokine induction in the brain and in long-term potentiation of synaptic activity in the hippocampus.
ROLE OF THE CORTEX IN CHRONIC PAIN PERCEPTION

Despite a plethora of data, there remain a host of uncertainties about their significance. Overall, clinical brain-imaging studies indicate reduced transmission of information through the thalamus to the cortex and increased activity in the prefrontal cortex, coupled with regional atrophy. The number of studies remains small, and hence our confidence in the reproducibility of these changes remains minimal. Still, the observations regarding changes in cortical and thalamic activity in subjects with chronic pain are in general consistent with the notion that chronic pain conditions preferentially engage brain areas involved in cognition and emotion with decreased activity in regions involved in the sensory evaluation of nociceptive input.

Evidence has been presented that brain activity, chemistry, and morphology may be reorganized in chronic pain conditions. Does this evidence imply that there is supraspinal reorganization above and beyond what is established in the periphery and spinal cord? That is, even if we establish a brain pattern of activity for some chronic pain condition, does this reflect some unique contribution of the brain to this state or is it simply a reflection of lower-level reorganization? The answer is not straightforward. However, only by answering such questions will brain imaging be able to provide new information on the myriad mechanisms described for peripheral and spinal cord reorganization with chronic pain. Overall, this evidence provides signs regarding supraspinal sensitization and the long list of changes that may underlie this phenomenon, a process in which the primary or critical parameters that control these changes remain essentially unknown.

CONCLUSION

This chapter outlines the peripheral and central events that accompany pain with an emphasis on the cellular, molecular, anatomic, and physiologic changes that accompany various types of pain conditions. The review also attempts to highlight the gaps that continue to become apparent as the field moves forward and unravels the large number of factors that shift in relation to pain. The gap between animal models of pain and human clinical conditions should be apparent. Yet in many cases there seems to be growing evidence from studies involving both groups that similar and parallel changes accompany persistent pain. The animal studies provide convincing evidence of changes in receptor properties in both the periphery and the spinal cord, as well as changes in excitability and neurodegeneration, especially in the spinal cord. Human studies, however, provide better evidence of topographic changes in pain encoding between acute and chronic pain states, especially the finding that distinct portions of the cortex may be involved in each. The accumulating evidence for cortical neurodegeneration poses new questions regarding the driving forces for chronic pain, namely, are the latter a consequence or predisposing events for such conditions? More important, the chapter indicates that pain perception cannot be viewed as unidirectional transmission of information from the periphery to the cortex but rather that pain is caused by an interaction between ascending and descending pathways that reorganize the system at all levels.

Images of brain activation by painful stimuli leave the impression that at least half of the brain participates in processing nociceptive information. At other times, many of the same areas participate in visual, motor, emotional, cognitive, or other signal processing. In that sense our current understanding of the nociceptive network in the brain is consistent with the current understanding of how the brain uses distributed processing for its many functions. It is not clear, however, to what extent any part of the cerebral cortex is specific for nociception. The best candidate region for such a function lies in the parasympathetic cortex, in the vicinity of the SI and SII cortices and portions of the ACC. In chronic pain, nociceptive processing in the cerebral cortex is partly preserved and partly altered, in particular with respect to prefrontal cortex functions. This reorganization may be a neuroplastic response to the chronicity of pain, it may reflect activation of antinociceptive processes, or it may even represent a factor predisposing to the development of chronic pain.

KEY POINTS

- Free nerve endings terminating in the skin and viscera are the machinery for signaling local mechanical, thermal, and chemical changes, as well as for modulating this local environment.
- The VR1 cation channel is activated at around 43°C and is also sensitive to capsaicin and acidity.
- Neuropathic pain is generally viewed as paradoxical because it involves severing portions of the nociceptive system and thereby usually causing various types of sensory deficits, which rather than decreasing pain transmission results in long sustained increased pain as a result of reorganization of the peripheral and central neural elements participating in pain perception.
- In intact healthy organisms, nociceptive input is transmitted through Aδ and C nociceptors. However, there is now very good evidence that following central sensitization caused by inflammation or neuropathic injury, peripheral input to the central nervous system through non-nociceptive, thickly myelinated, Aβ touch afferents may evoke pain.
- Neuromas generate spontaneous ectopic activity that directly contributes to the perception of spontaneous pain. Neuromas are also sensitive to mechanical and chemical stimuli; their activity is exacerbated by temperature. Both A and C fibers show ectopic activity, although the latter persists longer after injury, and sympathetic-sensory coupling may occur at the neuroma through noradrenergic sensitization.
- The sensory-discriminative dimension includes discrimination of intensity, pain quality, stimulus localization, and timing; this dimension is traditionally thought to involve lateral thalamic nuclei and the primary and secondary somatosensory cortices.
- The affective-motivational dimension includes perception of the negative hedonic quality of pain, autonomic nervous system manifestations of emotions,
KEY POINTS—cont’d

- and motivated behavioral responses; this dimension is traditionally thought to involve medial thalamic nuclei and the limbic anterior and medial cingulate cortices.
- The cognitive-evaluative dimension includes interaction with previous experience, cognitive influence on perceived pain intensity, and an overall evaluation of its salience; this dimension is traditionally thought to involve the prefrontal cortex.

An Introduction to Pharmacogenetics in Pain Management: Knowledge of How Pharmacogenomics May Affect Clinical Care

Charles E. Argo

CASE 11.1

A 58-year-old Asian male with no significant past medical history presents with acute herpes zoster in the left T4 dermatome. Presenting signs and symptoms include severe localized pain and tactile allodynia associated with a vesicular eruption. Even after the rash resolves, 3 months later he continues to complain of severe burning pain in addition to allodynia and hyperalgesia in the left T4 dermatomal region, suggesting that he has developed post-herpetic neuralgia (PHN). Ten milligrams of nortriptyline, a tricyclic antidepressant (TCA), is prescribed with a plan to titrate up to a higher dose to achieve effective pain relief if the initial 10-mg dose is not helpful enough. Unfortunately, he is unable to tolerate the initial dose because he quickly develops intolerable adverse effects (sedation, orthostatic hypotension, and dry mouth) shortly after he begins taking it.1 Tramadol and then hydrocodone/acetaminophen are prescribed but these are also poorly tolerated. He is then prescribed gabapentin at an initial dose of 300 mg taken at night, which is titrated over several weeks to an effective analgesic dose for PHN: 1800 mg/day in three divided doses. Although the burning pain is lessened, it is still not sufficiently controlled and the patient returns for further treatment. From the time of presentation for treatment, it has taken over 6 weeks for him achieve any notable degree of pain reduction.

This patient was treated according to available evidence-based, current guidelines,1,5 yet he did not obtain adequate analgesic benefit from the prescribed medications. Clinicians recognize that individual variations in responses to pain itself, as well as in the response to pharmacotherapies for pain relief, are routinely observed; however, advances in pharmacogenomics may allow us to better understand why patients may have variable responses to various analgesic therapies and may soon allow an opportunity for clinicians to identify the most appropriate pharmacotherapies for a patient before prescribing and hence improve patient-specific outcomes. The knowledge and use of relevant pharmacogenomic information may indeed help a clinician to truly individualize a patient’s care, an example of personalized health care.

In this example, the patient’s treatment responses require a careful evaluation of possible reasons for them. Variability in patient response, including intolerable adverse effects, can be due to nonadherence with the prescribed medication or medication schedule, a drug interaction inhibiting the medication’s effectiveness, mechanisms of pain generation that fail to respond to the prescribed medication’s mechanism of action, or a combination of these. It is also possible that the patient’s genetic background has affected his ability to clinically respond to or metabolize the prescribed medications, and this is where the emerging field of pharmacogenomics becomes important to recognize. This patient example illustrates the variable analgesic response and adverse event profile when analgesics are prescribed. As noted, clinicians are only too well aware how often individuals may not obtain the expected therapeutic benefit from analgesic medications.1 The response rates in well-designed studies of various analgesic therapies are approximately 50% to 60%; this “treatment success” rate is similar to trials of therapies used to treat congestive heart failure and epilepsy.5,7 Many key areas of medicine are similarly affected by poor responder rates in clinical trials of diverse drug types. Knowledge of relevant pharmacogenomic factors that may influence the effect of a prescribed analgesic should allow clinicians to improve analgesic treatment outcomes.

THE IMPACT OF PHARMACOGENOMIC RESEARCH ON CLINICAL MEDICINE

Pharmacogenomics is the study of the impact of genetics on pharmacotherapeutic responses and tolerability, in an effort to improve drug safety and efficacy through genetically guided, individually tailored treatments.4 As noted previously, the same drug can be associated with different clinical responses among a group of individuals. This is because each individual’s unique genetics provides the genetic blueprint for the generation of singular protein expression profiles, which subsequently leads to functional variations observed as clinical responses. Indeed, taking into account such genetic predisposition and receptor subtype expression has the potential to result in a more satisfactory reduction in symptoms or resolution of disease. This approach is certainly at the core of so-called personalized medicine. When the clinician is aware of a patient’s genetic predisposition and receptor subtype expression, this knowledge may
lead to more individually focused prescribing with improved efficacy and safety for the patient.8

Ongoing research on the genetic determinants of various diseases have been derived from the Human Genome Project, including The SNP Consortium (TSC).8 Single nucleotide polymorphisms (SNPs; pronounced “snips”) are the most important contributors to the observed regular variation in the genetic code, which lead to the human population’s diversity of appearance and, at a deeper level, to our diversity in physiology. SNPs are defined as deoxyribonucleic acid (DNA) sequence variations resulting from a single nucleotide (adenine [A], thymine [T], cytosine [C], or guanine [G]) change in the genome sequence. As an example, the most commonly observed change is when a C is replaced by a T, as in when the sequence AC GGCTAA is changed to ATGGCTAA.8 Overall there are approximately 9 million to 10 million common SNPs.9 In many cases, this minimal change amid a background of the approximately 3.3 billion base pairs of DNA contained in one somatic cell does not lead to any significant observable change in an individual. Many of these DNA changes do not translate into differences at the protein level. However, there are SNPs that in fact do lead to phenotypic differences, and some single base pair changes do affect a noticeable, clinically relevant change in phenotype. Unique SNPs have been identified that lead to lower activity of various enzymes, red hair color and fair skin, and a lack of or diminished expression of one of the red blood cell antigens.10,11

The most commonly observed DNA sequences of a gene are called “wild-type,” and the less common alleles are “variants” if they are prevalent in more than 1% of the population. The even less prevalent alleles have another name; DNA sequences in genes found in less than 1% of the population are called “mutations.”12 For example, within pain management, an autosomal dominantly inherited peripheral neuropathy, hereditary sensory, and autonomic neuropathy (HSAN) type I confers insensitivity to pain mediated through the progressive degeneration of the dorsal root ganglia (DRG) and motor neurons as the result of mutations within a specific location in chromosome 9.13,14 Individuals with this genetic background cannot sense pain, making them particularly prone to painless but potentially severe injuries, with detrimental complications, such as chronic skin ulcers and distal amputations. Additional types of changes to our DNA can occur, such as deletions and insertions, which also can result in catastrophic consequences. Large population studies have analyzed hundreds of thousands of SNPs in an attempt to establish the genetic linkages to a diversity of diseases.12 The Wellcome Trust Consortium published a particularly important study in the June 2007 issue of Nature. The authors assessed the genetic influence on seven major diseases by comparing the SNPs of 14,000 patients (2000 with each disease to those of 3000 healthy patients).15 Genomic hot spots (regions of DNA connected to biologic functions/diseases) were linked to a susceptibility to developing bipolar disorder, Crohn’s disease, coronary artery disease, diabetes (both type 1 and type 2), hypertension, and rheumatoid arthritis.15

Key terms used in pharmacogenomics can be viewed in Table 11.1.

The integration of genetic information into clinical practice has far-reaching implications. For example, the clinical integration of genetic information has been increasingly used in oncology to guide treatment. Other areas of medicine are also beginning to tailor pharmacotherapies based on an individual’s genetic information, and certain biomarkers are now known that can help to guide treatment in many areas of medicine including pain management. Pharmacogenomic testing has benefited patients and clinical medicine in general by improving the ability to stratify the risks of various treatments for individual patients by identifying groups of patients with a higher potential for poor efficacy or for treatment side effects (Table 11.2).16 The beneficial effects of utilizing information derived from pharmacogenomics in the future of clinical medicine may lead to improved success rates, decreased side effect burdens, and reduced health care costs.16

**The Impact of Pharmacogenomic Research on Pain Medicine**

Individuals have differential responses to pain and different likelihoods for developing chronic pain. In 2006, Tegeder and colleagues reported that GTP cyclohydrolase (GCH1), the rate-limiting enzyme for tetrahydrobiopterin (BH4) synthesis, is a key modulator of peripheral neuropathic and inflammatory pain, tracing the predisposition for high pain tolerance to this enzyme cofactor, which is upregulated in primary sensory neurons of the dorsal root ganglion following nerve injury. 18 This cofactor modulates both inflammatory and neuropathic pain. These investigators identified a “pain protective” polymorphism in 15% of the population within the gene that encodes for this essential cofactor involved in this specific pain pathway, which yields reduced pain sensitivity. 19 Individuals with this “pain protective” genotype could potentially confound analgesic trial results, unless they were identified and randomized. Polymorphisms in other genes have also been linked to pain sensitivity. 20

Genetic predisposition also affects an individual’s susceptibility to specific complications of common disease states such as diabetes-associated nephropathy. A genome-wide scan identified two novel candidate genetic loci associated with diabetic nephropathy, implicating new pathways in the pathogenesis of this debilitating complication of diabetes. 21 Pharmacogenomic research has the potential to lead to great strides in the optimization of analgesics as well. Genetic variance can impact the therapeutic response of specific pain medications or predispose an individual to adverse effects. Differences in clinical response to pain medications, in terms of efficacy, toxicity, pharmacokinetics, metabolism, and drug transport, have been linked in part to genetic variations. 4 In 2004, Fishbain and colleagues concluded that “genomic testing for enzymes of drug metabolism has significant potential for improving the efficacy of drug treatment and reducing adverse drug reactions,” notably for the pain therapies: tricyclic antidepressants, anti-inflammatory drugs, and opioids, among others. 4

**Tricyclic Antidepressants**

Consider the patient example, in which the TCA administered to the patient presenting with PHN led to intolerable adverse effects. TCAs are metabolized in the liver by the cytochrome P450 (CYP450) system, which is responsible for the breakdown of 40% to 50% of all commonly prescribed medications. 22 CYP450 is the most intensely studied gene

family, and polymorphisms within this class of enzymes can lead to reduced or accelerated metabolism of their substrates, including specific medications. As such, two individuals having the same weight and given the same drug dosage can have more than a 1000-fold difference in their plasma drug levels. This can be extremely important to recognize from a clinical viewpoint. In studies, individuals have been grouped by their phenotype: poor metabolizers, who have two nonfunctional enzyme alleles; intermediate metabolizers, who have at least one reduced functional allele of an enzyme; extensive metabolizers, who have at least one functional allele; and ultra-rapid metabolizers, who have multiple copies of a functional allele or an allele with a promoter mutation that confers increased transcription of that gene.

SNPs

In properly selected patients, opioids can be effective treatments for acute moderate to severe pain, as well as chronic moderate to severe pain. Similar to tricyclic antidepressants, most opioids are metabolized by the CYP450 enzyme class (Table 11.3). Hence, SNPs in CYP450s can have an impact on clinical analgesic and adverse effect responses. In particular, codeine has been associated with variable individual clinical responses. Codeine itself is a prodrug: a medication that is inactive until it is enzymatically converted to its active metabolite. Codeine must be converted to morphine via CYP2D6 to provide analgesia. In addition to codeine, CYP2D6 poor metabolizers may experience suboptimal analgesic efficacy when prescriber “routine” doses of tramadol. This is because the analgesic benefit attributed to its opioid-related mechanism of action requires that tramadol first be metabolized via a CYP2D6-based mechanism to an active metabolite. The metabolism of many currently available opioids can be affected by SNPs with the CYP450 system; however, three opioid analgesic medications are not metabolized through this system at prescribed doses: hydrocodone, morphine, and oxymorphone. Therefore, if it has been identified, perhaps by noting poor analgesic efficacy or intolerable adverse effects (or even possibly actual pharmacogenetic testing) that an individual has a SNP that alters the enzymatic activity of one or more of the CYP450 isoenzymes, an opioid analgesic (if otherwise appropriate for that patient) might be considered that is not metabolized through this mechanism in order to increase the likelihood of a successful treatment outcome.

The current clinical value of pharmacogenomic research illustrates that pharmacogenomic data may play a role in risk stratification and may help guide prescribers in their decision making. Relevant to the patient presented previously, 41% to 51% of individuals of Asian origin express an unstable CYP2D6 enzyme, whereas 12% to 21% of Caucasian people express an inactive CYP2D6 enzyme. However, in clear contrast, 10% to 29% of people of Ethiopian or Saudi Arabian descent have heightened CYP2D6 activity. When considered for the purposes of clinical decision making, this pharmacogenomic information can provide clues about how a specific patient may respond to codeine and

**NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)**

Pharmacogenomic research in pain management has identified wide interindividual variation in the analgesic efficacy of both nonspecific NSAIDs and selective inhibitors of cyclooxygenase-2 (COX-2) due to SNPs within the COX genes. A SNP in the promoter for the gene encoding COX-2 (the -1195G to A change) has a prevalence of greater than 10% and has been associated with mild asthmatic reactions. Indeed, another functional effect of the increased expression of COX-2 potentially mediated by several SNPs is the enhanced susceptibility to hypersensitivity in response to standard doses of aspirin and other NSAIDs that inhibit COX-2, otherwise known as aspirin-intolerant asthma (AIA).

Additionally, a large genotyping study has determined that individuals with specific variants of the COX-1 and COX-2 genes have an increased risk of cardiovascular disease when taking aspirin. Other studies have investigated an association between genotypes of the cytochrome P450 enzyme CYP2C9 and taking NSAIDs metabolized by that enzyme. An increased risk of developing gastroduodenal bleeding was noted in patients with this co-occurrence.

**OPIOID ANALGESICS**

**SNPs**

In properly selected patients, opioids can be effective treatments for acute moderate to severe pain, as well as chronic moderate to severe pain. Similar to tricyclic antidepressants, most opioids are metabolized by the CYP450 enzyme class (Table 11.3). Hence, SNPs in CYP450s can have an impact on clinical analgesic and adverse effect responses.

In particular, codeine has been associated with variable individual clinical responses. Codeine itself is a prodrug: a medication that is inactive until it is enzymatically converted to its active metabolite. Codeine must be converted to morphine via CYP2D6 to provide analgesia. In addition to codeine, CYP2D6 poor metabolizers may experience suboptimal analgesic efficacy when prescribed “routine” doses of tramadol. This is because the analgesic benefit attributed to its opioid-related mechanism of action requires that tramadol first be metabolized via a CYP2D6-based mechanism to an active metabolite. The metabolism of many currently available opioids can be affected by SNPs with the CYP450 system; however, three opioid analgesic medications are not metabolized through this system at prescribed doses: hydrocodone, morphine, and oxymorphone. Therefore, if it has been identified, perhaps by noting poor analgesic efficacy or intolerable adverse effects (or even possibly actual pharmacogenetic testing) that an individual has a SNP that alters the enzymatic activity of one or more of the CYP450 isoenzymes, an opioid analgesic (if otherwise appropriate for that patient) might be considered that is not metabolized through this mechanism in order to increase the likelihood of a successful treatment outcome.

The current clinical value of pharmacogenomic research illustrates that pharmacogenomic data may play a role in risk stratification and may help guide prescribers in their decision making. Relevant to the patient presented previously, 41% to 51% of individuals of Asian origin express an unstable CYP2D6 enzyme, whereas 12% to 21% of Caucasian people express an inactive CYP2D6 enzyme. However, in clear contrast, 10% to 29% of people of Ethiopian or Saudi Arabian descent have heightened CYP2D6 activity. When considered for the purposes of clinical decision making, this pharmacogenomic information can provide clues about how a specific patient may respond to codeine and
other opioids metabolized by CYP2D6 and, thereby, offer prescribing guidance (see Table 11.3). The patient presented earlier may be genetically predisposed to low CYP2D6 activity, and his inherent enzymatic capacity may be not be sufficient to obtain analgesia from the prodrug codeine as well as other opioids such as hydrocodone (hydrocodone is metabolized to hydromorphone through a CYP450-dependent process). Pharmacogenomic information may provide the connection between the opioid prescribed and the lack of expected clinical response or the presence of unexpected adverse effects. Opioid responsiveness is widely recognized as a highly individualized phenomenon that depends on many factors, including pain etiology, prior exposure to opioids and opioid tolerance level, and other psychophysiologic determinants. Consequently, pharmacogenomics can have a significant impact on the clinical response to opioid therapy.

CYP, cytochrome P450; UGT, uridine diphosphate glucosyltransferase.

Recognizing that morphine and most clinically used opioids act via the μ-opioid receptor, the concept of μ-opioid receptor multiplicity has been studied with the recognition that different splice variants of the MOR-1 gene exist with the potential to clinically affect the benefits or lack thereof of morphine as well as other opioid analgesics. This kind of information will likely affect the manner in which clinicians prescribe opioids in the future.
ALTERNATIVE SPlicing

Although most studies concerning opioid-response variability have focused on SNPs, other investigators are examining cellular mechanisms that may contribute to the interindividual variable response to opioid analgesics. Evidence has identified multiple µ-opioid receptor subtypes, often referred to as “splice variants,” with distinct properties that influence the pharmacodynamics of individual opioids. To understand this source of diversity, consider a brief review of the central tenets of molecular biology. Genetic material, DNA, is transcribed into ribonucleic acid (RNA) and then translated into proteins, with cellular structural, enzymatic, and receptor functions. SNPs are sources of variation in the DNA, while diversity is also introduced during the transcription of RNA, during which alternative splice variants are produced. This idea was proposed in the 1980s by Nobel Prize winner Walter Gilbert and has since been well characterized and is recognized as the major source of proteome diversity enabling the complexity of human traits.

Alternative splice variants of the µ-opioid receptor have been identified and have been correlated with the clinical phenomenon of incomplete cross-tolerance by which tolerance to one opioid does not translate to tolerance to other opioids. In addition, although most clinically used opioids are selective for the µ-opioid receptor, their ability to activate the receptor can vary, leading to widely different efficacies and side effect profiles between individual patients. In fact, the minimal effective analgesic concentration for morphine can vary among patients by as much as 10-fold. Further response variation within an individual is related to gene expression patterns changing over time and even diverging across organ systems and tissues, based on an individual’s state of health and the degree or type of physiologic or emotional stress present.

As previously mentioned, clinically significant response variation in both the efficacy and adverse events of opioids as well as other analgesics has been noted for many years. Chronic opioid therapy treatment guidelines developed by the American Pain Society and the American Academy of Pain Medicine recommend considering “opioid rotation” (e.g., switching from one opioid to another) if the initially prescribed opioid is neither well tolerated nor clinically effective after a reasonable trial. Genetic variance can impact the therapeutic response to opioids as well as other analgesics and can influence the pharmacodynamics of individual opioids. Evidence has identified multiple µ-opioid receptor subtypes, often referred to as “splice variants,” with distinct properties that influence the pharmacodynamics of individual opioids.

Grilo and colleagues completed a study of 67 patients with chronic noncancer pain. They found that the first long-acting opioid prescribed was effective for 36% of patients. However, the initially prescribed opioid had to be discontinued because of adverse effects in 30% or ineffectiveness in 34% of those studied. Eventually, a clinical response was obtained by changing to a second (31% responded), third (40% of the remainder responded), fourth (56% of the remainder responded), and fifth (14% of the remainder responded) opioid. These data, however, do not indicate that eventually a patient will respond to a particular opioid and thus it is important to note that the failure of one opioid does not predict the patient’s response to another opioid analgesic. The concept of opioid rotation is based not only on empirical clinical observations but also on the pharmacogenetic considerations discussed earlier. Safe and effective opioid rotation requires specific clinical knowledge; if opioid rotation is believed to be an appropriate approach to managing the care of an individual patient, guidelines are available for the calculation of equianalgesic dosing and other important steps in this process.

When a patient seeks treatment from a health care provider because of a symptom such as pain, the initial focus is on the patient’s medical history and the underlying pathology—a hunt to identify the broken body part, which is treated to eliminate the symptom. In chronic diseases there may be no cure currently available and the best that can be accomplished is alleviation of the symptoms. However, it is important to maintain a longitudinal perspective that a patient with symptoms has a learning history that existed before the onset of the symptoms, as well as contextual factors that are present throughout the course of the medical condition. Both will have important influence on how symptoms are experienced and how the patient adapts to the symptoms and responds to treatment.

Chronic pain, like many chronic diseases, is a demoralizing state that confronts individuals not only with the distress created by the symptoms but also with many other ongoing difficulties that compromise all aspects of their lives. Living with chronic disease requires considerable emotional resilience because it depletes people’s emotional reserves. Individuals with chronic pain have a continuing quest for relief that often remains elusive; this can lead to feelings of demoralization, helplessness, hopelessness, and outright depression.

It is also important to keep in mind that most people do not live in isolation but within a social context. Thus, chronic symptoms tax not only the individual but also the capacity of significant others who provide instrumental and emotional support. Health care providers share patients’ and significant others’ feelings of frustration as reports of symptoms continue despite providers’ best efforts and at times in the absence of pathologic signs that can account for the symptoms reported.

In chronic pain syndromes (e.g., osteoarthritis, fibromyalgia, diabetic painful neuropathy), the pain does not appear to have any obvious useful function. Pain that is chronic can significantly compromise quality of life and, if unrelenting, may actually produce physical harm by suppressing the body’s immune system.\(^1\) Historically, a number of models have been postulated to explain chronic pain. Several are outlined below.

### BIOMEDICAL MODEL OF CHRONIC PAIN

The traditional biomedical model of pain—which dates back to the ancient Greeks and was inculcated into medical thinking and practice by Descartes in the 17th century—assumes that people’s reports of pain result from a specific disease state represented by disordered anatomy and physiology. The diagnosis is confirmed by data from objective tests showing physical damage and impairment, and medical interventions are specifically directed toward correcting the organic dysfunction or organic source of pathology.

Health care providers often undertake Herculean efforts (frequently at great expense to the patient or third-party payer) in an attempt to establish the specific link between objective indications of tissue damage and the reported severity of pain. The expectation is that once the physical cause has been identified, appropriate treatment will follow. Treatment will then focus on eliminating or blocking the putative cause or causes of the pain by chemical (e.g., oral medication, regional anesthesia, implantable drug delivery systems), surgical (e.g., laminectomy, spinal fusion), or electrical (e.g., spinal cord stimulation, transcutaneous electrical nerve stimulation) manipulation of the pain pathway.

There are several perplexing features of chronic pain that do not fit neatly within the traditional biomedical model, specifically, its suggestion of an isomorphic relationship between pathology and symptoms. For example, pain may be reported even in the absence of an identified pathologic process. It is estimated that one third to one half of all visits to primary care physicians are prompted by symptoms for which no biomedical causes can be detected.\(^2\) In up to 86% of cases, the cause of back pain is unknown despite the performance of sophisticated imaging.\(^3\)

Conversely, significant pathology is noted in up to 35% of asymptomatic people with imaging studies such as computed tomography and magnetic resonance imaging.\(^4,6\) Yet these individuals do not appear to experience any pain. Thus, some report severe pain with no identifiable pathology, and those with demonstrable pathology may not complain of or even experience any pain.

People differ markedly in how frequently they report physical symptoms, in their propensity to visit physicians when experiencing identical symptoms, and, as noted, in their response to the same treatments.\(^7,8\) There are large numbers of people with chronic pain problems who do not seek medical attention. For example, in a survey of nurses, Linton and Buer\(^9\) found that the majority reported moderate to severe pain “often or always,” but they indicated that they had not missed a single day of work because of pain. Similarly, Hicks and colleagues\(^10\) observed that almost half of a community-dwelling sample of older people reported considerable back pain, yet the majority did not seek any medical care.

Often the nature of patients’ responses to treatment has little to do with their objective physical condition.\(^11\)
For example, White and associates\(^{12}\) noted that less than a third of people with clinically significant symptoms consult a physician. Conversely, 30% to 50% of patients who seek treatment in primary care do not have specific diagnosable disorders,\(^{13}\) and in up to 80% of people reporting back pain\(^ {3}\) and the majority of people with chronic headache, no physical basis for the pain can be identified.

There are several potential explanations, not the least of which is the availability of health insurance to cover the costs. As often happens in medicine, when biologic explanations for symptoms are unknown, inadequate, or inconsistent, psychogenic explanations are posed as alternatives.

**PSYCHOGENIC MODEL OF CHRONIC PAIN**

The psychogenic view is the reverse side of the coin of the biomedical model. In this case, if a patient’s report of pain occurs in the absence of objective physical pathology or is disproportionate to the pathology, the pain reports are attributed to a psychological etiology and thus are “psychogenic.” It may be treated as a psychiatric diagnosis within the fourth edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders, Revised*\(^ {14}\), pain disorder associated with psychological factors or even a pain disorder associated with psychological factors and a general medical condition.

Although the notion of psychogenic pain is ubiquitous, empirical evidence supporting it is scarce. A substantial number of patients with chronic pain do not exhibit significant psychopathology. Moreover, studies suggest that in the majority of cases, the emotional distress observed in these patients occurs in response to the persistence of pain and not as a causal agent\(^ {15,16}\) and may resolve once the pain is adequately treated.\(^ {17}\)

**SECONDARY-GAIN MODEL OF CHRONIC PAIN**

The secondary-gain (motivational) model is an alternative to the psychogenic model. From this perspective, reports of pain in the absence of or in excess of the physical pathology are attributed to the desire of the patient to obtain some benefit, such as attention, time off from undesirable activities, or financial compensation—secondary gains. In contrast to the psychogenic model, in the secondary-gain view the assumption is that the patient is consciously attempting to acquire a desirable outcome. Simply put, the complaint of pain in the absence of a pathologic process is regarded as fraudulent.\(^ {18}\)

**BEHAVIORAL CONCEPTUALIZATIONS**

Pain is an unavoidable part of human life. No learning is required to activate nociceptive receptors. However, pain is a potent and salient experience. Beyond mere reflexive actions, people must learn to avoid, modify, or cope with noxious stimulation. There are three major principles of behavioral learning that can help us understand the acquisition of adaptive as well as dysfunctional behavior associated with pain.

**CLASSIC (RESPONDENT) CONDITIONING**

In his classic experiment, Pavlov discovered that a dog could be taught, or “conditioned,” to salivate at the sound of a bell by pairing the sound with food presented to a hungry dog. Salivation of dogs in response to food is a natural response; however, by preceding the feeding with the sound of a bell, Pavlov’s dogs learned to associate the sound of the bell with imminent feeding. Once this association was learned, or “conditioned,” the dogs were found to salivate at the mere sound of the bell even in the absence of food.

The influence of classic conditioning can be observed in pain patients. Consider physical therapy, a mainstay of treatment for chronic pain patients, where treatment may evoke a conditioned fear response. For example, a patient who experienced increased pain following physical therapy may become conditioned and experience a negative emotional response to the presence of the physical therapist, to the treatment room, and to any contextual cues associated with the nociceptive stimulus. The negative emotional reaction may lead to tensing of muscles, which in turn may exacerbate the pain and thereby further strengthen the association between the presence of the physical therapist and pain.

Once a pain problem persists, fear of motor activities may become increasingly conditioned and result in avoidance of activity in the anticipation of avoidance of pain. Avoidance of pain is a powerful rationale for reduction of activity, where the muscle soreness associated with exercise functions as a justification for further avoidance. Consequently, although it may be useful to reduce movement in the acute stage of pain, limitation of activities can be maintained not only by the pain but also by an anticipatory fear that has been acquired through the mechanism of classic conditioning. Thus, cognitive processes may interact with pure conditioning. It is the anticipation that motivates a conscious decision to avoid specific behavior or stimuli.

With chronic pain, many activities that were initially neutral or even pleasurable may now elicit or exacerbate pain. As a consequence, they are experienced as aversive and actively avoided. Over time, a greater number of stimuli (e.g., activities) may be expected to elicit or exacerbate pain and will be avoided. This process is referred to as *stimulus generalization*. Thus, the anticipatory fear of pain and restriction of activity—and not just the actual nociception—may contribute to disability. Anticipatory fear can also elicit physiologic reactivity, which may aggravate the pain. As a result, conditioning may directly increase nociceptive stimulation and subsequently the perception of pain.

The conviction by patients that they should remain inactive is difficult to modify as long as avoidance of activity succeeds in preventing aggravation of the pain. By contrast, repeatedly engaging in behavior—*exposure*—that produces progressively less pain than was predicted (corrective feedback) will be followed by a reduction in anticipatory fear and anxiety associated with the activity.\(^ {19}\) Such transformations add support to the importance of a quota-based physical exercise program, with patients gradually and progressively increasing their activity levels despite fear of injury and discomfort associated with the use of deconditioned muscles.\(^ {20}\)
This exposure, in the absence of anticipated pain, provides the corrective feedback that should be positively reinforcing and increase the likelihood of continuing previously avoided activities.

**OPERANT CONDITIONING—CONTINGENCIES OF REINFORCEMENT**

The effect of environmental factors in shaping the experience of people with pain was acknowledged long ago. However, a new era in thinking about pain began with Fordyce's extension of operant conditioning to chronic pain. The main focus of operant learning is modifying the frequency of a given behavior—increasing desirable behavior and extinction of maladaptive behavior. The fundamental principle is that if the consequence of a given behavior is rewarding, its occurrence increases, whereas if the consequence is aversive, the likelihood of its occurrence decreases.

When a person is exposed to a stimulus that causes tissue damage, the immediate behavioral response is withdrawal in an attempt to escape from noxious sensations. Such reflexive behavior is adaptive and appropriate. Behavior associated with pain, such as limping and moaning, is called pain behavior. Pain behavior includes overt expressions of pain, distress, and suffering. A critical defining feature of overt behavior is that it is observable and thus has a communicative function. If behavior is observable, it is capable of evoking responses, and it is the consequences following the behavior that are particularly important because they can serve to maintain or diminish the likelihood of the behavior recurring. According to Fordyce, pain behavior can become subject to the principles of operant conditioning. Such behavior may be positively reinforced directly, such as by attention from a family member, acquaintance, or health care provider. The principles of learning suggest that behavior that is positively reinforced will occur more frequently. Pain behavior may also be maintained by escaping the noxious stimulation with the use of drugs or rest or by avoiding undesirable activities. In addition, well behavior (e.g., activity, working) may not be positively reinforced, and the more rewarding pain behavior may therefore be maintained.

The following example illustrates the role of operant conditioning. When back pain flares up, the individual may lie down and hold her back. Her husband may observe her behavior and respond by offering to rub her back. This response may positively reward the woman, and her pain behavior (i.e., lying down) may be repeated even in the absence of severe pain. In other words, her pain behavior is being maintained by the learned consequences. The woman’s pain behavior may be negatively reinforced if she is permitted to avoid undesirable activities. For example, her husband may suggest that they cancel their evening plans with his brother, an activity that she preferred to avoid in the past. In this situation, her husband provided extra attention, comfort, and the opportunity to avoid an undesirable social obligation.

Table 12.1 presents examples of basic operant principles in chronic pain. The operant learning paradigm does not explain the etiology of pain or initiation of the behavior but rather focuses primarily on maintenance of pain behavior and deficiency of well behavior. Adjustment of reinforcement principles will likely modify the probability of recurrence of pain behavior and well behavior.

It is important not to make the mistake of viewing pain behavior as being synonymous with malinger. Malingering involves the patient consciously and purposely faking a symptom such as pain for some gain, usually financial (secondary gain). In the case of pain behavior, there is no suggestion of conscious deception but rather the unintended performance of pain behavior resulting from environmental reinforcement contingencies. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent.

**SOCIAL-LEARNING PROCESSES**

From the social-learning perspective, pain behavior may be acquired through observational learning and modeling processes. That is, people can acquire behavioral responses that were not previously in their repertoire by the observation of others, particularly those whom they view as similar to themselves.

Children develop attitudes about health and health care and the perception and interpretation of symptoms and physiologic processes from their parents and the social environment. They learn appropriate and inappropriate responses to injury and disease and thus may be more or less likely to ignore or over-respond to the symptoms that they experience as a result of behavior modeled in childhood. The culturally acquired perception and interpretation of symptoms determine how people deal with disease states. The observation of others in pain is an event that captivates attention. Such attention may have survival value, may help avoid experiencing more pain, and may help learn what to do about acute pain.

From the earliest years, infants, toddlers, and young children are exposed to numerous painful episodes from bumps and falls. Thus they have plenty of opportunity to observe the reactions that they receive. Children of parents with chronic pain may make more pain-related responses during stressful times than would children with healthy parents. These children tend to exhibit greater illness behavior (e.g., complaints, days absent from school, visits to the school nurse) than do children of healthy parents. Models can influence the expression, localization, and methods of coping with pain. Physiologic responses may even be conditioned during observation of others in pain. Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior experience either directly or from the observation of others. This may
contribute to the marked variability in response to objectively similar degrees of physical pathology observed.

The biomedical, psychogenic, secondary-gain, and behavioral views are unidimensional. Reports of pain are ascribed to either physical or psychological factors. Rather than being categorical, either somatogenic or psychogenic, both physical and psychological components may interact to create and influence the perception and experience of pain.

Any physical abnormalities that are identified may be moderated by coexisting psychosocial influences. The complexity of pain is especially evident when it persists over time, during which a range of psychological, social, and economic factors interact with the physical pathology to modulate patients’ reports of pain and the impact of pain on their lives. In the case of chronic pain, health care providers need to not only search for the physical source of the pain through examination and diagnostic tests but also examine the patient’s mood, fears, expectancies, coping efforts, and resources; the responses of significant others; and the impact of pain on the patient’s life.

Persons experiencing pain, particularly chronic pain, have a continuing quest for relief that remains elusive, which can lead to feelings of frustration, demoralization, and depression, thus compromising the quality of all aspects of their lives. People with chronic pain are confronted with not only the stress of pain but also a cascade of ongoing problems (e.g., financial, interpersonal). Moreover, the experience of “medical limbo” (i.e., the presence of a painful condition that eludes diagnosis and carries the implication of either psychiatric causation or malingering on the one hand or an undiagnosed potentially disabling condition on the other) is itself a source of significant stress and can result in psychological distress.

Biomedical factors, in the majority of cases, appear to instigate the initial report of pain. Over time, however, psychosocial and behavioral factors may serve to maintain and exacerbate the level of pain, influence adjustment, and contribute to excessive disability. Following from this view, pain that persists over time should not be viewed as being solely physical or solely psychological; the experience of pain is maintained by an interdependent set of biomedical, psychosocial, and behavioral factors.

People with chronic pain frequently terminate active efforts to manage the pain and instead turn to passive coping strategies, such as inactivity, medication, or alcohol, to reduce the pain and emotional distress. They also absolve themselves of personal responsibility for managing their pain and as a substitute rely on family and health care providers. The thinking of chronic pain patients has been shown to contribute to the exacerbation, attenuation, and maintenance of pain, pain behavior, affective distress, adjustment to chronic pain, health care seeking, response to treatment, and disability.

The important role of the behavioral and environmental contingencies of reinforcement in chronic pain has already been described. However, another set of psychological factors—affective and cognitive factors—play equally important roles.

### Affective Factors

Pain is ultimately a subjective, private experience, but it is invariably described in terms of sensory and affective properties. As defined by the International Association for the Study of Pain, “[Pain] is unquestionably a sensation in a part or parts of the body but it is also always unpleasant and therefore also an emotional experience.” The central and interactive roles of sensory information and the affective state are supported by an overwhelming amount of evidence. The affective components of pain include many different emotions, but they are primarily negative emotions. Depression and anxiety have received the greatest amount of attention in chronic pain patients; however, anger has recently attracted considerable interest as an important emotion in chronic pain patients.

In addition to affecting one of the three interconnected components of pain, pain and emotions interact in a number of ways. Emotional distress may predispose people to experience pain, be a precipitant of symptoms, be a modulating factor that amplifies or inhibits the perception of pain severity, be a consequence of persistent pain, or be a perpetuating factor. Moreover, these potential roles are not mutually exclusive, and any number of them may be involved in a particular circumstance and interact with cognitive appraisal. For example, the literature is replete with studies demonstrating that the current mood state modulates reports of pain, as well as tolerance of acute pain.

Levels of anxiety have been shown to influence not only the severity of pain but also complications following surgery and the number of days of hospitalization required. The level of depression has been observed to be closely tied to chronic pain.

Although we provide an overview of research on the predominant emotions—anxiety, depression, and anger—associated with pain individually, it is important to acknowledge that these emotions are not as distinct when it comes to the experience of pain. They interact and augment each other over time.

### Anxiety

It is common for patients with symptoms of pain to be anxious and worried, especially when the symptoms are unexplained, as is often the case with chronic pain syndromes. For example, in a large-scale, multicenter study of patients with fibromyalgia syndrome, between 44% and 51% acknowledged that they were anxious. People with persistent pain may be anxious about the meaning of their symptoms and their future—will their pain increase, will their physical capacity diminish, or will their symptoms result in progressive disability wherein they ultimately need a wheelchair or are bedridden? In addition to these sources of fear, those with persistent pain may be worried that, on the one hand, people will not believe that they are suffering and, on the other, they may be told that they are beyond help and will “just have to learn to live with it.” Fear and anxiety also relate to activities that people with pain anticipate will increase their pain or exacerbate whatever physical factors might be contributing to the pain. These fears may contribute to avoidance and motivate inactivity and, ultimately, greater disability. Continual vigilance and monitoring for noxious stimulation and the belief that it signifies progression of disease may render even low-intensity aversive sensations less bearable. In addition, such fears will contribute to increased muscle tension and physiologic arousal, which may exacerbate and maintain the pain.
The threat of intense pain captures attention in such a way that individuals have difficulty disengaging from it. The experience of pain may initiate a set of extremely negative thoughts, as noted previously, and arouse fear—fear of inciting more pain and injury or fear of their future impact. Fear and anticipation of pain are cognitive-perceptual processes that are not driven exclusively by the actual sensory experience of pain and can exert a significant impact on the level of function and pain tolerance. People are motivated to avoid and escape from unpleasant consequences; they learn that avoidance of situations and activities in which they have experienced acute episodes of pain will reduce the likelihood of re-experiencing pain or causing further physical damage. They may become hypervigilant to their environment as a way of preventing the occurrence of pain.

Investigators have suggested that fear of pain, driven by the anticipation of pain and not by the sensory experience of pain itself, produces strong negative reinforcement for the persistence of avoidance behavior and the putative functional disability in pain patients. Avoidance behavior is reinforced in the short term through a reduction of the suffering associated with noxious stimulation. Avoidance, however, can be a maladaptive response if it persists and leads to increased fear, limited activity, and other physical and psychological consequences that contribute to disability and persistence of the pain.

Studies have demonstrated that fear of movement and fear of injury or reinjury are better predictors of functional limitation than biomedical parameters or even the severity and duration of the pain are. For example, Crombez and colleagues showed that pain-related fear was the best predictor of behavioral performance in trunk extension, flexion, and weight-lifting tasks, even after the effects of pain intensity are statistically controlled. Moreover, Vlaeyen and associates found that fear of movement and injury or reinjury was the best predictor of self-reported disability in chronic back pain patients and that the physiologic sensory perception of pain and biomedical findings did not add any predictive value. The importance of fear of activity appears to generalize to daily activities, as well as to the clinical experimental context. Approximately two thirds of people with chronic low back pain avoid back-straining activities because of fear of injury. For example, fear avoidance beliefs about the physical demands of a job are strongly related to disability and work lost during the previous year, even more so than the severity of pain or other pain variables. Interestingly, a reduction in pain-related anxiety predicts improvement in functioning, affective distress, pain, and pain-related interference with activity. Clearly, pain-related anxiety, and concerns about avoidance of harm all play important roles in chronic pain and need to be assessed and addressed during treatment.

Pain-related fear and concerns about avoidance of harm both appear to exacerbate symptoms. Anxiety is an affective state that is greatly influenced by appraisal processes; to cite the stoic philosopher Epictetus, “There is nothing either bad or good but thinking makes it so.” Thus, there is a reciprocal relationship between the affective state and cognitive-interpretive processes. Thinking affects mood, and mood influences appraisals and, ultimately, the experience of pain.

DEPRESSION

Clinical data suggest that 40% to 50% of chronic pain patients experience significant depression. Epidemiologic studies provide abundant evidence confirming a strong association between chronic pain and depression but do not address whether chronic pain causes depression or depression causes chronic pain. Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression, and that depression can cause chronic pain, and that they exist in a mutually reinforcing relationship.

One fact often raised to support the idea that pain causes depression is that the current depressive episode often began after onset of the pain problem. The majority of studies appear to support this contention. However, several studies have documented that many patients with chronic pain, especially disabled patients seen in pain clinics, have often had previous episodes of depression that predated their pain problem by years. It is important to acknowledge that studies based on patients treated at pain treatment facilities may be biased in that patients treated at these facilities have been shown to have exceedingly high levels of depression, which may have prompted referral, and they may not be representative of all individuals with persistent pain. One important prospective study demonstrated that levels of depression predicted the development of low back pain 3 years following the initial assessment. Patients with depression were 2.3 times more likely to report back pain than were those who did not report depression. Depression was a much stronger predictor of incident back pain than any clinical or anatomic risk factors. This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and to negative psychological symptoms (including anxiety and depression). They concluded that “pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation.” Once chronic pain has been diagnosed, it no longer matters which is the cause and which is the consequence—pain or depression. Both need to be treated.

It is not surprising that a large number of chronic pain patients are depressed. It is interesting to ponder the converse. Given the nature of the symptom and the problems created by chronic pain, why is it that all such patients are not depressed? Turk and colleagues examined this question and determined that patients’ appraisal of the effects of the pain on their lives and their ability to exert any control over the pain and their lives mediated the link between pain and depression. That is, patients who believed that they could continue to function despite their pain and who believed that they could maintain control despite their pain did not become depressed.

ANGER

Anger has been widely observed in people with chronic pain. Pilowsky and Spence reported “bottled-up anger” in 53% of chronic pain patients. Kerns and coworkers noted that internalization of angry feelings was strongly
related to measures of pain intensity, perceived interference, and the reported frequency of pain behavior. Summers and colleagues\(^6\) examined patients with spinal cord injuries and found that anger and hostility were powerful predictors of pain severity. Moreover, even though chronic pain patients in psychotherapy might present an image of themselves as being even tempered, 88% of the patients treated acknowledged their feelings of anger when explicitly sought.\(^6\)

Frustrations related to the persistence of symptoms, limited information on etiology, and repeated treatment failures, along with anger toward employers, insurers, the health care system, family members, and themselves, all contribute to the general dysphoric mood of these patients. The effects of anger and frustration on exacerbation of pain and acceptance of treatment have not received much attention, but it would be reasonable to expect that the presence of anger may serve as a complicating factor that increases autonomic arousal and blocks motivation and acceptance of treatments oriented toward rehabilitation and management of the disability rather than cure, which are often the only treatments available for chronic pain.\(^6\)

When a person with pain is angry, there are a range of possible targets (e.g., employer, insurance company, health care providers). Fernandez and Turk\(^6\) proposed that the specificity of targets toward which patients direct angry feelings may be important in understanding the relationship between pain and anger. There may be some targets of anger that are more relevant to the chronic pain experience than others.

Okifuji and colleagues\(^6\) found that 60% of patients expressed anger toward health care providers, 39% toward significant others, 30% toward insurance companies, 26% toward employers, and 20% toward attorneys. The target of anger most commonly acknowledged, however, was oneself (endorsed by approximately 70% of the sample). Overall, correlations between anger and pain severity have been shown to be statistically significant and range from .17 to .35.\(^6\)\(^1\)\(^6\)\(^6\)\(^6\)\(^6\) Okifuji and coauthors\(^6\) reported that anger was significantly correlated with pain intensity \((r = .30\) to \(.35)\). They also reported that anger was significantly correlated with disability \((r = .26)\) and was highly associated with depression \((r = .52)\).

The precise mechanisms by which anger and frustration exacerbate pain are not known. One reasonable possibility is that anger exacerbates pain by increasing physiologic arousal.\(^6\) For example, Burns and coauthors\(^6\) reported the results of a study in which it was demonstrated that anger-induced stress produces increased muscle tension, which in turn predicts greater severity of pain in chronic back pain patients. It was found that this effect was specific to anger; a measure of depression that was significantly correlated with pain was not associated with increased muscle reactivity.

A negative mood in chronic pain patients is likely to affect treatment motivation and adherence to treatment recommendations. For example, patients who are anxious may fear engaging in what they perceive as demanding activities, patients who are depressed and feel helpless may have little initiative to comply, and patients who are angry with the health care system are not likely to be motivated to respond to recommendations from yet another health care professional.

### COGNITIVE FACTORS

Persistent pain beliefs, appraisals, and expectations about pain, the ability to cope, social supports, the disorder, the medicoegal system, the health care system, and employers are all important because they may facilitate or disrupt an individual’s sense of control. These factors also influence patients’ investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectations regarding treatment, and acceptance of the treatment rationale.

Cognitive interpretations also affect how patients relate symptoms to others, including health care providers. Overt communication of pain, suffering, and distress will elicit responses that may reinforce pain behavior and impressions about the seriousness, severity, and uncontrollability of the pain. That is, reports of pain may induce physicians to prescribe more potent medications, order additional diagnostic tests, and in some cases perform surgery.\(^6\) Family members may express sympathy, excuse the patient from responsibilities, and encourage passivity, thereby fostering further physical deconditioning. The cognitive-behavioral perspective integrates the emphasis of operant conditioning on external reinforcement and the respondent view of conditioned avoidance within the framework of information processing.

People with persistent pain often have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, they often view themselves as helpless. Such negative, maladaptive appraisals about their condition, situation, and personal efficacy in controlling their pain and problems associated with the pain reinforce their experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals are posited as having an effect on behavior that leads to reduced effort, reduced perseverance in the face of difficulty, decreased activity, and increased psychological distress.

Pain and emotions interact in a number of ways, which in turn may interact with cognitive appraisal of the pain state. Research has consistently demonstrated that patients’ attitudes, beliefs, and expectancies about their plight, themselves, their coping resources, and the health care system affect reports of pain, activity, disability, and response to treatment.

### BELIEFS ABOUT PAIN

People respond to medical conditions in part based on their subjective ideas about illness and their symptoms. Health care providers working with chronic pain patients are aware that patients with similar pain histories and reports of pain may differ greatly in their beliefs about their pain. Behavior and emotions are influenced by interpretation of events and expectations rather than solely by objective characteristics of the event itself. Thus pain, when interpreted as signifying ongoing tissue damage or a progressive disease, is likely to produce considerably more distress and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve.
People build fairly elaborate views of their physical state, and these views or representations provide the basis for action plans and coping. Beliefs about the meaning of pain and individuals’ ability to function despite discomfort are important aspects of expectations about pain. For example, a cognitive representation that you have a very serious, debilitating condition, that disability is a necessary aspect of pain, that activity is dangerous, and that pain is an acceptable excuse for neglecting responsibilities will probably result in maladaptive responses.

Chronic pain patients often demonstrate poor behavioral persistence in exercise tasks. Their performance on these tasks may be independent of physical exertion or actual self-reports of pain but rather be related to previous pain reports or anticipation and fear of injury, reinjury, or exacerbation of their pain. These people appear to have a negative view of their ability and expect increased pain if they perform physical exercises. Thus, the rationale for their avoidance of exercise was not the presence of pain but their learned expectation of heightened pain and the accompanying physical arousal that might exacerbate the pain and reinforce their beliefs regarding the pervasive ness of their disability. When people experience pain and have a negative perception of their capability for physical performance, a vicious circle is formed, with failure to perform activities reinforcing the perception of helplessness and incapacity. Once again we can see how behavioral (conditioning) factors interact with cognitive processes.

Certain beliefs may lead to maladaptive coping, increased distress, and greater disability. People who believe that their pain will persist may be passive in their coping and fail to make use of strategies to cope with pain. People who consider their pain to be an unexplainable mystery may negatively evaluate their own ability to control or decrease pain and are less likely to rate their coping strategies as effective in controlling and decreasing pain. People’s beliefs, appraisals, and expectancies regarding the consequences of an event and their ability to cope and adapt to their symptoms and changed life circumstances are hypothesized to function in two ways. There may be a direct influence on physiologic arousal and mood and an indirect one through their effects on coping efforts.

Once beliefs and expectancies are formed, they become stable and are very difficult to modify. As noted, individuals with persistent pain tend to avoid experiences that could invalidate their beliefs and guide their behavior in accordance with these beliefs, even in situations in which these beliefs are no longer valid. Consequently, as noted previously, they do not obtain corrective feedback.

It is essential for people with chronic pain to develop adaptive beliefs about the relationships among impairment, pain, distress, and disability and to de-emphasize the role of experienced pain in their regulation of functioning. In fact, results from numerous treatment outcome studies have shown that changes in pain level do not parallel changes in other variables of interest, including activity level, medication use, return to work, rated ability to cope with pain, and pursuit of further treatment. If health care providers hope to achieve better outcomes and to reduce their frustration from patients’ lack of compliance with their advice, they need to learn about and to address patients’ concerns within this therapeutic context.

**SELF-EFFICACY**

Self-efficacy is a personal expectation that is particularly important in patients with chronic pain. A self-efficacy expectation is specifically defined as a personal conviction that you can successfully execute a course of action (perform the required behavior) to produce a desired outcome in a given situation. Given sufficient motivation to engage in a behavior, it is a person’s self-efficacy beliefs that determine the choice of activities that the person will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences. Efficacy judgments are based on four sources of information regarding capabilities, listed in descending order of effects: (1) past performance at the task or similar tasks, (2) the performance accomplishments of others who are perceived to be similar, (3) verbal persuasion about capabilities, and (4) perception of the state of physiologic arousal.

In chronic pain patients, self-efficacy positively affects physical and psychological functioning. Self-efficacy is also an important mediator of therapeutic change.

Prospective studies in patients who underwent orthopedic surgery have demonstrated that high self-efficacy before the start of rehabilitation and larger increases over the course of rehabilitation speed recovery and predict better long-term outcomes. Improvements in self-efficacy after self-management and cognitive-behavioral interventions have been shown to be associated with improvements in pain, functional status, and psychological adjustment.

The experience of performance mastery can be created by encouraging patients to undertake subtasks that are initially attainable but become increasingly difficult and subsequently approach the desired level of performance. In a quota-based physical therapy system, the initial goal is set below the initial performance to increase mastery of performance. It is important to remember that coping behavior is influenced by a person’s beliefs that the demands of a situation do not exceed the person’s coping resources. For example, Council and colleagues asked patients to rate their self-efficacy, as well as their expectancy of pain related to performance during movement tasks. Patients’ performance levels were highly related to their expectations of self-efficacy, which in turn appeared to be determined by their expectancy regarding levels of pain that would be experienced.

**CATASTROPHIC THINKING**

Pain catastrophizing can be defined as an exaggerated negative orientation toward actual or anticipated pain experiences. There has been much debate about the specific nature of catastrophizing as a psychological construct. However, current conceptualizations most often describe it in terms of appraisal or as a set of maladaptive beliefs.

It appears to be a particularly potent way of thinking that greatly influences pain and disability. Evidence for the role of pain catastrophizing in chronic pain adjustment is overwhelming and has been summarized in several review articles and studies.

Prospective studies have indicated that catastrophizing might be predictive of the inception of chronic musculoskeletal pain.
in the general population and of more intense pain and slower recovery after surgical intervention. Several investigators have demonstrated the therapeutic efficacy of reducing catastrophizing.

**COPING**

Self-regulation of pain and its effects depends on the individual’s specific ways of dealing with pain, adjusting to pain, and reducing or minimizing the pain and distress caused by pain—in other words, the individual’s coping strategies. Coping is assumed to be implemented by spontaneously used purposeful and intentional acts, and it can be assessed in terms of overt and covert behavior. Overt behavioral coping strategies include rest, medication, and the use of relaxation. Covert coping strategies include various means of distracting yourself from pain, reassuring yourself that the pain will diminish, seeking information, and problem solving. Coping strategies act to alter both the perception of the intensity of the pain and one’s ability to manage or tolerate the pain and continue everyday activities.

Studies have found active coping strategies (efforts to function despite pain or to distract oneself from pain, such as being active and ignoring the pain) to be associated with adaptive functioning and passive coping strategies (depending on others for help in pain control and restriction of activities) to be related to greater pain and depression. However, beyond this, there is no evidence to support the greater effectiveness of any individual active coping strategy over any other. It seems more likely that different strategies will be more effective than others for some people at some times but not necessarily for all people all of the time.

A number of studies have demonstrated that if patients are instructed in the use of adaptive coping strategies, their rating of intensity of pain decreases and their tolerance of pain increases. The most important factor in poor coping appears to be the presence of catastrophic thinking, not the nature of specific adaptive coping strategies.

Given our discussion of the psychological factors that play a role in pain, we can now consider how these factors can be integrated within a multidimensional model of pain. Pain is a complex subjective phenomenon that consists of a range of factors, each of which contributes to the interpretation of nociception as pain. Thus, each person uniquely experiences pain. A significant factor contributing to the current situation relates to diagnostic uncertainty. The diagnosis of pain is not an exact science. A major problem in understanding pain is that it is a subjective (internal) state. There is no pain thermometer that can accurately measure the amount of pain that a person feels or should be experiencing.

**BIOPSYCHOSOCIAL MODEL**

In contrast to the biomedical model’s emphasis on disease, the biopsychosocial model focuses on illness, which is the result of a complex interaction of biologic, psychological, and social variables. From this perspective, diversity in expression of illness (which includes its severity, duration, and consequences for the individual) is accounted for by the interrelationships among biologic changes, psychological status, and social and cultural contexts; all these variables shape the person’s perception and response to illness.

The biopsychosocial way of thinking about the different responses of people to symptoms and the presence of chronic conditions is based on an understanding of the dynamic nature of these conditions. That is, by definition, chronic conditions extend over time. Therefore, these conditions need to be viewed longitudinally as ongoing, multifactorial processes in which there is a dynamic and reciprocal interplay among biologic, psychological, and social factors that shapes the experience and responses of patients. Biologic factors may initiate, maintain, and modulate physical perturbations; psychological variables influence appraisal and the perception of internal physiologic signs; and social factors shape patients’ behavioral responses to the perceptions of their physical perturbations.

At the same time, psychological factors may influence biology by affecting hormone production, brain structure and processes, and the autonomic nervous system. Behavioral responses may also affect biologic contributors, such as when a person avoids engaging in certain activities to reduce the symptoms. Although avoidance may initially reduce the symptoms, in the long run it will lead to further physical deconditioning, which can exacerbate nociceptive stimulation.

The picture is not complete unless we consider the direct effects of disease factors and treatment on cognitive and behavioral factors. Biologic influences and medications (e.g., steroids, opioids) may affect the ability to concentrate, cause fatigue, and modulate peoples’ interpretation of their state, as well as their ability to engage in certain activities.

At different points during the evolution of a disease or impairment, the relative weighting of physical, psychological, and social factors may change. For example, during the acute phase of a disease, biologic factors may predominate, but over time, psychological and social factors may assume a disproportionate role in accounting for the symptoms and disability. Moreover, there is considerable variability in the behavioral and psychological manifestations of dysfunction, both across persons with comparable symptoms and within the same person over time.

To understand the variable responses of people to chronic conditions, it is essential that biologic, psychological, and social factors all be considered. Moreover, a longitudinal perspective is essential. A cross-sectional approach will permit consideration of these factors only at a specific point in time, and chronic conditions continually evolve. What is observed at any one point in time is a person’s adaptation to interacting biologic, personal, and environmental factors. In sum, the hallmarks of the biopsychosocial perspective are (1) integrated action, (2) reciprocal determinism, and (3) development and evolution. No single factor in isolation—pathophysiology, psychological, or social—will adequately explain chronic pain status. This can be contrasted with the traditional biomedical model, whose emphasis on the somatogenic-psychoanalytic dichotomy is too narrow in scope to accommodate the complexity of chronic pain.

From an integrative biopsychosocial perspective, pain is viewed as a subjective perception that results from the transduction, transmission, and modulation of sensory
input filtered through a person’s genetic composition and previous learning history and modulated further by the person’s current physiologic state, idiosyncratic appraisals, expectations, present mood state, and sociocultural environment.

**CONCLUDING COMMENTS**

It is abundantly clear that pain is not a monolithic entity. No isomorphic relationship exists among tissue damage, nociception, and pain report. The variability in patients’ responses to nociceptive stimuli and treatment is somewhat more understandable when we consider that pain is a personal experience influenced by attention, the meaning of the situation, and previous learning history, as well as by physical pathology. In the majority of cases, biomedical factors appear to instigate the initial report of pain. Over time, however, secondary problems associated with deconditioning may exacerbate and serve to maintain the problem. Inactivity leads to an increased focus on and preoccupation with the body and pain, and these cognitive-attentional changes increase the likelihood of misinterpretation of symptoms, overemphasis on symptoms, and the patient’s self-perception as disabled. Reduction of activity, anger, fear of reinjury, pain, loss of compensation, and an environment that perhaps unwittingly supports the pain patient role can impede alleviation of pain, successful rehabilitation, reduction of disability, and improvement in adjustment.

Pain that persists over time should not be viewed as either solely physical or solely psychological. Rather, the experience of pain is a complex amalgam maintained by an interdependent set of biomedical, psychosocial, and behavioral factors whose relationships are not static but evolve and change over time. The various interacting factors that affect a person with chronic pain suggest that the phenomenon is quite complex and requires a biopsychosocial perspective.

From the biopsychosocial perspective, each of these factors contributes to the experience of pain and the response to treatment. The interaction among the various factors is what produces the subjective experience of pain. There is a synergistic relationship whereby psychological and socioeconomic factors can modulate nociceptive stimulation and the response to treatment. In turn, nociceptive stimulation can influence patients’ appraisal of their situation and the treatment, their mood states, and the ways that they interact with significant others, including medical practitioners. An integrative, biopsychosocial model of chronic pain needs to incorporate the mutual interrelationships among physical, psychological, and social factors and the changes that occur in these relationships over time.28,29 A model and treatment approach that focuses on only one of these three core sets of factors will inevitably be incomplete.

The current state of knowledge suggests that pain must be viewed as a complex biopsychosocial phenomenon that incorporates physical, psychosocial, and behavioral factors. Failure to incorporate each of these factors will lead to incomplete understanding and unsuccessful treatment of people who experience and live with chronic pain.

**KEY POINTS**

- Focusing exclusively on the symptoms, anatomy, and physiology of patients with chronic pain is inadequate because a range of individual variables, prior experiences and learning history, and social context all influence reporting of symptoms, adaptation, disability, and response to treatments.
- To understand patients with chronic pain, a longitudinal perspective must be taken.
- Chronic pain is not exclusively somatogenic or psychogenic, but rather both somatic and psychosocial factors interact and are synergistic.
- All people, not just those experiencing chronic pain, are influenced by their attitudes, beliefs, and expectations.
- People with chronic pain avoid activities (e.g., exercise) that they fear will either exacerbate their pain or increase the possibility of further physical pathology and increase behavior (e.g., reclining) that they believe will prevent the occurrence of pain or injury.
- Responses from significant others (e.g., family, health care providers) that are positive (e.g., attention, sympathy) will increase the likelihood of more adaptive behaviors.
- People learn, even without their awareness, what to expect and how to respond by observation of others, especially those whom they perceive as being similar to themselves.
- Anxiety, depression, and anger are prevalent in people with chronic pain, and these emotional states influence the perception of nociception, adaptation, and response to treatment.
- People with persistent pain often have negative expectations about their ability and responsibility to exert any control over their pain and view themselves as helpless, all of which contributes to a general state of demoralization.
- A self-efficacy expectation, or a personal conviction that you can successfully execute a course of action (perform the required behavior) to produce a desired outcome in a given situation, is particularly important in patients with chronic pain because it is a person’s self-efficacy beliefs that determine the choice of activities that the person will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences.
- Pain catastrophizing, an exaggerated negative orientation toward actual or anticipated pain experiences, appears to be a particularly potent way of thinking that greatly influences pain and disability.
- In contrast to the biomedical model’s emphasis on disease, the biopsychosocial model focuses on illness, which is the result of a complex interaction of biologic, psychological, and social variables.
- Pain that persists over time should not be viewed as being either solely physical or solely psychological; rather, the experience of pain is a complex amalgam maintained by an interdependent set of biomedical, psychosocial, and behavioral factors whose relationships are not static but evolve and change over time.

Physical examination serves to further explore and confirm the findings from the clinical history. Objective data obtained from the examination are essential to accurately diagnose the etiology of the pain. This chapter provides an overview of a structured approach to the physical examination of a pain patient, along with the anatomic and physiologic basis of the physical findings.

The key components of the physical examination include a general physical examination, a detailed neurologic examination, a detailed musculoskeletal examination, and an examination for cutaneous or trophic findings. The musculoskeletal examination includes inspection, palpation, percussion, auscultation, and provocative maneuvers.

### GENERAL PHYSICAL EXAMINATION

Vital signs, including temperature, heart rate, respiratory rate, blood pressure, and weight, should be noted at each visit. This information is useful in forming an impression of the overall health and comorbid conditions of the patient.

A few moments should be spent in observing and documenting the general appearance and gait of the patient. Whenever possible, the examining physician should make every effort to bring the patient back to the examining room from the waiting room. This allows the physician the opportunity for examination as the patient transitions from sitting to standing and ambulates to the examining room. This observation time allows an “unofficial” examination that may reveal inconsistencies not noted on the “official formal” examination.

Attributes include how the patient dresses and personal hygiene. Pain behavior, posture, and anatomic abnormalities such as contractures, amputation, and asymmetries should also be noted. Maladaptive postural dynamics play an important role in generating myofascial pain. Excessive lumbar lordosis places strain on the lumbar extensor muscles and results in low back pain. Similarly, forward flexion of the cervical spine with drooping of the shoulders strains the cervical paraspinal and scapular muscles and thereby causes neck and upper back pain.

Evaluation of gait includes assessment of stride length, base, arm swing, and stability. An unsteady, wide-based ataxic gait can be seen in patients with cerebellar and proprioceptive disorders. In patients with hip and lower extremity pain, the stance phase is reduced in the affected limb, along with a shortened swing phase on the uninvolved side, which results in an antalgic gait pattern. A waddling gait can be seen in patients with weakness of the hip girdle muscles or bilateral degenerative hip joint disease. A multitude of gait deviations can occur in patients with footdrop, including vaulting, stepping gate, circumduction, and persistent abduction of the affected limb.

### NEUROLOGIC EXAMINATION

The following are components of the neurologic examination:

1. Mental status examination
2. Cranial nerve testing
3. Motor strength examination
4. Deep tendon reflexes
5. Sensation
6. Coordination
7. Special tests

### MENTAL STATUS EXAMINATION

A reasonable assessment of mental status can often be made as part of history taking and inquiry into activities of daily living and function. A basic mental status examination includes assessment of the level of consciousness; orientation to person, place, time, and situation; registration and short-term memory; attention and concentration; and assessment of language for aphasia. The Folstein Mini-Mental Status Examination is a useful screening tool for detecting cognitive deficits and dementia.

Assessment of mood, affect, suicidal and homicidal ideation, and neurovegetative symptoms such as sleep, appetite, and energy level should be inquired about routinely. This helps uncover comorbid psychiatric conditions (e.g., depression, anxiety, and psychosis), which can have a profound impact on the treatment of pain patients.

### CRANIAL NERVE TESTING

The cranial nerve examination localizes pathology primarily at the level of the brainstem. Central pain conditions associated with brainstem pathology (e.g., strokes, tumors, demyelinating disease, and vascular malformations) can be associated with cranial nerve deficits.
CRANIAL NERVE I

OLFATORY NERVE
Test one nostril at a time. Odors such as coffee, mint, or cloves can be used. Noxious odors such as ammonia should be avoided because they activate trigeminal nerve receptors in the nasal passages.

The most common cause of smell dysfunction is nasal and sinus pathology. Dementia, neurodegenerative conditions, and basal frontal tumors can also result in smell dysfunction.

CRANIAL NERVE II

OPTIC NERVE
Visual acuity is determined with a Snellen chart. Visual fields are tested by the confrontation method at the bedside. More formal visual field testing with perimetry can be requested if indicated. Pupillary reaction to light and accommodation tests the optic and ophthalmic nerves. Funduscopic examination is done to evaluate the optic disc and retina. Papilledema and enlargement of the blind spot can be seen in conditions associated with elevated intracranial pressure, including idiopathic intracranial hypertension, which is a relatively common cause of intractable headache.

CRANIAL NERVES III, IV, AND VI

OPHTHALMIC, TROCHLEAR, AND ABDUCENS NERVES
These nerves control eye movement and can be tested by asking the patient to track a moving object in the eight positions of cardinal gaze. Eyelid elevation and pupillary constriction are controlled by the third cranial nerve and are evaluated by assessing the direct, consensual, and accommodation reflexes. Sympathetic fibers innervate the pupillary dilator muscles. Horner’s syndrome can be detected in several clinical conditions, including after stellate ganglion blockade. This syndrome includes ipsilateral ptosis, miosis, and anhidrosis. However, the mechanism of these changes involves sympatholysis and is independent of cranial nerve function.

CRANIAL NERVE V

TRIGEMINAL NERVE
This nerve supplies sensory input to the face, mouth, tongue, and scalp up to the vertex. The mandibular division of the trigeminal nerve also supplies the muscles of mastication (i.e., temporalis, masseter, medial, and lateral pterygoid muscles). Sensation along the ophthalmic, maxillary, and mandibular divisions of the trigeminal nerve can be tested with temperature, pinprick, and light touch. The trigeminal nerve also provides the afferent limb of the corneal blink reflex.

Peripheral lesions of the trigeminal nerve result in ipsilateral loss of facial sensation with weakness and atrophy of the ipsilateral jaw muscles.

CRANIAL NERVE VII

FACIAL NERVE
The facial nerve innervates the muscles of facial expression, the submandibular and lacrimal glands, and taste in the anterior two thirds of the tongue. Testing is usually limited to checking facial motor function (e.g., forehead wrinkling, eye closure, smile, pursing lips, and corneal blink). Supranuclear lesions of the seventh nerve typically spare the forehead, whereas nuclear and infranuclear lesions do not.

Sensory testing of the facial nerve is not routinely performed but can be accomplished by applying sweet, sour, and salt stimuli to the ipsilateral half of the anterior two thirds of the tongue.

CRANIAL NERVE VIII

VESTIBULOCOCHLEAR NERVE
The vestibulocochlear nerve mediates hearing and balance. Hearing can be assessed with a 512-Hz tuning fork. The Rinne and Weber tests are commonly used to assess for sensorineural and conductive deafness.

In the Weber test, the base of a gently vibrating tuning fork is placed on the midforehead or the vertex. The patient is asked which ear hears the sound better. Normally, the sound is heard equally in both ears. With unilateral sensorineural hearing loss, sound is heard better in the unaffected ear. With unilateral conductive hearing loss, sound is heard better in the affected ear.

The Rinne test is conducted by placing the base of a gently vibrating tuning fork on the mastoid bone behind the ear. When the patient can no longer hear the sound, the fork is quickly moved next to the patient’s ear. In patients with sensorineural deafness and normal hearing, air conduction is better than bone conduction. With conductive deafness, bone conduction is better than air conduction.

Nystagmus noted on eye movement testing may be a sign of vestibular dysfunction. In patients with complaints of episodic vertigo, the Dix-Hallpike maneuver is useful for making the diagnosis of benign paroxysmal positional vertigo.

CRANIAL NERVE IX

GLOSSOPHARYNGEAL NERVE
The glossopharyngeal nerve subserves taste in the posterior third of the tongue and sensation in the pharynx. It provides the afferent limb of the gag reflex.

CRANIAL NERVE X

VAGUS NERVE
The vagus nerve innervates the pharyngeal and laryngeal muscles and forms the efferent limb of the gag reflex. Symptoms of vagus nerve lesions include dysarthria and dysphagia.

CRANIAL NERVE XI

ACCESSORY NERVE
The cranial segment of the accessory nerve supplies the muscles of the larynx, whereas the spinal segment innervates the trapezius and sternocleidomastoid muscles. These muscles are tested by ipsilateral shoulder shrug and contralateral head turn maneuvers.

CRANIAL NERVE XII

HYPOGLOSSAL NERVE
The hypoglossal nerve provides motor supply to the tongue. Testing is performed by tongue protrusion and pushing
CHAPTER 13 — HISTORY AND PHYSICAL EXAMINATION OF THE PAIN PATIENT

153

the tongue against the cheek on either side. Lesions of the hypoglossal nerve produce ipsilateral deviation on tongue protrusion.

**MOTOR STRENGTH EXAMINATION**

Manual muscle testing is performed by asking the patient to place each muscle in its position of maximal mechanical advantage. Muscle strength is commonly assessed with the Medical Research Council scale (Table 13.1). Grades 1 to 3 are relatively objective and less prone to interobserver variation. Grade 1 implies a palpable contraction but with no associated movement noted. Grade 2 implies an ability to move the limb with gravity eliminated (this may require special positioning to assess). A grade 3 finding on motor examination is consistent with the ability to move against further resistance. In the case of the gastrocnemius, a grade 3 muscle is able to perform one toe raise with the patient standing and lightly holding onto something for balance. A grade 4 muscle is able to perform 5 toe raises, and a grade 5 gastrocnemius is capable of performing 10 toe raises. Grades 4 and 5 are difficult to standardize among different examiners. Factors such as a patient’s body habitus, age, and expected functional status, as well as examiner strength, contribute to the difficulty of grading muscle strength above grade 3.

The screening muscle strength examination should correspond to a template that evaluates sequential nerve roots and peripheral nerves. Tables 13.2 and 13.3 provide a summary of the commonly tested muscles along with their corresponding nerve root and peripheral nerve innervation.

The muscle strength examination depends significantly on patients’ comprehension and effort. Suboptimal or voluntary lack of effort may be apparent as “give-way weakness,” with the patient applying intermittent resistance to the examiner interspersed with moments of nearly complete cessation of effort. Weakness as a result of radiculopathy, focal compressive peripheral neuropathy, diffuse peripheral neuropathy, or myopathy should fit specific patterns. A nonphysiologic pattern should raise suspicion for potential psychogenic weakness. The Hoover test is useful to detect psychogenic weakness of the lower extremities. The patient is examined while lying supine in bed and is asked to elevate the paretic leg. The examiner’s hand should be placed underneath the contralateral heel. A positive Hoover test result occurs if the patient fails to exert downward force on the examiner’s hand. The Hoover sign is based on the crossed extensor reflex mediated by interneurons in the spinal cord. This reflex was first described by Sherrington and can be demonstrated in decorticate animals.

**REFLEX TESTING**

The deep tendon reflexes are mediated by a monosynaptic arc. The afferent limb is provided by sensory fibers, which innervate muscle spindles. These fibers project centrally toward the spinal cord and synapse with alpha motor neurons in the ventral horn. The alpha motor neurons comprise the efferent limb of the reflex arc. It is important to note that normal individuals can have diminished deep tendon reflexes. The Jendrassik maneuver can be used to elicit deep tendon reflexes in this situation. The patient is asked to interlock the fingers of both hands and pull them apart. Jaw clenching can also be used to achieve a similar effect. Lesions of the afferent or efferent limb of this arc can cause diminished or absent deep tendon reflexes. This includes conditions such as peripheral neuropathy and radiculopathy. However, patients with small-fiber neuropathy have preserved deep tendon reflexes because the neural deficit spares large myelinated Ia fibers.

Deep tendon reflexes are best examined with a Queen Square or Troemner hammer while the patient is seated.
comfortably in the upright position. Table 13.4 explains the grading of deep tendon reflexes. Table 13.5 reviews the important deep tendon reflexes and their corresponding nerve root level.

Upper motor neuron lesions cause hyperreflexia. The Babinski and Hoffman signs may be present in patients with upper motor neuron dysfunction. A subtly positive Hoffman response can be seen in young women, as well as in people taking selective serotonin reuptake inhibitor antidepressants, and in these scenarios may not represent pathology. The Babinski sign is elicited by stroking the lateral aspect of the sole of the foot with a blunt object (e.g., a disposable wooden spatula). A positive sign is indicated by extension of the great toe (Fig. 13.1). Care should be taken to not stimulate the more medial aspect of the sole, which will evoke a withdrawal response. Hoffman’s sign is elicited by briskly flicking the dorsal or volar aspect of the distal phalanx of the middle finger. Reflex flexion of the index finger and thumb constitutes a positive response.4

**SENSATION**

Sensory examination should include the modalities of temperature, pinprick, proprioception, and vibration. Pinprick and temperature are mediated by Aδ and C small fibers and are transmitted in the spinal cord by the lateral spinothalamic tract. Proprioception and vibration are mediated by Aβ large fibers and are carried by the dorsal columns in the spinal cord. Pinprick testing can be performed with a clean disposable safety pin. A distal-to-proximal pattern of testing is useful in evaluating patients with length-dependent peripheral neuropathy. In patients with nerve root pathology, testing in a dermatomal pattern is recommended (Fig. 13.2). Temperature sensation can be assessed rapidly by using the cold metal portion of a tuning fork and warm water in a test tube. The format for testing is identical to that for pinprick testing.

Proprioception is assessed at individual synovial joints. The most sensitive test for proprioception involves the interphalangeal joint of the big toe. The toe is grasped at its lateral margins between the thumb and index finger of the examiner’s hand. The big toe is then abduced from the remaining toes and moved superiorly and inferiorly in increments of 5 degrees while the patient’s eyes are closed. The patient is then asked to identify whether the toe is being moved up or down. If proprioception is impaired at the toe, the same test can be repeated at the ankle, knee, and distal interphalangeal joint of the index finger.

Vibration sense is usually examined by placing a vibrating 128-Hz tuning fork over a distal bony prominence. The dorsal surface of the interphalangeal joint of the big toe, medial malleolus, tibial tuberosity, and patella are the relevant lower extremity landmarks. The distal phalanx of the index finger, distal end of the radius, and olecranon process of the ulna are the important sites for testing vibration in the upper extremity. Recently, the Rydel-Seiffer 64-Hz quantitative tuning fork has been shown to have better correlation than the traditional 128-Hz tuning fork with sural nerve sensory nerve action potential and ankle reflex results.5

**COORDINATION**

Cerebellar function can be divided into midline/vermal and hemispheric functions. The vermis controls axial coordination and balance, whereas the hemispheres coordinate the limbs. Vermian function is assessed by observation of gait and standing balance. Hemispheric function is assessed with the finger-to-nose and heel-to-shin tests. Other tests include rapidly alternating movements (e.g., sequential hand pronation and supination) and examination for motor tone, which is reduced in patients with cerebellar disease. Chronic alcohol abuse and long-term use of medications such as phenytoin can cause acquired cerebellar degeneration.4
MUSCULOSKELETAL EXAMINATION

The musculoskeletal examination serves to evaluate the integrated functioning of bones, joints, supporting ligaments, and muscular tissue. Information from the examination can be used to localize possible sources of pain in various structures, including the skin, subcutaneous tissue, tendons, joints, ligaments, and periosteum. The format of the musculoskeletal examination follows the steps of inspection, palpation, range of motion, and special tests. The components tested are the spine (cervical, thoracic, lumbar) and the extremities with their respective joints.
**SPINAL EXAMINATION**

Inspection of the cervical and thoracolumbar spine provides information on posture and alignment. Abnormal kyphosis, lordosis, or scoliosis should be noted. Palpation of the spinous processes can reveal localized tenderness, which is seen in patients with conditions such as vertebral compression fractures, epidural tumor, or abscess. A step-off (i.e., a sudden change in prominence of the spinous processes) is also indicative of a vertebral compression fracture with resultant loss of height. Tenderness in the paraspinal regions can be seen in patients with facet arthropathy and myofascial pain syndrome. Normal range of motion of the cervical spine is 60 degrees of forward flexion, 75 degrees of extension, 45 degrees of lateral flexion, and 80 degrees of lateral rotation. Range-of-motion testing should be performed with the patient in both the supine and sitting positions. Improvement in range of motion in the supine position suggests that muscle spasm is responsible for restricting cervical mobility. However, there is no positional improvement in cervical range of motion with cervical arthropathy. Normal thoracolumbar spine range of motion is 90 degrees of forward flexion, 30 degrees of back extension, 25 degrees of lateral flexion, and 60 degrees of lateral rotation. Pain that is provoked by back extension and lateral rotation is suggestive of facet arthropathy in that these maneuvers result in zygapophyseal joint loading. Lumbar discogenic pain is often restricted to the axial spine and is associated with intolerance of the sitting position and pain provoked by coughing, sneezing, and Valsalva maneuvers. A positive abduction tension release sign is highly specific in determining whether the shoulder pain is secondary to C5-6 root compression or shoulder pathology. The test is performed by asking the patient to abduct the affected arm such that the forearm is placed in a resting position on top of the patient’s head. With shoulder pathology, attempts to achieve this position will cause pain. In patients with C5-6 root compression, this test position will commonly result in a marked reduction in pain in the shoulder and medial scapular (rhomboid) region. The Spurling maneuver is highly specific for confirming the diagnosis of cervical radiculopathy. The patient is asked to perform simultaneous lateral flexion and extension of the neck toward the symptomatic side. Provocation of ipsilateral neck and arm pain constitutes a positive Spurling sign.6 7

**EXAMINATION OF THE EXTREMITIES**

Inspection and, when indicated, measurement of the extremities may reveal discrepancies in limb length, deformities, and alterations in muscle bulk. Range of motion can be demonstrated by asking the patient to perform specific tasks such as raising the hands above the head. The lower extremities can be assessed during evaluation of gait. The pattern of gait abnormality can direct the clinician to the underlying cause of dysfunction, such as footdrop, leg length discrepancy, or hip or knee pain.6 7 9 10

**UPPER EXTREMITY**

**SHOULDER JOINT EXAMINATION**

Inspection should evaluate for symmetry, bulk of the deltoid muscles, and posture. Palpation of the shoulder joint should include the sternoclavicular joint, clavicle, acromioclavicular joint, glenohumeral joint, and the scapular spine and scapulothoracic articulation. Normal range of motion for the shoulder joint is 180 degrees of flexion and extension in the sagittal plane, 180 degrees of abduction and adduction in the frontal plane, 90 degrees of external rotation, and 40 degrees of internal rotation. Common causes of shoulder pain include glenohumeral arthritis, acromioclavicular arthritis, subacromial or subdeltoid bursitis, supraspinatus and bicipital tendonitis, and rotator cuff tendonitis, tears, and labral lesions, commonly noted as SLAP (superior labrum anterior to posterior) lesions. A variety of special tests are used to diagnose these conditions. The tests most commonly used in clinical practice are described below.

Pain on shoulder abduction and elevation is seen with impingement syndrome. The etiology involves entrapment of soft tissue between the humeral head and the coracoacromial arch. Subacromial bursitis, supraspinatus tendinitis, and partial or complete tears of the rotator cuff tendons can be present at the same time. In case of a complete tear, the patient will be unable to abduct the arm if it is tested to isolate supraspinatus function. Horizontal abduction in the plane of the scapula with the thumb turned down—the tipped can test—is a sensitive test for rotator cuff pathology. Untreated tears of the rotator cuff tendons result in disuse atrophy of the scapular muscles. The drop arm test is used to diagnose complete rotator cuff tears. The patient’s arm is passively abducted to 90 degrees and then released. Failure to maintain shoulder abduction suggests a complete rotator cuff tear. The diagnosis can be investigated further with magnetic resonance imaging.

**Adhesive Capsulitis**

Frozen shoulder, or adhesive capsulitis, is characterized by diminished range of motion at the scapulothoracic and glenohumeral joints. There is progressive fibrosis of the shoulder joint capsule, which disrupts normal shoulder mobility.

**MYOFASCIAL EXAMINATION**

Myofascial pain is manifested by the presence of tender palpable bands of muscle called trigger points. Active myofascial trigger points are associated with complaints of spontaneous pain and restricted range of motion. Latent trigger points are tender and palpable on direct examination, but they do not produce spontaneous pain.

Myofascial examination should start with assessment of posture and joint function to determine any underlying cause of the regional myofascial pain. Myofascial trigger points can be identified by gentle palpation in the direction of muscle fibers. Trigger points can be felt as a ropelike region of nodularity. Trigger points also are exquisitely tender, and palpation produces local as well as referred pain. The referral pain pattern may mimic a radicular or peripheral nerve distribution. Commonly affected muscles include the trapezius, gluteus, and cervical and lumbar paraspinous musculature, but many others may be affected as well.8
and scapulothoracic rhythm. Normally, the shoulder joint can be abducted to 180 degrees. Scapulothoracic motion begins at 90 degrees of shoulder abduction, and there is a 2:1 ratio of glenohumeral to scapulothoracic motion. Adhesive capsulitis results in gradual loss of range of motion, with little to no shoulder movement present in advanced cases.

ELBOW JOINT
Inspection of the elbow joint includes assessment of humeral and radial-ulnar symmetry. The carrying angle between the arm and forearm is measured with the patient standing and the arms at the side and facing anteriorly. The normal carrying angle is 10 to 15 degrees of valgus for men and up to 18 degrees for women. Readily palpable landmarks of the elbow joint include the olecranon process and the medial and lateral epicondyles. Normal range of motion at the elbow starting from the anatomic position is 0 degrees of extension to 150 degrees of flexion at the humeroulnar joint and 170 degrees of pronation and supination at the radioulnar joint.

Lateral Epicondylitis
Overuse of the forearm extensor muscles results in inflammation of the common extensor tendon insertion at the lateral epicondyle. Patients report constant elbow pain that is worse with wrist movement. Bedside testing is performed by asking the patient to extend the wrist and resist forcible wrist flexion. Pain over the lateral epicondyle confirms the diagnosis of lateral epicondylitis. In severe cases, passive flexion of the wrist may also replicate pain in the extensor mass.

Medial Epicondylitis
This condition is similar to lateral epicondylitis and results from overuse of the forearm flexor muscles. Pain is experienced over the medial epicondyle and can be reproduced by forcibly extending the patient’s flexed wrist.

WRIST JOINT
Inspection plus palpation of the wrist joint is used to evaluate joint symmetry. Range of motion is 60 degrees of extension, 70 degrees of flexion, 20 degrees of abduction, and 30 degrees of adduction. The most common clinically encountered specific wrist joint pain disorder is carpal tunnel syndrome. This entity is a result of entrapment of the median nerve at the wrist, which causes symptoms of wrist pain with associated numbness and weakness of the hand. A diagnosis of carpal tunnel syndrome is supported by the presence of the Tinel and Phalen signs. In the Tinel sign, percussion of the proximal volar wrist crease produces paresthesias in the thumb and index and middle fingers of the symptomatic hand. To elicit the Phalen sign, the patient is asked to forcibly flex both wrists against one another for 1 minute. Reproduction of sensory dysesthesias in a median nerve distribution is consistent with a positive Phalen test. Caution must be used when interpreting the results of these tests because neither test has a high degree of specificity or sensitivity. The “gold standard” test for evaluation of suspected carpal tunnel syndrome is formal electrodiagnostic testing.

EVALUATION OF THE DIGITS
The digits are inspected to evaluate for symmetry and the presence of any deformities. Heberden’s nodes at the distal interphalangeal joints and Bouchard’s nodes at the proximal interphalangeal joints can be seen in patients with osteoarthritis. Range of motion can be assessed by asking patients to open and close their fist. Normal range of motion in the sagittal plane is 90 degrees at the metacarpophalangeal joints, 120 degrees at the proximal interphalangeal joints, and 70 degrees at the distal interphalangeal joints. The first metacarpophalangeal joint has 50 degrees of motion in abduction, 50 degrees in adduction, and 35 degrees in opposition.

EVALUATION OF THE HIP JOINT
Inspection of the hip joint should pay attention to symmetry, muscle bulk, and surgical scars. Normal range of motion at the hip is 100 degrees of flexion, 30 degrees of extension, 20 degrees of adduction, and 40 degrees of abduction. With the hip joint in a flexed position, range of motion is 45 degrees for internal rotation and 40 degrees for external rotation. Hip pain may result from pathology of the acetabulum, femoral neck or head, periosteum, or joint capsule. It may also result from abnormalities in a surrounding structure such as the bursae or may be referred from the lumbar spine or sacroiliac joint. Hip joint pathology classically results in referral of pain to the groin and anteromedial or lateral aspect of the thigh over the greater trochanter region. However, referral of pain from knee pathology can also cause anteromedial thigh pain. Additionally, lateral thigh pain can be seen as a “typically atypical” referral pain pattern of an L5 radiculopathy, with pain involving the L5-innervated gluteal muscles.

As one can see, pain referral patterns alone are often insufficient to diagnose the etiology of hip pain, and an appropriate imaging evaluation is helpful in this regard.

TROCHANTERIC BURSITIS
Patients report a deep, dull, aching pain with radiation to the lateral hip region. The pain is worse at night. Inflammation primarily involves the trochanteric bursa, which lies between the gluteus maximus and gluteus medius tendons. The diagnosis is supported by tenderness with palpation over the greater trochanter and pain on hip extension and resisted hip abduction.

PATRICK’S TEST
Patrick’s test evaluates hip and sacroiliac joint pathology. With the patient in the supine position, the examiner passively flexes, abducts, and externally rotates the hip. Pain in the groin suggests hip joint pathology, whereas sacroiliac pain indicates dysfunction of the sacroiliac joint (Fig. 13.3).

STRAIGHT-LEG RAISE TEST
With the patient in the supine position, the examiner passively elevates one leg by holding it at the ankle. The hip is flexed to an angle of 70 to 90 degrees with the knee extended (Fig. 13.4). A positive straight-leg raise test produces pain starting at the hip with radiation down to the ankle. Pain that remains localized to the posterior thigh region is caused by tension on the hamstrings. A crossed straight-leg raise sign is present if testing of the uninvolved leg produces contra-lateral symptoms. Both the straight and crossed straight-leg raise tests place the lumbosacral nerve roots under tension, and a positive test is suggestive of lumbosacral radiculopathy. Straight-leg testing can also be performed with the
patient in the seated position. In this setting the patient is asked to extend the knee. This stretches the lumbosacral roots as the hip is flexed to 90 degrees when the patient is seated. If augmentation is needed, the patient can be asked to dorsiflex the foot, or the examiner can passively dorsiflex the patient’s foot if needed.

**EVALUATION OF THE KNEE**

Inspection should assess symmetry, position of the patella, surgical scars, and the bulk of the surrounding musculature, including the quadriceps femoris muscle. Particular attention should be placed on inspection of the vastus medialis because this muscle atrophies rapidly when patients have chronic knee pain and reflex inhibition of quadriceps function. Varus deformity of the knee is a result of medial compartment loss, whereas valgus deformity is caused by lateral compartment loss. Bilateral genu valgum (knock-knees), genu varum (bowed legs), or genu recurvatum (back knees) should be noted as well. Palpation should include the surrounding bursae (i.e., the pes anserinus and prepatellar bursae) because these are common sources of pain. Normal range of motion at the knee joint is 150 degrees in the sagittal plane.
CHAPTER 13 — HISTORY AND PHYSICAL EXAMINATION OF THE PAIN PATIENT

SPECIAL TESTS

Drawer Sign
With the patient’s knee in the flexed position and the foot anchored to stabilize the lower part of the leg, the examiner draws the tibia anteriorly. Movement of the tibia in the forward direction constitutes a positive anterior drawer sign and suggests a tear of the anterior cruciate ligament. Similarly, if the tibia moves posteriorly when pulled backward, this is a positive posterior drawer sign and is caused by a torn posterior cruciate ligament (Fig. 13.5).

Patellar Femoral Grinding Test
Knee pain on rising to a standing position or while climbing stairs can occur with chondromalacia patellae. With the patient’s knee extended, the examiner exerts downward pressure on the patella into the femoral groove. Patients with chondromalacia patellae will complain of pain with this maneuver.

Apley’s Compression or Grinding Test
This test is used to evaluate for medial and lateral meniscal tears. With the patient in the prone position, the knee is flexed to 90 degrees, downward force is applied to the heel, and the tibia is rotated medially and laterally against the femur (Fig. 13.6). Pain provoked in the medial or lateral aspect of the knee indicates a tear in the respective collateral ligament.

EVALUATION OF THE ANKLE

Inspection should include evaluation of bony landmarks, symmetry, and edema. Normal range of motion of the ankle is 20 degrees of dorsiflexion and 40 degrees of plantar flexion through the tibiotalar joint. The 30 degrees of inversion and 15 degrees of eversion noted at the ankle are a result of subtalar motion, not tibiotalar motion.

Pain and excessive motion on pulling the ankle joint anteriorly indicate a tear in the anterior talofibular ligament, whereas similar findings on forced inversion occur with tears of the calcaneofibular ligament. The posterior

Figure 13.5 Drawer sign test for the cruciate ligaments. The standard drawer sign test for the cruciate ligaments immobilizes the foot and stresses the lower part of the leg on the femur. Pulling the leg forward tests the anterior cruciate ligament (ACL), whereas posterior pressure tests the posterior cruciate ligament (PCL). (Redrawn from Calliet R. Knee Pain and Disability. 3rd ed. Philadelphia: FA Davis; 1992:1-69.)

Figure 13.6 Examination of ligament injury, including the meniscus (Apley’s test). The Apley test checks the integrity of the knee ligamentous structures and the menisci. It is performed in two aspects. Left, With the patient prone and the knee flexed to a right angle, downward pressure is applied to the lower part of the leg. The leg is then rotated to test the menisci. This maneuver compresses the menisci between the femoral condyles and the tibial plateau, as in the McMurray test. With the lower part of the leg internally rotated, the medial meniscus is tested. Grating, crepitus, limitation, and pain imply meniscal damage. From the same position, the leg is elevated (right), which places traction on the ligaments. Excessive motion, deduced by comparison to the contralateral side, indicates laxity or injury to the knee ligaments and capsule. (Redrawn from Calliet R. Knee Pain and Disability. 3rd ed. Philadelphia: FA Davis; 1992:1-69.)
talofibular ligament is usually damaged only in patients with a significant history of preceding trauma.

**EVALUATION OF THE FOOT**

Functional assessment of the foot is targeted toward its anterior, middle, and posterior segments. The anterior segment consists of the 5 metatarsal and 14 phalangeal bones; the middle segment includes the navicular, cuboid, and 3 cuneiform bones; and the posterior segment includes the talus and calcaneus (Fig. 13.7).

The posterior segment of the foot transmits body weight to the ground. The middle segment provides flexibility and the ability to adapt gait to uneven surfaces. The anterior segment acts as a fulcrum to provide forward thrust during ambulation. The impact of the foot against the ground is cushioned by its longitudinal and transverse arches.

Foot pain is a common symptom in patients (Fig. 13.8). The more common pain syndromes that are diagnosed by physical examination are described in the following sections.

**TARSAL TUNNEL SYNDROME**

In tarsal tunnel syndrome, the posterior tibial nerve is entrapped beneath the lancinate ligament, posterior to the medial malleolus. Patients complain of pain and paresthesias affecting the toes and sole of the foot. Physical examination may demonstrate atrophy of the intrinsic foot muscles and hypoesthesia of the sole of the foot. Percussion posterior to the medial malleolus can provoke paresthesia in the ipsilateral sole and toes in patients with tarsal tunnel syndrome.

**MORTON’S NEUROMA**

Morton’s neuroma is characterized by pain between the metatarsal bones, usually between the third and fourth toes and less commonly between the second and third toes. The pain is reproducible on palpation of the space between the metatarsal heads. The etiology of Morton’s neuroma is not well understood, but it probably represents a form of interdigital neuritis. Interestingly, surgically resected specimens in patients with Morton’s neuroma do not show any significant changes in nerve histology when compared with control tissue obtained from cadavers.

**METATARSALGIA**

Pain in patients with metatarsalgia occurs on weight bearing and is localized to the plantar aspect of the metatarsal heads. The pain occurs maximally over the first metatarsal head and can be reproduced by direct palpation. With foot inversion, weight is shifted to the heads of the second and third metatarsal bones, and repetitive stress can result in pain over these sites as well. Patients may walk with a characteristic antalgic gait, with the foot being held in the inverted position. This can serve as a useful clue to the diagnosis.

**FOOT STRAIN**

Foot strain affects the middle segment of the foot. Repetitive patterns of overuse result in elongation of the longitudinal arch and alterations in the normal alignment of the talus and calcaneus. Elongation of the longitudinal arch produces excessive strain on the plantar fascia, medial collateral ligament, and talocalcaneal ligament. Physical findings include flattening and pain on compression of the longitudinal arch.

**PLANTAR FASCIITIS**

Plantar fascitis is manifested as plantar foot pain on weight bearing. Patients often have a history of prolonged standing in footwear lacking arch support or on hard surfaces.
Inflammation develops at the point of attachment of the plantar fascia to the calcaneus. Calcaneal bone spurs can develop from chronic straining of the plantar fascia. Clinically, tenderness on palpation can be elicited over the anterior portion of the calcaneus with radiation into the plantar fascia. A common finding is pain the first thing in the morning. Patients will frequently note severe plantar foot pain with weight bearing on arising and temporary improvement with weight bearing or after the morning shower.

PAINFUL HEEL SYNDROME

Painful heel syndrome is a result of degenerative changes in the weight-bearing aspect of the calcaneus and occurs primarily in morbidly obese individuals or those who stand or walk excessively. Pain is often worse in the morning on waking up or after prolonged rest. Examination is significant for tenderness on palpation over the posterior portion of the plantar aspect of the calcaneus.

TESTS FOR A NONORGANIC ETIOLOGY OF PAIN

WADDELL’S SIGNS

Waddell’s tests were intended to evaluate patients with low back pain for functional overlay. There are five signs in total, and the presence of any three of these five signs in a patient was considered suggestive of a nonorganic pain etiology.\(^\text{11}\)

1. Tenderness to palpation
   - Widespread skin tenderness with light touch
   - Tenderness on deep palpation that is not restricted to a single anatomic area

2. Simulation
   - Low back pain provoked by axial loading pressure on the skull of a standing patient or rotation of the shoulders and pelvis in the same plane resulting in increased low back pain

3. Distraction
   - For example, a patient with a positive response to the straight-leg raise test in the supine position but no pain on the same test repeated in the sitting position

4. Regional disturbance in function
   - Weakness involving multiple muscle groups in a nonmyotomal distribution with “give-way” effort
   - Sensory loss in a segmental pattern (e.g., glove-stocking rather than a dermatomal distribution) observed in a patient in whom polyneuropathy is not an appropriate diagnosis

5. Overreaction
   - Disproportionate facial or verbal behavior (e.g., moaning and grimacing on light touch, posturing, and withdrawing from the examiner)

However, there are several limitations of Waddell’s signs. Widespread superficial tenderness is commonly found in patients with fibromyalgia, and tenderness on deep palpation is part of myofascial pain syndrome. Sensory loss in a glove-stocking distribution is present with peripheral polyneuropathy. Moreover, studies have not found a consistent relationship between the presence of Waddell’s signs and subscale scores on the Minnesota Multiphasic Personality Inventory. In fact, recent data suggest that Waddell’s signs cannot accurately distinguish between organic and nonorganic causes of pain.\(^\text{12}\)

The physical examination may be helpful in elucidating the cause of a patient’s pain complaints; however, when used alone it has limitations, and the results of physical examination need to be considered in the context of the patient’s history, as well as in the context of the results of diagnostic studies.

REFERENCES
Electrodiagnosis is a broad term that includes multiple electrodiagnostic techniques, including needle electrode examination (NEE); motor and sensory nerve conduction studies (NCSs), including late responses; and evoked potentials (EPs). Electrodiagnostic techniques such as electromyography (EMG) and EPs are very useful adjuncts to physical examination of patients in pain. Conditions in which EMG or EPs may be of use include painful peripheral neuropathies, entrapment neuropathies, traumatic nerve injuries, radicular and multiradicular problems, lumbar spinal stenosis, arachnoiditis, and painful myopathies.

In recent years there has been increased reliance on anatomic measures such as intradermal nerve biopsy for small-fiber neuropathy and magnetic resonance imaging (MRI) for larger neural structures. This “anatomic” approach fails to recognize the differences and respective advantages and shortcomings of physiologic versus anatomic testing and, above all, fails to recognize the inherent nature of pain, a subjective experience that can only be correlated with the clinical picture.

The problems inherent in applying electrodiagnostic techniques to the diagnosis and management of pain are no different from those encountered in history taking, physical examination, radiologic evaluation, and therapeutic diagnostic testing (e.g., nerve blocks). Pain is a subjective experience, often without an objective “litmus test,” and final diagnosis of the etiology and presumptive treatment of a pain syndrome is a clinical one that can be supported only by relevant data, including findings on EMG.

Electrodiagnostic techniques can be applied virtually without complications to large portions of the body and hence the nervous system to gain an overall understanding of the distribution of abnormalities, if present, or relative normalcy if not. The distribution of abnormalities correlates strongly with the etiology of a disease process causing pain. Questions that can be posed and answered through the use of electrodiagnostic techniques include the following:

- Is a disease of nerves present?
- If so, is it a mononeuropathy, polineuropathy, or mononeuritis multiplex?
- Does the distribution of abnormalities suggest involvement at the nerve root, plexus, or nerve level?
- If there is a disease process involving a single (or multiple) nerve such as injury or compression, is it improving, worsening, or static?
- Is the nerve involved motor, sensory, or mixed?
- Is the process one of nerve, muscle, or both?
- Are small fibers selectively involved or is this mainly a large-fiber disorder, or are both involved?
- Is there autonomic as well as somatic involvement?
- Are more proximal structures rather than distal ones involved?
- Is the central nervous system involved?

These are the types of inquiries that add substantially to diagnostic information about the etiology, severity, and prognosis of painful disorders. Although many painful disorders do not affect either the peripheral or central nervous system, electrodiagnostic testing can often add reassuring negative results to the diagnostic picture.

Electrodiagnosis is an extremely useful investigative technique for evaluating patients with pain because it satisfies two fundamental steps in the assessment of a neuropathic painful syndrome before any attempt at therapy: (1) rigorously establishing the presence or absence of a peripheral nervous system lesion and (2) determining the relevance of an established peripheral neuropathic lesion to the subjective clinical complaint. In addition, with the advent of new treatments, including enzyme replacement and potential insertion of genetic material into cells, early diagnosis and the ability to monitor treatment outcomes objectively become of great importance. Recent enzyme replacement therapy for Pompe’s disease is an example of the potential diagnostic, therapeutic, and prognostic importance of electrodiagnosis.

The parent organization of electrodiagnosis is the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM), which has promulgated a Recommended Policy for Electrodiagnostic Medicine Position Statement. This document seeks to lay out the scope of electrodiagnosis by using consensus expert opinion to ensure adequate examination while attempting to conserve scarce resources by listing the indications for testing and the maximum number of studies per diagnosis in 90% of cases. Since there has been some abuse of the number of studies done on patients and since many pain specialists are not familiar with the techniques of electrodiagnosis, this may serve as an important source of information on the appropriate measures to be used when these diagnostic methods are being considered.

**ELECTROMYOGRAPHY**

EMG is a method of testing both the physiologic state and the anatomic integrity of lower motor neuron structures (anterior horn cells, nerve roots, plexuses, peripheral nerves, neuromuscular junction, and muscles), their sensory components, and some spinal and brainstem reflex pathways. The term electromyography previously caused...
considerable confusion because strictly speaking, it is needle electrode evaluation (NEE) of muscle function but often was expanded to include nerve conduction velocity (NCV) or NCSs and other tests. However, its common usage has come to mean needle EMG, determination of NCV, and less frequently, testing such as the H-reflex and F-response, cranial nerve reflexes (e.g., the blink reflex), and studies of the neuromuscular junction. The all-inclusive term EMG is used here in an effort to avoid confusion among tests.

Longmire pointed out the puzzling dichotomy regarding pain and electrodiagnostic testing in the medical literature. In standard textbooks on electrodiagnostic testing, little or no reference is made to painful syndromes and their diagnosis despite their excellent discussion of physiology, technique, and clinical correlation. On the other hand, a perusal of pain textbooks reveals cogent attempts to correlate neurophysiologic studies with pain management. The reason for the paucity of references appears to be at least in part the attitudes of pain specialists themselves, who point out that “large caliber afferent fibers are physiologically unrelated to pain, a submodality mediated by small caliber fibers. Additionally, the test is unable to explore the bases for positive sensory phenomena, generated by dysfunction even of large caliber afferent channels.”

ELECTRICAL TESTING OF NERVES AND MUSCLES

BRIEF HISTORY

As early as 1791, Galvani found that electricity was produced by muscular contractions. The first experimental work with EMG was performed by Lord Adrian in 1925. In 1928, Proebster first described the presence of “spontaneous irregular action potentials in denervated muscle.” In its progression to clinical application, EMG made a major step forward with use of the cathode ray oscilloscope by Erlanger and Gasser, as well as the concentric needle electrode and loudspeaker. Vast numbers of nerve injuries in World War II and later conflicts added further impetus to the study of nerve and muscle by electrodiagnostic technique.

THE ELECTRODIAGNOSTIC METHOD

Electrical diagnostic measurement systems have only four basic components:

1. Electrodes
2. Stimulator
3. High-gain differential amplifier
4. Recording display or central processing device

The EMG apparatus amplifies and displays biologic information derived from either surface or needle electrodes. Electrical information may be recorded from muscles, nerves, or other nervous system structures and is displayed on an oscilloscope. In addition to the visual display on the oscilloscope, a permanent recording may be made, audio amplification may allow it to be heard over a loudspeaker, and analog-digital analysis of signals may be used. Nerves are electrically stimulated to measure conduction.

For NCSs, skin surface electrodes are generally used for recording compound muscle or nerve action potentials. Rarely, needle electrodes are used. For needle EMG, needle electrodes are used with a strong trend toward disposable needles. For sensory testing, ring electrodes are used for measurement (Fig. 14.1). Modern EMG equipment is manufactured by numerous companies and is generally standardized to allow reliable and reproducible testing by different laboratories, but normative data, including data for special populations such as geriatric, pediatric, diabetic, and even active workers, may differ among laboratories and require standardization by each laboratory.

NEE is an invasive procedure but complications are rare; however, patients should be apprised of them. The most common is transient muscle soreness. Aseptic precautions should be observed. Precautions for testing include extra care with patients who are taking warfarin or other anticoagulants or who have hemophilia or other blood dyscrasias, but since most muscles tested are superficial, they can easily be compressed and the bleeding abated. Severe thrombocytopenia is a relative contraindication and should be considered carefully. Patients positive for human immunodeficiency virus (HIV) represent a transmission risk, but the use of disposable needles (which should be universal) should protect against this hazard. One should carefully consider persons who have a cardiac pacemaker or transcutaneous stimulator when doing stimulation for NCSs. Certain muscles, such as the rhomboids and abdominals, which are sometimes interrogated by NEE in pain patients, and the diaphragm (almost never), carry a risk for pneumothorax and infectious peritonitis, respectively. Beyond placing a needle through an infected site, there are probably no absolute but only relative contraindications to EMG. Extremely anxious patients and some children occasionally require.
some sedation. Aftereffects are negligible, with rare bruising, although occasionally a highly disturbed, suggestible, or litigious patient may complain vehemently of increased pain or disability. To the contrary, patients may occasionally report a salutary effect on their condition.\textsuperscript{18}

**PHYSIOLOGY**

**PHYSIOLOGIC MECHANISMS IN THE PRODUCTION OF MUSCLE POTENTIALS**

When an impulse arrives at the region of the junction between a nerve and muscle, at the nerve terminal, a depolarization takes place and triggers the opening of voltage-gated calcium channels, which in turn triggers the release of acetylcholine in the synaptic cleft between the axon terminal and the neuromuscular junction. Acetylcholine activates nicotinic receptors, which are ligand-gated sodium channels that activate the tubule system of the muscle. The stimulus is transmitted along the fiber by an excitable membrane that surrounds the muscle fiber. The action potential results from breakdown of the surface membrane potential, which is associated with critical changes in ionic permeability. In a resting muscle fiber, the potential difference across the surface membrane is 90 mV, with negative inside and positive outside. During excitation, the resting potential temporarily reverses to 40 mV, negative outside. This action potential travels along the muscle fiber at velocities ranging from 3.5 to 5 m/sec in different fibers.\textsuperscript{19}

In recording extracellularly, as with EMG, the electrode picks up the action potential as it is conducted through the medium that surrounds the active fiber. The impedance of the external medium is small in comparison to the impedance of the fiber interior, and hence the voltage of the extracellularly recorded potentials is maximally only 2\% to 10\% of the intracellularly recorded potential changes. The functional unit (Fig. 14.2) in reflex or voluntary activity is the motor unit; a motor unit is the group of muscle fibers innervated by a single anterior horn cell.

Conduction along the fine intramuscular branches of the anterior horn cell axon occurs so rapidly that all muscle fibers in a motor unit are activated nearly simultaneously. The number of muscle fibers per motor unit varies considerably from muscle to muscle; for example, in the gastrocnemius the motor unit consists of about 1600 muscle fibers, whereas in the small muscles of the eye there are only 5 to 10 fibers. The motor units in various muscles cover different areas of the muscle’s cross section (e.g., brachial biceps, 55 mm; rectus femoris, anterior tibial, and opponens pollicis, 8 to 9 mm). The distribution of fibers is such that fibers from several different motor units are intermingled, which is why four to six motor units can be identified by EMG from the same intramuscular recording point. In normal muscle, these single motor unit potentials can be differentiated only during weak voluntary effort.\textsuperscript{15,20}

The potentials from different motor units are recognized by their frequency of discharge, which varies for each motor unit (some are more or less excitable). Moreover, the various potentials often differ in appearance because of the differential distance of the recording electrode from the individual fibers of the activated motor units and the differential distribution of the motor end plates in the several units within “range” of a concentric or single needle electrode in one position in the muscle. An upward deflection on the oscilloscope is considered electrically negative, and a downward deflection is considered electrically positive. In the immediate vicinity of a potential there is an upward, or negative, deflection.

**PHYSIOLOGY OF NERVE CONDUCTION**

The cell membrane (axolemma) of a nerve axon separates the intracellular axoplasm from the extracellular fluid.\textsuperscript{8} The unequal distribution of ions between these fluids produces a difference in potential across the cell membrane. This resting potential is about 70 mV and is negative on the inside with respect to the outside of the cell membrane. When a nerve fiber is stimulated, it causes a change in the membrane potential; a rapid but brief flow of sodium ions occurs through ionic channels inward across the cell membrane and gives rise to an action potential.

The way in which an action potential is conducted along an axon depends on whether the axon is myelinated or unmyelinated.\textsuperscript{21} In a myelinated fiber, the action potential is regenerated only at the nodes of Ranvier, so the resulting action potentials “jump” from node to node, thereby resulting in saltatory conduction. The velocity of nerve conduction depends on the diameter of the myelinated fiber. Small myelinated fibers may conduct as slowly as 12 m/sec,

![Figure 14.2 A, Schematic illustration of three normal motor units, “a,” “b,” and “c.” Note: Muscle fibers of different motor units are normally intermingled. Below the motor units are action potentials of five individual muscle fibers of a motor unit and its summated motor unit potential. B, Myopathic changes in motor unit “a.” Of the original five muscle fibers, three have undergone degeneration, thus reducing the size of the motor unit. C, Neurogenic transformation of motor unit “a.” Anterior horn cell “b” is shown undergoing degeneration, and its two muscle fibers are not innervated by axons of anterior horn cell “a,” thus leading to an increase in the territory and size of motor unit “a.”](Image1)

---

\[\text{Image1}\]
whereas large motor and sensory fibers conduct at a rate of 50 to 70 m/sec in humans. In an unmyelinated fiber in humans, the conduction rate is about 2 m/sec.

Several factors affect conduction velocity other than whether the axon is myelinated:

• Temperature of the limb (low temperatures decrease conduction velocity)\(^2^2\)
• Age of the patient (infants have slow conduction velocities and older adults have increasingly slowed conduction velocities)
• Height of an individual (increased height may increase the internodal distances of the nodes of Ranvier)\(^8\)

**BASIC ELECTROMYOGRAPHY EXAMINATION**

EMG must be combined with clinical examination of the patient by the electromyographer. This includes grading of muscle strength. It is of prime importance for the electromyographer to personally correlate the clinical data and that obtained by EMG. Each examination must be planned individually. There is no “cookbook” formula to follow. Because the EMG examination is an extension of the clinical examination, the patient must be evaluated fully and the problem tentatively assigned to the portion of the anterior horn cell system that seems most likely to be involved. The electromyographer determines the segment or segments of the peripheral nervous system suspected to be involved, and the examination is planned to either substantiate or invalidate the presumptive clinical diagnoses.

**CONDUCTING THE EXAMINATION**

Needle examination of a patient is designed to determine the following:

1. Integrity of a muscle and its nerve supply
2. Location of any abnormality
3. Any abnormalities of the muscle itself

The electrodes may be monopolar or concentric (Fig. 14.3). The examination proceeds through the following steps (Fig. 14.4):

1. Determination of activity of the muscle in the relaxed state\(^9,15\)
2. Evaluation of any insertional activity that arises
3. Assessment of the activity seen on weak voluntary effort
4. Determination of the pattern seen on maximum voluntary effort, which is known as the *interference pattern* (there is interference in discerning individual muscle action potentials from the resting baseline)

**NEEDLE FINDINGS IN NORMAL MUSCLE**

**INSERTIONAL ACTIVITY**

When the needle is inserted into a normal muscle, it evokes a brief burst of electrical activity that lasts no more than 2 to 3 msec, a little longer than the actual movement of the needle.\(^10\) This activity is described as insertional activity and is generally 50 to 250 mV in amplitude (see Fig. 14.4A). These insertional potentials are believed to represent discharges from muscle fibers produced by injury, mechanical stimulation, or irritation of the muscle fibers.

**SPONTANEOUS ACTIVITY (ACTIVITY AT REST)**

When the needle is stationary and the muscle is relaxed, there is no electrical activity present in normal muscle except when the needle is in the area of the end plate. Two types of end-plate “noise” are normal (see Fig. 14.4C): (1) low-amplitude and undulating, which probably represents extracellularly recorded miniature end-plate potentials, and (2) high-amplitude intermittent spike discharges, which probably represent discharges of single muscle fibers excited by intramuscular nerve terminals irritated by the needle. Any other spontaneous activity at rest is abnormal.

---

![Figure 14.3](image1.png) Commonly used monopolar and concentric needle electrodes. (Courtesy of Oxford Instruments Medical, Inc., Hawthorne, NY.)

![Figure 14.4](image2.png) A, Trace showing normal insertional activity. B, No spontaneous activity in a normal muscle at rest. C, Spontaneous end-plate potentials. D, Normal biphasic and triphasic motor unit potentials during weak voluntary contraction.
An increased duration of insertional activity may be seen with loss of innervation or with primary disease of muscle fiber. Reduction may occur in patients with myopathies or more advanced degeneration in which muscle tissue has been replaced by fat or fibrous connective tissue.

**VOLUNTARY ACTIVITY**

Voluntary activity of the muscle is analyzed after the muscle is studied at rest (see Fig. 14.4D). Electrical activity (termed a *motor unit action potential*) is noted. As mentioned previously in the discussion on physiology, a motor unit refers to the number of muscle fibers supplied by one motor neuron and its axon. This number varies from muscle to muscle and may be as few as 10 to more than 1000 muscle fibers. When a motor neuron discharges, it activates all the muscle fibers of the motor unit. The force of contraction determines the number of motor units brought into play. This begins with a single motor unit that fires and can be identified on the screen by its distinctive morphology. As effort is increased, other motor units come into play, which can still be individually discerned and have their own individual morphology and audio representation on the loudspeaker. As the contraction increases, the firing rate of each individual motor unit action potential increases, and the action potential is subsequently joined by other motor unit action potentials, whose firing rates also increase. This phenomenon is known as *recruitment* (Fig. 14.5). In normal muscles, the strength of a voluntary muscle contraction is directly related to the number of individual motor units that have been recruited and their firing rate.

Analysis of motor units includes (1) waveform, (2) amplitude, and (3) interference patterns.

**Waveform**

Most units are biphasic or triphasic. The number of phases is determined by the “baseline crossings.” Motor units that cross the baseline or have more than five phases are called *polyphasic motor units*. Though occasionally seen in healthy muscle, they do not exceed 15% of the total number of motor units. In some muscles, polyphasic motor units are more prevalent. Polyphasic potentials are a measure of fiber synchrony.

**Amplitude**

The amplitude depends on the number of fibers in the motor unit and the type of EMG needle used. Monopolar needles are associated with higher-amplitude potentials than bipolar or coaxial needles are. Normal amplitude ranges from 1 to 5 mV. Because the motor unit is the sum of the action potentials of each muscle fiber of the unit, a large motor unit has a larger amplitude; conversely, a smaller motor unit has a smaller amplitude.

**Interference Patterns**

With maximum voluntary effort, a large number of motor units are brought into play and their firing rate increases. They tend to “interfere” with each other and are not recognized further as individual units. This gives rise to a situation called an *interference pattern* (see Fig. 14.5). A normal muscle has a “full” interference pattern.

**NEEDLE FINDINGS IN ABNORMAL MUSCLE**

Various abnormalities may occur that indicate the presence of total denervation—neurogenic paresis, peripheral type, or neurogenic paresis, anterior horn cell type. In addition, myogenic paresis may be detected. Generally, on the basis of abnormal findings and with a well-determined examination, the presence of a radiculopathy, generalized neuropathy, focal neuropathy or mononeuropathy, or plexopathy can be determined. The following are needle abnormalities in abnormal muscle:

1. Insertional activity (decreased or increased)
2. Spontaneous activity (fibrillations, positive sharp waves, or fasciculations) (Fig. 14.6)
3. Abnormalities in voluntary motor unit activity, especially recruitment (see Fig. 14.5)
4. Abnormal motor unit morphology (e.g., excessive or extreme polyphasia)
CHAPTER 14 — ELECTROMYOGRAPHY AND EVOKED POTENTIALS

Nerve conduction studies are of value in the following cases:

1. Determining whether a disease of nerve is present
2. Determining the distribution of a neuropathy (e.g., mononeuritis, polyneuropathy, mononeuritis multiplex; this may be a valuable point in the differential diagnosis of the cause of a neuropathy)
3. Determining at what point in a nerve a conduction block is present and locating an entrapment site
4. Studying the progress of disease of a peripheral nerve (e.g., Is it getting better? Worse? Staying the same?)
5. Seeing whether reinnervation of a previously sectioned nerve has taken place
6. Establishing in a disease of the myoneural junction (e.g., myasthenia gravis) the fact that conduction along the nerve is adequate or normal

There are a few important limitations to the use of NEE in muscle disease. Some disorders may not result in abnormal findings on EMG, including certain congenital conditions and endocrine disorders such as steroid myopathy and polymyalgia rheumatica, an important cause of muscle pain and weakness in the elderly. EMG affects primarily type I fibers during minimal voluntary effort before the interference pattern makes discernment of individual motor units difficult.

Conduction velocity studies are carried out by inserting a needle electrode into a muscle innervated by the nerve under study or by the use of surface electrodes over that muscle (Fig. 14.7). For example, the first dorsal interosseous muscle may be examined to determine the function of the ulnar nerve (Fig. 14.8). The nerve is stimulated at the elbow in the case of the ulnar nerve, and the latency of the response is determined. The response is generally a spike-like large motor unit action potential. The ulnar nerve is then stimulated in the wrist or the axillary region, or both. The difference in latencies between the two points of stimulation and the distance between the two points of stimulation provide the basis for calculation of conduction velocity. Conduction velocity is determined by the following formula:

\[
MCV \text{ (m/sec)} = \frac{DMM}{(PML - DML)}
\]

where DMM is the distance between the two stimulus points in millimeters, PML is proximal motor latency (in milliseconds), DML is distal motor latency (in milliseconds), and MCV is motor conduction velocity in meters per second. Normal values are usually established for each nerve in individual laboratories, but normal values for commonly tested sensory and motor nerves are generally available (Table 14.1). Median nerve stimulation is comparable to ulnar nerve stimulation (Fig. 14.9).

F WAVE

DEFINITION

Motor conduction velocity along the whole axon, including the proximal portions, can be studied by eliciting the F-wave response, a small, late muscle response that occurs as a result of backfiring of anterior horn cells. F waves may be obtained from almost any mixed nerve that can be stimulated, but the median, ulnar, peroneal, and posterior tibial nerves are the most commonly used (Fig. 14.10). If the standard distal motor conduction velocities are normal but the F-wave value is prolonged, slowing must be occurring somewhere more proximal to the distal normal segment. (The method used to determine F-wave latency varies from laboratory to laboratory; the F-wave value with each successive shock stimulus shows a variability of several milliseconds, with some examiners averaging 10, 30, or 50 responses and some taking the shortest of 10, 20, or more responses.) Limb temperature and arm or leg length may also be important to know. Comparison with the opposite limb may be most helpful if that limb is asymptomatic.

PITFALLS AND COMMENTS

In addition to the variability in F waves and how they are obtained in different laboratories, many electromyographers overuse (or at least overperform) the F-wave study when proximal slowing in a nerve or nerve root is not even in the differential diagnosis. The most accepted use of the study is for suspected early Guillain-Barré syndrome, when results of the usual studies are still normal—typically in the
first 10 days of the illness. It is highly controversial in the evaluation of radiculopathies.28,29

HOFFMAN REFLEX (H-REFLEX)

DEFINITION
The H-reflex is obtained by electrostimulation of the posterior tibial nerve in the popliteal space at a slow rate with a long duration and submaximal electrical shock; it is recorded with surface electrodes over the gastrocnemius-soleus (Fig. 14.11). The impulse travels up the sensory fibers to the spinal cord, synapses with the alpha motor neuron, and returns down the motor fibers to the calf muscle. H-reflex latencies are therefore long, in the range of 40 to 45 msec. They are carried mostly in the S1 nerve root distribution and cannot be recorded consistently from other muscles. To determine a delay or an asymmetry, one should always study the opposite leg for comparison.30–33

PITFALLS AND COMMENTS
The H-reflex is somewhat more useful than the F wave, but the main reason for the study is to evaluate patients with suspected S1 radiculopathy whose history or findings on physical examination are suggestive but the EMG is normal.34 Usually, when an absent H-reflex is noted, which suggests a problem with S1 nerve root conduction, an absent or depressed ankle reflex has already been noted on the physical examination, so the study is, for many, redundant. Pitfalls occur when the opposite leg is not studied to show...
a normal H-reflex as a contrast. If the H-reflex is absent bilaterally, it may reflect more generalized disease, such as peripheral neuropathy. Older patients often do not have good H-reflexes as a normal finding. In addition, a unilaterally absent H-reflex with normal findings on needle EMG does not indicate when the injury occurred; the findings may have been the result of a previous injury.

**QUANTITATIVE SENSORY TESTING (PSEUDOMOTOR AXON REFLEX TEST)**

Quantitative sensory testing takes various forms, including the quantitative somatosensory thermotest using a controlled ramp of ascending or descending temperature through a Peltier device. Measurement of the threshold for cold sensation reflects the function of small-caliber Aδ myelinated afferents. The threshold for warm sensation reflects the function of warm-specific small unmyelinated afferent channels. Cold pain and heat pain thresholds test the function of unmyelinated C-fiber, polymodal nociceptors, and, to a lesser extent, Aδ-fiber nociceptors. Certain abnormal patterns are characteristic of dysfunction of small-caliber peripheral nerve afferents. To obtain maximal information from a quantitative somatosensory thermostest, it is necessary to test for cold, pain, and heat sensations.
which is mandatory in the evaluation of painful syndromes.\textsuperscript{37} Quantitative sensory testing performed at different sites along an extremity in patients with polyneuropathy yields useful information about staging of the pathologic process along the extremity. The quantitative pseudomotor axon reflex test (QSART) is a quantitative thermoregulatory sweat test. It has been used to detect postganglionic pseudomotor failure in neuropathies\textsuperscript{38,39} and preganglionic neuropathies with presumed trans-synaptic degeneration.\textsuperscript{40} In patients with distal small-fiber neuropathy, it is the most sensitive diagnostic test.\textsuperscript{41} Various commercial devices have been used to differentiate axonal from demyelinating polyneuropathy.\textsuperscript{42}

**Clinical Correlations of Electromyographic Testing**

Clinical correlations can be based on a careful history, clinical examination, and electrodiagnostic studies. Electrodiagnostic studies are best for distinguishing neuropathy from myopathy and determining whether a neuropathy is

![Image](https://via.placeholder.com/150)

**Figure 14.11** A, Placement of recording electrodes and site of stimulation of the posterior tibial nerve for recording of the Hoffman (H) reflex from the soleus muscle. B, H-reflex pathways. An electrical impulse generated on stimulation of the tibial nerve travels along the sensory axon (afferent) within the spinal cord and along the motor axon (efferent). C, Motor response (M) and H-reflex (H). Five consecutive traces are shown. Starting from the top, each trace is obtained with increasing stimulus intensity. With minimal stimulus only, the H response is obtained. As the intensity of the stimulus is increased, the M response begins to appear and the H response begins to decrease until it finally becomes unobtainable.

NERVE TRAUMA

Often after an injury, such as a laceration, the nerve is completely severed. At rest, denervation potentials are recorded in the muscles supplied by that nerve in the form of positive sharp waves or fibrillation potentials, and on EMG, no motor unit action potentials are seen. Sometimes, however, an injury is incomplete and the type of nerve lesion is uncertain.

**Neurapraxia**

Neurapraxia is the mildest form of nerve injury. It consists of loss of conduction without associated changes in axonal structure. This form of conduction block often occurs with compressive or ischemic nerve injuries, such as a mild entrapment syndrome or compression (e.g., “Saturday night palsy”). In neurapraxic injuries, focal demyelination occurs. Serial nerve conduction determinations along the course of the nerve enable one to locate the site of the conduction block. The prognosis for complete recovery is generally good, and healing occurs within days or weeks, barring further injury.

**Axonotmesis**

In axonotmesis, a more severe form of nerve injury, the axon is disrupted in its myelin sheath. The neural tube, which consists of the endoneurium and epineurium, remains intact. The nerve undergoes Wallerian degeneration, with fragmentation of the axon distal to the site of injury. Motor and sensory paralysis occurs along with associated atrophy of the muscles supplied and loss of reflexes. After about 4 to 5 days, the distal segments of the nerve become inexcitable. In 1 to 2 weeks, positive sharp waves are seen; fibrillations in the involved musculature occur in 2 to 3 weeks. The intact neural tube forms a lattice for the regenerating axon, and the prognosis for recovery is generally good.
Neuromyotomy

Neuromyotomy is the most severe form of nerve injury and consists of severe disruption or transection of the nerve. Nerve regeneration and recovery are often incomplete, and surgical reanastomosis may be required. Neuromas may form and are commonly associated with pain. Only serial determinations over time can determine the difference between axonotmesis and neuromyotomy.

NONTRAUMATIC NEUROPATHIES

In a patient with a nontraumatic neuropathy, segmental demyelination is generally associated with slowing of NCV and temporal dispersion of evoked responses. With axonal degeneration, however, a reduction in the evoked response amplitudes with mild or minimal slowing of NCV is typical. EMG provides early information regarding reinnervation before clinical recovery is evident. The earliest positive evidence of reinnervation is the appearance during voluntary effort of motor unit potentials that are of low amplitude in the beginning but are highly polyphasic (“nascent”) units. They may be present several weeks before clinical evidence of functional recovery is apparent.

POLYNEUROPATHY

EMG and evaluation of nerve conduction are useful in diagnosing polyneuropathy and in determining whether the pathologic process is axonal and demyelinating. A diagnosis of polyneuropathy is made when abnormal nerve conduction and EMG findings are bilateral and symmetrical.

Generalized peripheral neuropathies frequently associated with pain are noted in Box 14.1.43-48 The following electrodiagnostic findings are characteristic of axonal neuropathy:

1. Abnormally low or absent sensory nerve action potentials and compound muscle action potential amplitudes
2. Normal distal latencies
3. Near-normal motor and sensory conduction velocities

If a disease process affects the large-diameter axons, some slowing of conduction occurs; the velocity is seldom reduced by more than 20% to 30% of normal. However, fibrillations and positive sharp waves are present in muscles innervated by the affected nerves and are generally worse distally. The feet are more involved than the hand muscles, and the leg muscles are involved more than the arm muscles. Motor unit potentials are decreased in number with deficient recruitment and an incomplete interference pattern. Some motor units have increased amplitude and duration.

In contrast, diffuse demyelinating neuropathy is characterized by a reduction in conduction velocity, usually more than 40% of the normal range. Distal latencies are also prolonged. The sensory nerve action potentials and compound muscle action potentials usually exhibit low amplitudes and temporal dispersion. Needle EMG shows no fibrillations or positive sharp waves unless secondary axonal degeneration is present. In a pure demyelinating neuropathy, there is no denervation of muscle fibers. Motor units are decreased in number; the decreased recruitment is attributable to conduction block in some fibers. Usually, no significant change in the duration, amplitude, or morphology of motor units occurs, but the number of polyphasic potentials may be increased if the terminal axons have become demyelinated.

Once it has been determined by EMG whether a neuropathy is primarily axonal or demyelinating, one can then consider clinically which neuropathies are diffusely axonal and which are demyelinating. Subacute and chronic diffuse axonal types include most toxic and nutritional neuropathies, uremia, diabetes, hypothyroidism, HIV infection, Lyme disease, paraneoplastic disease, dysproteinemia, and amyloidosis.

Demyelinating polyneuropathies include hereditary motor and sensory neuropathy types I and III, Refsum’s disease, multifocal leukodystrophy, and Krabbe’s disease. Acute nonuniform demyelinating diseases include Guillain-Barré syndrome, diphtheria, and acute arsenic intoxication, whereas chronic versions include inflammatory demyelinating peripheral neuropathy, idiopathic disease, and neuropathies accompanying HIV disease, as well as various paraproteinemias, dysproteinemias, and osteosclerotic myeloma.49

MONONEUROPATHIES AND ENTRAPMENT NEUROPATHIES

With an entrapment neuropathy, the most commonly involved nerves are the median, ulnar, radial, common peroneal, and tibial. Entities such as trauma, vasculitis, diabetes mellitus, leprosy, and sarcoidosis can affect any nerve in the body. Electrophysiologic studies are of great assistance in localizing the lesion in the individual nerve and in differentiating mononeuropathy from diffuse polyneuropathy, plexopathy, and radiculopathy.

MEDIAN NERVE

The median nerve is most commonly entrapped at the wrist as it passes through the carpal tunnel, but it may also be injured at the elbow where it passes between the two heads.
of the pronator teres or, less frequently, is compressed by a dense band of connective tissue (the ligament of Struthers immediately above the elbow) (see Fig. 14.9). The median nerve is derived from the C6 through T1 nerve roots (lateral and medial cords of the brachial plexus). The diagnosis of carpal tunnel syndrome is made by demonstrating localized slowing of sensory and motor conduction across the wrist as evidenced by prolonged sensory and motor distal latencies. In addition, with late changes there may be denervation in the form of fibrillations, positive sharp waves, and reduced motor units with polyphasia in the hand muscles innervated by the median nerve. The need for reference values for special populations, including diabetics and active workers, has been emphasized in a recent AANEM monograph. A recent review has emphasized that carpal tunnel syndrome may represent a focal intracanal condition such as pregnancy, lipoma, an arterial condition, and the hereditary neuropathy of amyloidosis.

**Pronator Teros and Anterior Interosseous Syndromes.** The pronator teres and anterior interosseous syndromes consist of proximal compression or entrapment neuropathies of the median nerve. Patients with pronator teres syndrome may also have normal distal latency but no evidence of denervation in the median-innervated hand and forearm muscles except for the pronator teres. The anterior interosseous nerve is a motor branch of the median nerve, with its origin just distal to the pronator teres.

**Ulnar Nerve**

The ulnar nerve is derived from the C8 and T1 cervical nerve roots (medial cord of the brachial plexus). It is usually injured at the elbow but occasionally at the wrist in the canal of Guyon or deep in the palm (silver beater’s palsy). EMG helps differentiate C8 and T1 radiculopathies fromplexopathy or more distal ulnar nerve palsy (see Fig. 14.8). When the lesion is in the wrist at the canal of Guyon, usually both sensory and motor fibers are involved and the amplitude of the sensory nerve action potential and muscle action potential is reduced. Distal sensory and motor latency across the wrist is prolonged, and there is no focal slowing of motor NCV or decrement in compound muscle action potential across the elbow. With a lesion in the deep palmar branch, no sensory abnormality occurs and all the changes are in the motor distribution distal to the lesion. When the abnormality is at the elbow, there may be localized slowing of NCV across the elbow, often as much as 25% to 40% below normal. Normal values may depend on the method used (arm straight vs. arm bent). The sensory potential may be affected, as may EMG findings in the ulnar hand muscles.

**Radial Nerve**

The radial nerve is a continuation of the posterior cord of the brachial plexus and receives fibers from the C5 to C8 cervical roots. It is usually involved at the spiral groove of the humerus, often secondary to a humeral fracture. With a lesion at the spiral groove, the triceps muscle is noted to be spared on EMG, but all the extensor muscles of the forearm are involved. An isolated superficial radial nerve palsy sometimes occurs at the wrist, with the only abnormality being in the radial sensory nerve action potential.

**Posterior Interosseous Syndrome.** The posterior interosseous nerve syndrome (sometimes known as complicated lateral epicondylitis) is caused by entrapment of this branch of the radial nerve at the arcade of Fröhse between the two heads of the supinator. EMG shows involvement of the extensor carpi ulnaris, extensor digitorum longus, extensor pollicis longus, and extensor indicis with sparing of the more proximal supinator and extensor carpi radialis longus and brevis. Sensation is unaffected.

**Common Peroneal Nerve**

The common peroneal nerve is derived from the L4 through S1 roots but primarily from L5. It may be compressed at the head of the fibula. Peroneal NCSs show reduced compound action potentials, as recorded from the extensor digitorum brevis on stimulation above the fibular head, and normal compound action potentials below the fibular head and at the ankle.

**Posterior Tibial Nerve at the Ankle**

The posterior tibial nerve is derived from the L4 through S3 roots and may be compressed in the tarsal tunnel. NCSs show prolongation of the distal motor and sensory latency of the tibial nerve. There may be EMG changes in the appropriate foot muscles. This syndrome is relatively uncommon.

**Sciatic Nerve**

The sciatic nerve arises from the L4, L5, S1, S2, and S3 nerve roots. A controversial syndrome is entrapment by the piriformis muscle as it passes through the greater sciatic notch. A lesion of the sciatic nerve is defined and localized by detailed needle examination of muscle in the lower limb.

**Other Uncommon Neuropathies**

There are numerous potential mononeuropathies, including those involving the long thoracic nerve, dorsal scapular nerve, suprascapular nerve, musculocutaneous nerves, and axillary nerves in the shoulder girdle and upper extremity, as well as those in the pelvic girdle, including the femoral, obturator, saphenous, lateral femoral cutaneous, genitofemoral, ilioinguinal, and superior and inferior gluteal nerves. Needle EMG reveals denervation changes in muscle innervated by individual nerves. NCSs are rarely useful in their evaluation.

**Radiculopathies**

Radiculopathies are diseases of the nerve roots and must be differentiated fromplexopathies, as well as from complex individual nerve root lesions. Roots are commonly involved by compression, especially in the cervical and lumbar region, but they may also be involved in diseases such as diabetes mellitus, herpes zoster, carcinomatous infiltration, and lymphomatous infiltration of nerves, as well as by rare sarcoidosis and infectious processes. Determination of motor and sensory nerve conduction is rarely useful because the lesion in a radiculopathy is proximal to the dorsal root ganglion and motor conduction studies are usually normal, although they may be reduced in amplitude if the lesion is severe enough to cause axonal loss. The H-reflex is absent or latency-delayed when the S1 root is involved. Typically, nerve root lesions are identified by abnormal needle examination results in the appropriate paraspinal and limb
muscles.57 Because most limb muscles are supplied by more than one nerve root (Tables 14.2 and 14.3), a normal study does not exclude the diagnosis of radiculopathy; however, when the findings on EMG are abnormal, they provide objective evidence of functional impairment in the nerve root and localize the lesion to one or more roots in addition to revealing the severity of involvement.58,61-63

PLEXOPATHIES

In plexopathies, motor NCSs are useful in excluding a peripheral nerve lesion; otherwise, the findings are normal except that the amplitudes of compound muscle action potentials may be reduced. Sensory NCSs are usually helpful in excluding other causes. Again, needle examination is most helpful, but it requires knowledge of which muscles are supplied by which portions of the plexus.

ANTERIOR HORN CELL DISEASE

Disorders of the anterior horn cell do not generally cause pain except for acute poliomyelitis (acute febrile stage). When diseases such as amyotrophic lateral sclerosis cause pain, the etiology is usually multifactorial (spasticity, musculoskeletal, positioning) and not usually discernible with EMG.

DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Findings on EMG are almost always normal in diseases of the central nervous system.

PRIMARY MUSCLE DISORDERS

One of the clearest applications of EMG is for differentiating myopathies from neuropathic processes.64-66 The differentiation in EMG studies between myopathy and neuropathy should be obvious by needle examination. In myopathy, the potentials are reduced in amplitude and may be very polyphasic, recruit paradoxically (i.e., more potentials seen on the screen than would be expected for the corresponding amount of effort), and are accompanied by marked signs of irritability. In polymyositis and metabolic muscle disorders, sensory nerve conduction is always normal. The compound muscle action potential amplitude may be low, but otherwise motor conduction results are normal. EMG findings are commonly normal in myofascial pain syndromes and fibromyalgia, but in polymyositis and metabolic muscle disorders (e.g., glycogen and lipid storage disease), muscle pain, cramps, and weakness can occur. Box 14.264-66 lists the painful myopathies.

Unusual diseases characterized by muscle cramping, including stiff man syndrome (Moersch-Woltman syndrome), simply show muscle contraction and spasms. Conditions with continuous muscle fiber activity (Isaacs-Mertens syndrome) show continuous, low-amplitude, fibrillation-type potentials.64-66

USEFULNESS AND LIMITATIONS OF ELECTROMYOGRAPHY

EMG and NCSs are useful in localizing neuromuscular disease sites and in providing information about the nature of the process (demyelinating, axonal, primary muscular, radicular) but cannot give the cause (diabetes, Guillain-Barré syndrome, myositis, tumor, ruptured disk). Figure 14.12 presents a summary of EMG findings in various conditions. In addition, a normal result does not mean that the patient does not have pain. Electrodiagnostic studies in the EMG laboratory, as usually performed, measure only activity related to the motor nerve fibers, the larger sensory nerve...

**Figure 14.12** Summary of electromyographic findings in various conditions. Diagrams show electromyograms from normal muscle and from muscles with paresis of neurogenic and myogenic origin with a schematic presentation of the muscle fibers from three motor units (affected fibers are dotted). Two recording electrodes, I and II, and the corresponding recordings I and II are shown. Up is negative. **A**, Normal. At rest: no action potentials. **Weak voluntary effort**: single motor unit potentials. **Maximal voluntary effort**: interference pattern, no synchronization.  
**B**, Total denervation with diffuse atrophy of muscle fibers. At rest: diphasic and positive denervation potentials. **Voluntary effort**: no motor unit potentials.  
**C**, Peripheral neurogenic paresis with patchy loss of muscle fibers. At rest: denervation potentials. **Voluntary effort**: increased action potential duration, polyphasic potentials. The pattern of single motor unit potentials or a mixed pattern during maximal voluntary effort is shown. There is no synchronization between the various leads.  
**D**, Neurogenic paresis in diseases of the anterior horn cells with patchy loss of muscle fibers. At rest: denervation potentials. **Voluntary effort**: increased action potential duration and voltage, polyphasic potentials. Single motor unit potentials with maximal voluntary effort are shown, often synchronous in different leads.  
**E**, Myogenic paresis with diffuse atrophy of muscle fibers. At rest: spontaneous discharges of short duration (in severe cases). **Voluntary effort**: diminished action potential duration, diminished action potential voltage, polyphasic potentials. An interference pattern occurs with maximal effort; a short duration of the single spike potentials is often seen. (From Buchthal F. *An Introduction to Electromyography*. Copenhagen: Scandinavian University Books; 1957:40.)
fibers, and the muscles. Sympathetic and small unmyelinated nerve fiber functions are not evaluated except by quantitative sensory testing.

The timing of EMG in relation to injury or the onset of symptoms may be very important. Early after nerve injury (0 to 14 days), EMG may show only electrical silence, which is not helpful. If any motor units are seen at that time, the nerve to that muscle is at least partially intact. Fibrillation potentials appear only after 2 to 3 weeks. If reinnervation is occurring, small, very polyphasic recovery or “nascent” units will be noted. Serial studies after nerve injury are more helpful than a single study.

**EVOLED POTENTIALS**

EPs are electrical responses of the nervous system to external sensory stimuli. It has been known for decades that these responses are present; however, their clinical usefulness did not become possible until the development of computerized averaging and advanced signal processing in the late 1960s. Since then, the importance of EPs in diagnosing diseases of the peripheral and central nervous system has undergone exponential growth.

The utility of EPs is based on their ability to provide objective and reproducible data concerning the status of the sensory nervous system. EP testing can demonstrate abnormalities in the sensory system when clinical signs and symptoms are ambiguous. In addition, evidence of clinically unsuspected lesions may be provided when the history and findings on physical examination are normal. EP testing may help delineate the anatomic distribution of nervous system lesions and help monitor their progression or regression; such testing may be used to demonstrate the integrity of nervous system pathways placed at risk during surgery.

**GENERAL PRINCIPLES**

EP responses have very low amplitude (0.1 to 20 mV); consequently, they are obscured by random noise consisting primarily of spontaneous electroencephalographic activity, muscle artifact, and environmental interference. Extraction of the EP response is accomplished by signal averaging. This process summates the “time-locked” EP response, which occurs at the same interval after the stimuli and minimizes unwanted noise.

Although EPs can be elicited by a wide variety of stimuli, the most commonly used stimuli are visual, auditory, and somatosensory. This gives rise to the visual evoked potential (VEP) test, the brainstem auditory evoked potential (BAEP) test, and the somatosensory evoked potential (SEP) test. In each of these tests the EP response consists of a sequence of upward and downward deflections (e.g., peaks and waves). The characteristics to be evaluated are the presence or absence, polarity, configuration, amplitude, latency, and interinterval between individual peaks (interpeak latency [IPL]).

Standardized nomenclature for identification of individual peaks or waves has not been universally established, although some general principles for labeling have been agreed on. Peaks or waves, or both, may be identified by their polarity and the latency at which they occur. For example, the positive peak occurring at 100 msec in the VEP is commonly designated P100. Labeling may also be based on the anatomic site at which the response is recorded (e.g., Erb’s point), or the deflections may simply be numbered in sequence (e.g., waves I through V in the BAEP).

Normal values for the components of the EP response are affected by numerous factors, including the technique and equipment used by different laboratories. Therefore, each laboratory generally establishes its own normal values by using 2.5 or 3 SD from the mean to determine the limits of normality. Normal values are also influenced by subject factors, including gender, age, body size, and temperature. Clinical interpretation of the EP requires consideration of these factors.

**EQUIPMENT**

Most laboratories use commercially available EP equipment that should meet the standards established by the American Association of Electrodiagnostic Medicine and the American Electroencephalographic Society. In simplest terms, the EP is recorded by attaching electrodes to the patient over specific areas on the extremities, spine, and scalp, depending on the type of test being performed. After the electrodes are attached to record the EP signals, repetitive stimuli timed with the recording process are presented to the patient. The EP signal is collected by the recording electrodes and amplified, filtered, averaged, and displayed for evaluation, printing, and storage. Careful application of the recording electrodes is critical to obtain an EP response of good quality. The electrode site must be cleaned, and the electrode must be attached with a medium that conducts electricity. Standard metal electroencephalographic cup electrodes are commonly used, although other types of electrodes, including needles, may be used.

Placement of electrodes on the scalp is standardized according to the International 10-20 System. This system refers to placement of electrodes either 10% or 20% of the total distance between prominent landmarks on the skull (Fig. 14.13). The specific configuration of electrode placement for a given test is referred to as the montage.

**SPECIFIC TESTS OF EVOKED POTENTIALS**

The three tests of EPs that are used most often measure the visual, brainstem auditory, and somatosensory pathways.
Testing of cognitive function and transcranial magnetic stimulation to determine central motor conduction may also be performed. In patients with pain, SEP testing generally offers the greatest clinical utility and is therefore discussed here in the greatest detail.

**VISUAL EVOKED POTENTIALS**

VEPs are used to evaluate pathologic conditions affecting the visual pathways. VEPs are generated primarily in the visual cortex and may be affected by abnormalities anywhere along the visual pathway from the cornea to the occipital cortex. Because the anterior visual pathway from the cornea to the retina may be evaluated directly by ophthalmologic examination, the VEP is used mainly to assess the optic pathway posterior to the retina.

The most common stimulus used to elicit the VEP is a reversing checkerboard pattern, typically transmitted through a video monitor and producing checks that alternate from black to white and vice versa. This is referred to as a *pattern-reversal* VEP. Flashes of light may also be used to produce VEPs, but they result in greater variability in response and are less sensitive to abnormalities in the pathway than pattern-reversal testing is.

*Flash-elicited* VEPs are used primarily when an individual cannot cooperate with pattern-reversal testing and gross determination of visual pathway integrity is required (e.g., in infants or comatose patients and during general anesthesia). A flash stimulus is also used to produce the electroretinogram, a specialized type of VEP that reflects the function of the retina and distal portion of the optic nerve.

During performance of pattern-reversal VEPs, each eye is tested separately to localize the lesion to the affected side. Because the visual pathways cross at the optic chiasm, evaluation of chiasmal and retrochiasmal pathology requires that the individual temporal and nasal portions of the visual fields of each eye be tested. This is referred to as *partial-field stimulation*, whereas *full-field stimulation* is used to evaluate prechiasmal lesions.

For pattern-reversal VEPs, the patient is seated comfortably in front of the video monitor producing the alternating checkerboard pattern. The distance of the patient from the monitor and the size of the checks are adjusted to produce a visual angle of 10 to 20 degrees. This stimulates the central part of the retina, which is responsible for the greatest proportion of the VEP response. If the patient wears eyeglasses, they should be worn during the test because decreased visual acuity will alter the results. Recording electrodes are placed on the scalp, typically over the midline occiput, vertex, and forehead (Oz, Cz, and Fpz, respectively, in the International 10-20 System). Additional electrodes are placed lateral to the midline occipital electrode if partial-field stimulation is performed. The eye not being tested is patched, and the patient is instructed to gaze at the center of the monitor screen. The checkerboard pattern reverses one to two times per second, and 100 reversals (trials) are generally required to produce a clearly defined response. The test is repeated under identical conditions to demonstrate reproducibility of the response.

The VEP response consists of three peaks (Fig. 14.14). The primary peak of interest is positive with a latency of approximately 100 msec and is referred to as the P100. The remaining two peaks are negative and occur at latencies of about 75 and 145 msec, respectively. They are more variable than the P100 and are of less clinical usefulness. Normal values vary among laboratories, although the upper limits of normal generally range from 117 to 120 msec, with differences in latency between eyes no greater than 6 to 7 msec for the P100 response.

**Clinical Utility**

VEPs are used for the evaluation of many conditions affecting the visual system. In clinical settings, the VEP is used primarily for the diagnosis of multiple sclerosis. Numerous studies have shown that a high percentage of patients with multiple sclerosis exhibit VEP abnormalities, most commonly a prolongation of P100 latency. As in conventional NCSs, conditions producing demyelination elicit an increase in response latency, whereas axonal loss produces a reduction in response amplitude (Fig. 14.15). Of patients undergoing VEP testing for evaluation of multiple sclerosis, 63% have abnormal results. Abnormality rates of at least 85% have been reported in patients known definitely to have multiple sclerosis. Additionally, abnormalities have been found to persist for years after a single episode of optic neuritis, even if the individual remains free of symptoms. The addition of BAEP and SEP testing improves the diagnostic yield over that of VEP alone.
VEP abnormalities have been reported in patients with migraine headaches, with some researchers claiming the ability to classify the type of migraine. Abnormalities may be more common if the VEP is performed soon after the migraine attack. Flash-elicited VEPs may reveal a higher frequency of abnormality than seen with pattern-reversal testing. Nevertheless, the use of VEPs for the diagnosis of migraine headache remains controversial.

Diseases of the eye, such as cataracts, glaucoma, and diminished visual acuity, may produce VEP abnormalities, most frequently a decrease in P100 amplitude. Because a direct correlation exists between visual acuity and VEP amplitude, VEP testing may be used to determine visual acuity. This is done primarily in patients who are unable to undergo conventional refraction, such as infants and patients with severe mental retardation.

Diseases affecting the anterior visual pathways, such as tumors and ischemia, may produce VEP abnormalities. Tumors and infarctions in the posterior optic pathways may also produce VEP abnormalities, especially with partial-field stimulation. Unfortunately, “masking” effects from the normal side in patients with unilateral retrochiasmal lesions may result in normal VEPs. At present, the use of VEPs for diagnosis of retrochiasmal disease remains complicated and contentious. Diseases associated with VEP abnormalities are listed in Box 14.3.

Monitoring visual pathway integrity during surgical procedures that jeopardize the visual system has become increasingly widespread. Various techniques involving the use of strobe lights, light-emitting diode goggles, and fiberoptic contact lenses have been developed to stimulate the optic system in anesthetized patients. In addition to providing information concerning pathway integrity, VEPs can help identify optic nerve elements that may be embedded in tumors, thereby reducing the risk for accidentally disrupting these structures.

Audit Evoked Potentials

Just as visual stimuli are used to produce VEPs for evaluation of the visual pathway, auditory stimuli may be used to assess the auditory pathway. The auditory pathway extends from the middle ear structures through the eighth cranial nerve and brainstem and into the auditory cortex. The auditory evoked potential (AEP) is produced by presenting auditory stimuli to each ear, which results in a sequence of waveforms that bear a close relationship to these auditory pathway structures and allows relatively specific localization of pathology in the auditory pathway, particularly in the eighth cranial nerve and brainstem.

Although the AEPs parallel hearing, they do not test hearing per se; rather, they reflect a synchronous neural discharge in the auditory system. Thus an individual may have a normal behavioral audiogram and a grossly abnormal AEP or, conversely, a normal AEP and central auditory deafness.

Brainstem Auditory Evoked Potential

The BAEP is one of several tests included under the general heading of “auditory evoked potentials” that are differentiated by recording techniques and latency of responses. Of these tests, the BAEP is most used clinically. The BAEP is also referred to as the auditory brainstem response (ABR) and the brainstem auditory evoked response (BAER).

Method. Recording the BAEP response is accomplished by presenting an auditory stimulus to each ear individually and recording the response from electrodes placed on the scalp and on or near each ear. Typically, a montage of four electrodes is used on the forehead, vertex, and each earlobe (Fpz, Cz, A1/A2, respectively). The auditory stimulus

Figure 14.15 Abnormal visual evoked potential response from a patient with multiple sclerosis demonstrating prolonged latency and reduced amplitude of the left eye (O.S.) P100 response. The response from the right eye (O.D.) is normal.
used most frequently consists of a brief (100-msec) electrical pulse referred to as a “click.” Usually, these clicks are presented to the patient through standard audiologic earphones or insert earphones that fit into the ear canal. Clicks are presented normally at an intensity of 65 to 70 dB above the normal hearing level and at a rate of 10 to 50 clicks/sec. Averaging of 1000 to 2000 stimuli is usually necessary to produce a well-defined BAEP response.

The typical response consists of a series of seven positive waves numbered by Roman numerals I through VII (Fig. 14.16). For the purpose of clinical evaluation, the first five waves are used because waves VI and VII are not present consistently. The BAEP waveform normally occurs within the first 10 msec following presentation of the stimulus; the latency of each wave and the IPL among waves I, III, and V are measured (IPL, or interpeak latency, refers to the latency between each individual wave). Generally, the amplitude of the BAEP response varies too much to be clinically useful, but the ratio of amplitudes between waves I and V may be abnormal in patients with demyelinating disease.

Normal values for the waves and IPLs vary among laboratories, but average normal values are presented in Table 14.4. Many factors may affect the absolute latencies of the BAEP waves (e.g., peripheral hearing loss). IPLs offer a more reliable measure of pathology in the auditory pathway since they frequently remain constant despite changes in the absolute latencies of the waves themselves. Several technical factors, such as varying the stimulus rate or intensity, alter the BAEP. These factors must be considered when the results obtained are evaluated.

Because clinical use of the BAEP relies on the relationship between individual BAEP waves and the anatomic structures that produce them, identification of individual generator sources of BAEPs has been researched extensively. Some controversy remains, particularly concerning waves IV and V, which appear to have multiple generator sources: wave I is thought to be produced by the auditory portion of the eighth cranial nerve; wave II by the eighth cranial nerve and the cochlear nucleus; wave III by the lower pons (probably in the superior olivary complex); and waves IV and V in the upper pons and lower midbrain, possibly in the lateral lemniscus or inferior colliculus.

The status of the patient does not usually affect the ability to obtain a BAEP response. This response may even be obtained from patients who are under general anesthesia or are comatose. Mild to moderate peripheral hearing loss may alter absolute wave latencies, although IPLs are not generally changed significantly, thus allowing interpretation of the BAEP. Marked hearing loss, however, may make interpretation of the BAEP extremely difficult or impossible because of degradation of the response. If possible, behavioral audiometry should be performed before BAEP testing to allow more accurate interpretation of the results.

Clinical Utility. BAEPs are useful in evaluating various disease states affecting the auditory pathways. In addition to their VEP abnormalities, patients with multiple sclerosis may demonstrate abnormal BAEPs. Reported rates of abnormality range from 32% to 72%.

The most common BAEP abnormalities are increased IPLs and a decreased wave V-to-wave I amplitude ratio. Although the BAEP has been found to be useful in evaluating patients with multiple sclerosis, most studies have found it the least sensitive diagnostically when compared with the VEP and SEP. BAEPs are extremely useful in the diagnosis of acoustic neuromas and other tumors of the cerebellopontine angle. BAEP abnormality rates greater than 90% have been noted in most studies. In addition, the
BAEP was superior to routine audiometry and computed tomography in early detection of these lesions. An increase in wave I–to–wave III IPL is the most common BAEP abnormality (Fig. 14.17).99-101

Brainstem tumors and strokes frequently produce abnormalities in the BAEP if the areas involved lie in the auditory pathway. Prolongation of interpeak or absolute latencies, or both, and absence of waves may be seen, depending on the anatomic site of the lesion.74,78,97

The BAEP aids in evaluation of comatose and head-injured patients. Coma produced by toxic or metabolic causes does not generally produce BAEP abnormalities, whereas BAEPs are frequently abnormal in patients with coma secondary to structural brainstem lesions. In patients with head injuries, BAEPs have been predictors of outcome: more severe BAEP abnormalities indicate a poorer prognosis.102,103 AEP abnormalities have also been described in patients with minimal head injuries, such as postconcussive syndrome.104 Many other disorders have been associated with BAEP abnormalities,57,74,105 including degenerative disorders such as Friedreich’s ataxia, vertebrobasilar transient ischemic attacks, basilar migraine, and spasmodic torticollis.106,107

As with VEPs and the visual pathway, BAEPs may be used to monitor integrity of the auditory pathway during surgical procedures. Operative monitoring of BAEPs has been used most frequently during resection of acoustic neuromas and tumors of the cerebellopontine angle.68 The primary use of BAEPs has been to determine hearing sensitivity in patients who are unable to undergo behavioral audiometry (e.g., infants). Estimates of hearing sensitivity are usually obtained by progressively decreasing the intensity of the auditory stimulus until no discernible BAEP response is obtained. Because click stimuli are broadband with a frequency range between 1000 and 4000 Hz, filtered clicks and tone bursts with narrower frequency spectra have been used to obtain better frequency specificity of hearing.94,106,109

Other Auditory Evoked Potentials

Although the BAEP is the most commonly used AEP, other AEPs have been developed to expand clinical utility. The electrocochleogram begins within the first 3 msec after the presentation of auditory stimuli and reflects electrical activity of the cochlear hair cells and the auditory nerve. This measurement has been used clinically to evaluate patients with Meniere’s disease, to monitor damage caused by ototoxic drugs, and to evaluate sensorineural hearing loss.110

The 40-Hz, middle-latency, and long-latency AEPs occur later in latency than does the BAEP. They are thought to be generated primarily by structures above the brainstem and therefore may be useful in evaluating more central auditory disorders, as well as in determining hearing sensitivity. These responses are less reliable and more commonly affected by the patient’s state than the BAEP is.94,111

SOMATOSENSORY EVOKED POTENTIALS

SEPs are responses evoked by stimulation of sensory nerves. Allowing assessment of somatosensory pathway function, SEPs have been obtained by stimulating sensory and mixed nerves in the upper and lower extremities, dermatomal sensory areas of the skin, and cranial nerves. Recording of the SEP response depends on stimulation of large, fast-conducting sensory fibers in the peripheral nerve. From the peripheral nerve, the SEP pathway enters the spinal cord through the dorsal root ganglion and ascends in the ipsilateral dorsal columns. The pathway crosses at the medial lemniscus, travels to the contralateral ventroposterolateral nucleus of the thalamus, and then proceeds to the primary sensory cortex.

The correlation between SEPs and disorders affecting joint and position sense is generally accepted. SEPs are usually normal in patients with abnormalities affecting only pain and temperature sensation.67,70 Cortical evoked potentials have been recorded following noxious stimuli, although these pain-related potentials currently offer limited clinical usefulness.74 Recent studies have suggested that some individuals with altered pain-temperature sensation may have abnormalities in pain-related EPs. Some disagree on whether this reflects abnormalities in spinothalamic function or whether these potentials are related to the cognitive processing of pain.112-119

Method

Numerous methods have been described to record SEPs, with attempts at standardization occurring only recently.120-122 Consequently, recording technique, waveform nomenclature, and normal values may vary between investigators.70,71 Certain general principles, however, apply to most studies. The stimulus of choice for the SEP is electrical and consists of a square wave pulse delivered to the patient by surface or,
The sources of these responses remain controversial, although N9 may be generated by fibers in the brachial plexus. N13 is thought to be generated by the dorsal column nuclei and N20 by thalamocortical radiations and possibly the primary sensory cortex. Occasionally, a negative peak of approximately 11-msec latency (N11) precedes the N13 response and is believed to reflect activity in the posterior columns and the dorsal root entry zone of the spinal cord.

**Lower Extremity Somatosensory Evoked Potential**

Recording the SEP from nerves situated in the lower extremity generally includes placement of recording electrodes on the lumbar spine over the L3 spinous process, on the lower thoracic spine at T12, and on the scalp over the primary sensory cortex (Cz). In studies of the extremity, SEP responses are difficult to record above the thoracic spine; thus cervical spine recording sites are not usually included.

As in upper extremity SEPs, a reference electrode and ground electrode are necessary. Like the median nerve in the upper extremity, the tibial nerve provides a characteristic SEP of the lower extremity. When the tibial nerve is stimulated at the ankle, the responses expected include the following (Fig. 14.19):

1. A negative peak with an approximate latency of 19 msec recorded at L3 (designated L3S)
2. At T11, a negative peak at about 21 msec (designated T11S)
3. At the scalp, a positive peak at approximately 37 msec (designated P37), followed by a negative peak with a latency of about 45 msec (designated N45)

The L3S response is thought to reflect activity in the nerve roots of the cauda equina. The T11S response is thought to be generated by the dorsal fibers of the spinal cord, and the scalp potentials are considered reflections of thalamocortical activity.

In general, cortical responses can be obtained easily, with as few as 100 to 200 stimuli being required. Lumbar and thoracic spinal responses are difficult to acquire and may not be recordable in obese or uncooperative patients without the use of sedation. Frequently, 1000 to 2000 stimuli are required to obtain clearly defined responses.
Interpretation
Interpretation of SEPs depends on the presence or absence of expected waves and, when present, their absolute latencies and IPLs. Latencies beyond 2.5 to 3 SD from the mean are deemed abnormal. If the SEP is considered a wave traveling from the stimulation site at the peripheral nerve and ascending proximally through the various recording sites on its way to the cortex, it can be seen that a lesion along the ascending somatosensory pathway will result in normal responses distal to the lesion and abnormal responses proximally. Thus, if the brachial plexus response (N9) is normal and the cervical spine potential (N13) is delayed or absent, a lesion is located central to the brachial plexus but below the lower medulla in the cervical root or cord. Similarly, if the brachial plexus potential (N9) is absent or prolonged, a lesion distal to the plexus in the peripheral nerve is likely.

Because diseases of the peripheral nerves that cause slowing of conduction velocity (e.g., demyelinating neuropathies) prolong the latency of all peaks proximal to the nerve, IPLs are useful to confirm normal conduction through the central nervous system despite peripheral nerve abnormalities. Conduction through the central nervous system is referred to as central conduction time and is measured from N13 to N20 in the upper extremity and from L3S to P37 in the lower extremity. Besides peripheral nerve disease, decreased body temperature and increased limb length result in prolongation of absolute peak latencies, thus making determination of central conduction time critical.67,74,113

Clinical Uses of Somatosensory Evoked Potentials
Peripheral Nerve Disease. The occurrence of central nervous system amplification of the peripheral nerve vol-
ley permits cortical SEPs to be recorded when sensory nerve responses are not recordable by conventional tech-
niques.113,116,117 Therefore, in cases of severe peripheral nerve disease in which conventional determination of nerve conduction is impossible, NCV may be calculated by stimu-
ulating a peripheral nerve at two sites and subtracting the latencies of the corresponding scalp-recorded SEPs. Simi-
larly, conduction can be determined in cases of peripheral nerve entrapment in which conventional nerve conduction responses are difficult or impossible to obtain, as in the case of entrapment of the lateral femoral cutaneous nerve (meralgia paresthetica).116

Radiculopathy. Much has been published on the use of SEPs in the diagnosis of radiculopathy.116,118-138 These studies have shown that SEPs recorded from nerves derived from several nerve roots (e.g., median and peroneal nerves) have limited value in diagnosing radiculopathies because abnormalities in a single involved root would be “overshadowed” by contributions from uninvolved roots supplying that nerve. To circumvent this problem, techniques to derive SEPs from single nerve roots have been investigated. This has been accomplished by stimulation of an area of skin derived from a single dermatome (e.g., the great and first toe web space innervated by the L5 nerve root).129-132 Another method has involved stimulation of segmentally innervated cutaneous sensory nerves (e.g., using the sural nerve to evaluate the S1 nerve root) (Fig. 14.20).133

Results from these “segmentally specific” techniques have ranged from excellent to “essentially useless,” with reported abnormality rates in radiculopathy ranging from 7% to 92%,134-137 Some of the controversy stems from differences in the diagnostic criteria used to determine abnormality. Because any slowing of NCV from a focal lesion of an individual nerve root would be “diluted” by normal conduction along the remainder of the nerve, abnormalities in latency are found less often than a reduction in amplitude. Since amplitude varies even among normal individuals, reduction of amplitude as an indication of abnormality is less reliable than abnormalities in latency.83,123,128

Abnormalities in latency were observed in some individuals, and the diagnostic yield was improved when latency and amplitude values were compared with those of an opposite uninvolved extremity that was used as a control. Reports of using spinal rather than cortical SEPs after segmental sensory stimulation suggest a more reliable method for diagnosis of radiculopathies.138

Despite the controversy, some consensus exists regarding the usefulness of SEPs in diagnosing radiculopathies. They are purportedly useful for radiculopathies in which sensory symptoms predominate and diagnosis by other techniques such as EMG is difficult.126,129,133,139 Nevertheless, EMG
Studies have shown that SEPs may be frequently abnormal in myelopathy but not with radiculopathy alone.

Surgical decompression of these lesions, SEP abnormalities correlated well with the presence of spinal stenosis, with dermatomal SEPs reported to be superior to EMG in diagnosing central and lateral recess lumbar stenosis. SEP abnormalities have improved after surgical decompression of these lesions. In central spondylosis, SEP abnormalities correlated well with the presence of myelopathy but not with radiculopathy alone.

Thoracic Outlet Syndrome. Although ulnar nerve SEPs are controversial, they have been used in an attempt to identify thoracic outlet syndrome. In patients with suspected thoracic outlet syndrome who demonstrated no objective signs of neurologic involvement (e.g., weakness of the hand muscle, numbness, and abnormal findings on EMG), ulnar nerve SEPs were generally normal.

In neurogenic thoracic outlet syndrome, SEP abnormalities included prolonged, attenuated, or absent N9 or N13 peaks, or both, and an increased N9-to-N13 IPL. Normal findings on SEP studies of the median nerve in the involved extremity and side-to-side comparisons were also used to confirm the diagnosis. In cases treated surgically, postoperative improvement in ulnar SEPs was reported.

Brachial Plexopathy. Studies have shown that SEPs may provide useful information for the management of patients with brachial plexopathies. The ability to record SEPs helps confirm axonal continuity and may help determine whether lesions are preganglionic or postganglionic. As in the case of radiculopathy, segmentally specific testing rather than stimulation of multisegmented nerves provides more specific and accurate information.

SEPs are limited in that they test the sensory portions of nerves, which allows only inference concerning motor function. Furthermore, when multiple lesions are present, SEP abnormalities may reflect just the most distal lesions. Therefore, in a patient with a postganglionic lesion, a preganglionic lesion involving the same nerve fibers may go undetected.

Lumbar Spinal Stenosis and Cervical Spondylosis. SEPs have been useful in the diagnosis of lumbar and cervical spinal stenosis, with dermatomal SEPs reported to be superior to EMG in diagnosing central and lateral recess lumbar stenosis. SEP abnormalities have improved after surgical decompression of these lesions. In central spondylosis, SEP abnormalities correlated well with the presence of myelopathy but not with radiculopathy alone.

Spinal Cord Lesions. SEPs are frequently abnormal in patients with spinal cord lesions affecting the posterior columns. Intramedullary and extramedullary tumors, traumatic spinal cord injury, and vascular lesions may produce these abnormalities. Complete spinal cord lesions generally abolish all recordable SEP responses above the lesion. Partial lesions may or may not produce SEP abnormalities, depending on the extent of posterior column involvement. In traumatic spinal cord injury, good correlation between SEP results and the severity of spinal cord injury has been noted. The prognosis for recovery is better when the SEPs are normal in the early post-traumatic period.

Trigeminal Nerve Lesions. SEPs recorded from the trigeminal nerve are reported to be abnormal in approximately 41% of patients with idiopathic and multiple sclerosis-related trigeminal neuralgia. In patients undergoing retrogasserian injection of glycerol, alteration in SEP waveforms correlated well with successful treatment as measured by pain relief. Trigeminal SEPs have been used successfully in the diagnosis of paraspinal and cerebellopontine angle tumors affecting the trigeminal nerve, even if the involvement was subclinical. In addition, information concerning the site of the lesion along the trigeminal pathway can be obtained.

Lesions of the Brainstem and Cerebral Hemisphere. Tumor, infarct, and hemorrhage involving the somatosensory pathway of the brainstem and cerebrum generally produce SEP abnormalities. SEPs may be particularly useful in patients with thalamic pain, in whom abnormalities in N20 and P23 have been reported following median nerve stimulation. Thalamic lesions involving areas other than the ventroposterolateral nucleus are usually associated with normal SEPs. Lesions involving the thalamocortical radiations or the sensory cortex may produce a normal N20 and an abnormal P23 response unless retrograde degeneration of the thalamic nuclei has occurred, which results in abnormalities in both responses.

Median nerve SEPs have demonstrated prognostic value in patients with right hemiplegia. Abnormalities in N20 and P23 correlate with a poorer prognosis for functional
recovery. In cases of traumatic head injury and coma, SEPs have proved valuable in localizing lesions and as a predictor of both favorable and unfavorable outcomes.

Multiple Sclerosis. SEPs are used frequently in conjunction with VEPs and AEPs to evaluate patients with suspected multiple sclerosis. The incidence of SEP abnormalities is higher in patients with sensory symptoms. Furthermore, SEP abnormalities are more frequent in the lower extremities. The sensitivity of SEPs in the diagnosis of multiple sclerosis has been comparable to that of VEP testing. Some studies have demonstrated SEPs to be equal to or better than MRI for diagnosis of this disease. SEP abnormalities include prolongation of latencies and attenuation or absence of responses.

Monitoring during Surgery. SEPs have been used to monitor the integrity of the somatosensory pathway and cerebral status during various vascular and neurosurgical procedures, most notably carotid endarterectomy and scoliosis surgery. The use of SEP surgical monitoring has become routine in many communities, and its applications continue to expand.

Other Uses. SEP abnormalities have been found in various degenerative, hereditary, and metabolic disorders. Abnormal SEPs have been reported with Friedreich’s and other cerebellar ataxias, Huntington’s chorea, motor neuron disorders, Guillain-Barré syndrome, Charcot-Marie-Tooth disease, vitamin B12 deficiency, diabetes, and hyperthyroidism. SEPs have been used in conjunction with electroencephalography to determine brain death. SEP abnormalities include prolongation of latencies and attenuation or absence of responses.

Motor EPs have found their greatest usefulness in determining central conduction through the motor structures of the brain and spinal cord. By recording from distant sites (e.g., muscles in the extremities), one can determine motor conduction throughout the entire motor pathway. This test is performed in a manner similar to that for SEPs, with the exception that the stimulus is applied centrally and recorded peripherally.

Clinical Utility
Motor EPs have found wide clinical utility in the diagnosis of disorders that affect the central or peripheral motor pathways. Abnormalities in motor EPs have been described in patients with multiple sclerosis, Parkinson’s disease, cerebrovascular accident, myelopathy in the cervical and lumbar spines, plexus lesions, and motor neuron disorders. Cortical hyperexcitability has been demonstrated in migraine patients with transcranial magnetic stimulation. Motor EPs are also finding a role in intraoperative monitoring of neuronal structures placed at surgical risk.

EVENT-RELATED POTENTIALS
Unlike the previously discussed EPs, which are recorded from simple sensory or motor stimuli, event-related potentials record cortical activity evoked by a stimulus with cognitive significance. Various techniques have been developed to assess the temporal aspects of cognitive processing. The most common technique uses the presentation of randomly occurring infrequent stimuli interspersed among more frequently occurring stimuli of a different type (i.e., an infrequent deep tone occurring randomly among more frequently occurring high-pitched tones). The subject is instructed to attend only to (or to count) the infrequent stimuli, which results in an evoked waveform with a latency of approximately 300 msec and positive polarity. This waveform is referred to as the P300 response. Prolongation of the P300 response is associated with disorders that impair cognition, such as dementia, neurodegenerative disorders, schizophrenia, and autism. It has also been used as a predictor of early outcome after emergence from traumatic coma.

CONCLUSION
In conclusion, electrodiagnostic techniques such as EMG and EP testing remain useful techniques for the diagnosis of central and peripheral neuropathies. Even though they have been found helpful in diagnosing some disorders of the central nervous system, they are much more useful in disorders of the peripheral nerves and less frequently found in painful myopathies. Neuromuscular junction disorders, amyotrophic lateral sclerosis, and other anterior horn cell disorders, except poliomyelitis in its acute stage, rarely produce pain.

Clinical use of electrodiagnostic techniques has expanded rapidly because of improvements in equipment and increased standardization of techniques. Recent advances in magnetic stimulation are allowing evaluation of central motor pathways and deep peripheral nerves that was not possible previously with SEPs and conventional nerve conduction techniques. Advancements in quantitative electroencephalographic and topographic brain mapping are being applied to EPs and promise additional information beyond that provided currently by EP testing alone.
Although electrodiagnostic techniques may find, confirm, and localize a nerve or muscle disease process, the relevance of the electrodiagnostic finding to the patient’s pain symptomatology must be determined by the referring physician and the electromyographer, who should work together to assess all available history, physical examination findings, other laboratory tests, and imaging findings before finalizing the diagnosis and establishing a treatment plan.

**KEY POINTS**

- Electromyography (EMG) and evoked potentials (EPs) are physiologic tests, and their relationship to anatomy must be inferred.
- Little has been written about the use of EMG and EPs in relation to pain, largely because pain is mostly carried by C fibers and Aδ fibers and these are poorly represented in EMG in comparison to larger fibers.
- EMG and EPs need to be correlated with the clinical picture to arrive at a proper diagnosis and may be considered an extension of the clinical examination.
- EMG and nerve conduction studies (NCSs) may differentiate between neuropathic and myopathic conditions and determine whether single nerves, multiple nerves or plexuses, or nerve roots are involved.
- From the distribution of pathology on EMG and NCSs, an anatomic distribution can be inferred and the differential diagnosis of painful conditions narrowed.
- Needle EMG determines the state of a given muscle (i.e., normal, neuropathic, or myopathic). Needle examination of multiple muscles determines the pattern of involvement, if present, and gives an anatomic diagnosis of a painful condition.
- NCSs may indicate normal conduction, conduction block, or slowed conduction and may differentiate among entrapment neuropathies, axonal neuropathies, and demyelinating neuropathies and hence narrow the differential diagnosis of a painful condition affecting the nerves primarily.
- There are few significant side effects with EMG, NCSs, or EPs and very few absolute contraindications to their performance.
- The needle portion of the EMG is performed at rest, with minimal voluntary effort, and with maximum voluntary effort.

Imaging is a significant, but not independent, component of the multifaceted evaluation of the patient with spine or limb pain. Imaging must be interpreted in concert with the history, physical exam, electrodiagnostic evaluation, and responses to image-guided anesthetic or provocative procedures. It does not stand alone, but can only be understood in its proper context: the individual patient’s unique syndrome of pain or neurologic dysfunction.

Pain of spinal origin is extremely common; low back pain is the second most common cause of symptomatic office visits in the United States.1,2 There is a nearly 75% lifetime prevalence of back pain in the United States,3 and one third of U.S. adults report back pain in the previous 3 months.1 Advanced imaging is applied to this complaint with ever-increasing frequency; the number of lumbar magnetic resonance imaging (MRI) scans among Medicare beneficiaries rose fourfold from 1994 to 2005.4 Over 40% of patients with acute low back pain underwent immediate imaging in a private insurance claims database study.5 In another Medicare-based study of low back pain patients without red flags for systemic disease, nearly 30% underwent imaging (radiography or advanced imaging) within 28 days.6 In a study in an emergency department environment, the use of advanced imaging (computed tomography [CT] or MRI) for low back pain tripled from 2002 to 2006.7 Approximately one third of Medicare low back pain patients who undergo outpatient MRI studies have not received any prior conservative therapy.8

Despite this intensity of imaging and the downstream effects of increasing minimally invasive interventions and surgical procedures that flow from them, there is no evidence that patient outcomes are improving. Measures of physical functioning, work/school limitations, and mental health in U.S. adults with back or neck complaints were similar or worse in 2005 than in 1997.9 A regional study (North Carolina) demonstrated that the proportion of adults with chronic low back pain causing activity impairment rose from 3.9% in 1992 to 10.2% in 2006.10 A review article by Chou, Deyo, and Jarvik examined the evidence for our inefficient utilization of imaging in the back pain patient, underlying causal forces and mechanisms for initiating improvements.11 The purpose of this chapter is to foster the rational decision making they advocate in the use of spine imaging, based on evidence, as we in the pain management community seek to improve patient outcomes.

**THE GOAL OF IMAGING**

The primary goal of imaging in the patient with spine or limb pain is to identify patients who are suffering from an undiagnosed systemic process causal of the pain/dysfunction syndrome. This is an uncommon phenomenon. An analysis by Jarvik and Deyo12 suggests that 95% of low back pain is due to benign processes. In patients presenting to a primary care setting with low back pain, only 0.7% suffer from undiagnosed metastatic neoplasm. Spine infection, including pyogenic and granulomatous diskitis, epidural abscess, or viral processes, is present in only 0.01% of subjects. Noninfectious inflammatory spondyloarthropathies, such as ankylosing spondylitis, account for 0.3% of presentations. Osteoporotic compression fractures are the most common systemic pathologic process to present as back pain, accounting for 4% of patients.12 Imaging seeks to identify the approximately 5% of patients with back or limb pain who have undiagnosed systemic disease as the etiology of their pain. A related imaging goal is to characterize and assist in therapy planning in the very small percentage of patients who have neural compressive disease resulting in radiculopathy or radicular pain syndromes that fail conservative therapy and require surgical or minimally invasive intervention.

**SPECIFICITY: ASYMPTOMATIC IMAGING FINDINGS**

The low prevalence of systemic disease as a cause of back pain implies that most imaging studies primarily describe what are often, and inappropriately, termed “degenerative” phenomena. These may include anterior and lateral vertebral body osteophytes, loss of T2 signal in the intervertebral disk, and structural changes of facet arthrosis. Degeneration is a pejorative term implying disease; these changes have no relationship to pain syndromes and correlate only with age. They are best referred to as age or age-related change. These age changes are typically relatively uniform across the spine, although the lowest lumbar segments are over-represented. Evidence for the lack of specificity of such imaging findings for spine pain syndromes is evident in cadaver studies, imaging studies in asymptomatic populations, and population studies.

Nathan13 described the presence of anterior and lateral osteophytes in 100% of cadavers at the age of 40, whereas posterior osteophytes are present only in a minority of cadavers at 80 years of age. Hult14 studied adults with spine radiographs and showed that by age 50 years, 87% will have radiographic evidence of disk age-related change (narrowing of the disk space, marginal sclerosis with osteophytes, vacuum phenomena). In a second study including a cohort of asymptomatic workers, Hult15 noted radiographic evidence of disk
“disease” in 56% of those aged 40 to 44 years, which rose to 95% in subjects 50 to 59 years old. With the evolution of more sophisticated spine imaging techniques, this lack of specificity of degenerative findings has not improved. Hitselberger and Witten16 studied plain myelography of asymptomatic volunteers and noted that 24% showed abnormalities that would have been considered significant in a clinical context of back or leg pain. A study of lumbar spine CT in asymptomatic volunteers by Wiesel and colleagues17 showed that in patients older than 40 years, 50% had “significant” abnormalities. Similarly, Boden and colleagues18 evaluated MRI of the lumbar spine in asymptomatic volunteers; in patients older than 60 years, 57% had abnormalities that would have been considered significant and would separate patients with pain from asymptomatic volunteers. Imaging studies of asymptomatic volunteers are compiled in Table 15.1.20-25

A study by Kanayama26 in 200 healthy adults (mean age 40, with no current complaint or therapy for back pain nor any history of lumbar surgery) segregated lumbar MRI findings by segmental level (Table 15.2). Asymptomatic T2 signal loss and disk herniations were most common at the L4 and L5 segmental levels; this series also had a high prevalence of asymptomatic high intensity zones (HZ) (24% at L4 and L5). More recent studies have addressed the prevalence of disk “degenerative” imaging findings (T2 signal loss, loss of disk space height) in younger populations, primarily in Scandinavian countries; these are MRI population-based studies without regard to symptomatology. Kjaer and colleagues,27 studying children age 13 years, found a 21% prevalence of disk “degeneration.” In a study of adolescents, Salminen and colleagues28 found a 31% prevalence of disk “degeneration” in 15-year-olds, which rose to 42% in 18-year-olds. Takatalo and colleagues29 evaluated 558 young adults aged 20 to 22 years. Using the 5-point Pfirrmann classification of disk degeneration, they noted disk degeneration of grade 3 or higher in 47% of these young adults. There was a higher prevalence in males (54%) than in females (42%). Multilevel degeneration was identified in 17%.

As in the lumbar region, age changes in the cervical and thoracic spine are common, asymptomatic, and increase in prevalence with age. Matsumoto studied nearly 500 asymptomatic patients with MRI; he noted a loss of T2 signal within cervical disks in 12% to 17% of patients in their twenties, but in 86% to 89% of patients older than 60 years of age.30 Asymptomatic cervical cord compression was observed in 7.6% of patients, largely over the age of 50. Similarly, Boden studied 63 asymptomatic subjects with MRI and noted cervical disk “degeneration” in 25% of those younger than 40, and in excess of 60% of patients older than 40 years of age.31 Asymptomatic subjects older than 40 years of age had a 5% rate of disk herniations and a 20% rate of foraminal stenosis. Teresi studied 100 asymptomatic subjects with MRI and noted asymptomatic cervical cord compression in 7.6% of patients, largely over the age of 50. Similarly, Boden studied 63 asymptomatic subjects with MRI and noted cervical disk “degeneration” in 25% of those younger than 40, and in excess of 60% of patients older than 40 years of age.31 Asymptomatic subjects older than 40 years of age had a 5% rate of disk herniations and a 20% rate of foraminal stenosis.

The evidence is deep and overwhelming. The structural spine imaging findings most commonly referred to as “degenerative changes” or “degenerative disk disease,” including anterior and lateral osteophytes, loss of T2 signal in the disk, loss of disk space height, disk bulges and protrusions, and facet arthrosis, are ubiquitous and unassociated with pain syndromes; their only association is with age. They can only be avoided by a youthful death. They are not a disease state and are best referred to as normal age change or age-related change.

A consequence of this high prevalence of asymptomatic age-related changes is that the imager must know the nature of the pain syndrome if he or she is to properly focus on findings significant to the unique patient under consideration. There must be concordance of the imaging finding and the pain syndrome it is postulated to elicit. Imaging cannot prove causation, hence the need for anesthetic and provocative procedures. Communication regarding the nature of the pain syndrome is essential, whether this occurs through a robust electronic medical record, an intake document at the imaging site, or direct interaction of the imager with the patient.

**SENSITIVITY: PHYSIOLOGIC IMAGING**

There is also a major sensitivity fault associated with spine imaging. The majority of patient symptoms referable to the spine occur in axially loaded positions, either sitting or standing. A substantial portion of radiographs and most advanced imaging (CT and MRI) are obtained in a recumbent position, removing the effects of axial load and physiologic posture. This may fail to reveal the lesion responsible for the index pain.

There is ample evidence of the effect of axial load and physiologic posture on the biomechanical and structural characteristics of the spine, derived from biomechanical, cadaver, and imaging studies. Lumbar intradiskal pressures are higher when sitting or standing than when in a recumbent position. The cadaver study of Inufusa demonstrated a reduction in the cross-sectional area of the lumbar central canal and lateral recesses in extension, with an increase in flexion. Lumbar neural foraminal cross section is also diminished in extension and increased in flexion. Fujikawa noted a reduction in cadaveric lumbar neural foraminal area with side bending or rotation toward the index foramen; an increase in area was observed with side bending or rotation away from the foramen. Schmid observed a 40-mm² reduction in the cross-sectional area of the dural sac at the L3-L4 level with movement from flexion to extension. The lumbar neural foraminal cross-sectional area was reduced by 23% in moving from an upright neutral to an upright extended position. Danielson noted a significant decrease in the dural sac cross-sectional area with axial loading in 56% of subjects, most commonly at L4-L5; this was more common with increasing age. Dynamic reduction in dural sac area with loading was less frequent in normal volunteers than in a population of patients with neurogenic intermittent claudication. Hansson and colleagues identified the ligamentum flavum as the most important structure resulting in dynamic reduction in the lumbar central canal area under physiologic loading. Physiologic posture (lumbar lordosis) is likely more important than axial load. Multiple studies in patients with upright imaging have demonstrated the enlargement of lumbar disk bulges or protrusions with axial load, which may be further exacerbated with extension. Synovial cysts, which may be provocative of radicular pain syndromes or contribute to neurogenic intermittent claudication, may be undetectable on recumbent imaging when synovial fluid remains in the facet joint space. Upon the assumption of axial load and apposition of the facet articular surfaces, the fluid is forced from the joint space into the cyst, where it may act as a neural compressive lesion. The cervical spine similarly exhibits dynamic physiologic change with posture and load. Cadaveric studies have demonstrated increased disk bulging and buckling of the ligamentum flavum in cervical spine extension; the ligamentum flavum effect was most significant. MRI studies of patients noted an increase in central canal stenosis with both extension and flexion of the cervical spine relative to neutral posture; the decrease was most marked in extension. Cervical neural foramina diminish in cross section, width, and height in extension and increase in all these parameters in flexion.

In summary, physiologic extension and axial load reduce the area of all lumbar spine compartments; these are increased in flexion. The cervical central canal is diminished in areas in extension more so than in flexion; it is maximal in the neutral position. Cervical foramina increase in all dimensions in flexion and diminish in extension. These dynamic changes constitute the greatest sensitivity fault in imaging: conventional supine imaging may fail to reveal a lesion that is causal of the patient’s symptoms when that lesion is only expressed in physiologic postures.

Several methods have been devised to overcome this sensitivity fault. Radiographs should always be obtained upright; this allows assessment of sagittal and coronal balance in a physiologic posture. Flexion-extension radiographs may detect instability not observed on neutral upright views, but the yield...
of diagnostic information is very low. In studies in both the lumbar and cervical spine segments, less than 1% of flexion-extension radiographic studies provided information over that noted on static upright radiographs. The cost and radiation exposure is best deferred to a presurgical setting, not during an initial evaluation of the back or neck pain patient.

Advanced imaging can be performed with axial loading devices on conventional CT or MRI scanners. These devices can improve the sensitivity to the detection of clinically significant central canal compromise. The 2011 North American Spine Society’s evidence-based guidelines on evaluation and treatment of spinal stenosis suggest axially loaded imaging in the setting of suspected neurogenic intermittent claudication and stenosis unconfirmed by conventional imaging, with a canal diameter of less than 110 mm. Willén and colleagues demonstrated that surgical results of cases of occult lumbar spinal stenosis detected only by axially loaded MRI were comparable to those of stenosis observed in unloaded MRI examinations.

MRI scanning in an upright position—sometimes referred to as dynamic, positional, or kinetic MRI—is now commercially available and widely marketed. The practical challenge is that currently available systems are of low field strength (0.6T), with an unavoidable reduction in image quality. This reduction in image quality can have important consequences for clinical image interpretation. If current low field strength dynamic systems were applied selectively to cases where conventional imaging failed to demonstrate a correlative lesion causal of the patient’s pain, the patient would likely benefit. All too often, however, the cost of these systems results in their routine use, or even promotion as the best available imaging tool for all spine conditions. This practice could harm patients, as diminished image quality reduces sensitivity to the detection of sinister lesions, which is the primary goal of imaging the back pain patient (Fig. 15.1).

**VALIDITY**

Spine imaging must be undertaken with a full understanding of the specificity and sensitivity faults inherent in its use. The ultimate question, of course, is one of validity: Does performing an imaging study of the spine segment in question result in improved patient outcomes through a more timely and accurate diagnosis of the process causing the patient’s pain? This is well studied, particularly in the application of imaging to the acute presentation of back pain. Chou and colleagues performed a meta-analysis of the six randomized controlled trials (n = 1804) examining the role of imaging in the acute presentation of back or limb pain with no clinical features suggesting systemic disease. They identified no benefit in pain, function, quality or life, or patient-rated improvement in patients undergoing imaging (radiographs, CT, or MRI) at presentation versus those undergoing clinically directed conservative care. Although routine imaging might have been expected to provide reassurance, imaging patients did not have better psychological outcomes.

Carragee and colleagues elegantly demonstrated the lack of utility of imaging in the acute setting in a 5-year prospective observational study. A cohort of asymptomatic subjects deemed to be at risk for back pain resulting from labor-intensive vocations underwent lumbar spine MRI. This patient cohort was followed periodically over the subsequent 5 years; a subset of these subjects presented to a medical care provider with acute back or leg pain during this 5-year period and a second lumbar MRI was obtained. Less than 5% of the MRI scans obtained at the time of acute presentation with back or leg pain showed clinically relevant new findings; virtually all of the “positive findings” noted on the images at the time of presentation with back/leg pain had been present on the baseline studies obtained when the patient was asymptomatic. Only direct evidence of neural compression in patients with a corresponding radicular pain syndrome was considered to be useful imaging information. Of particular note, psychosocial factors, not the morphology seen on imaging, were the best predictors of the degree of functional disability caused by back or leg pain.

A study by Modic, also in the acute presentation of low back pain or radiculopathy, showed no relationship between the extent of disk herniations and presenting signs or symptoms. The type, size, or location of a herniation at presentation, or change in size or type over time, did not correlate with clinical outcomes. MRI imaging characteristics did not have measurable value in planning conservative care. The study emphasized that the surgical decisions must be based on clinical grounds, given the inability of imaging to predict outcomes. The Modic study, like that of Carragee, demonstrated that psychosocial factors predict functional disability better than imaging parameters.

Although the depth of evidence regarding the inability of imaging to improve outcomes in back and limb pain patients is most profound in the acute setting, it applies more broadly as well. Chou and colleagues explored the seemingly counterintuitive finding that routine imaging does not lead to better outcomes in back or limb pain. This lack of utility can be attributed to the favorable natural history of back and limb pain, the low prevalence of sinister disease as causal of back pain, the weak correlation between imaging findings and symptoms (the specificity fault), and the minimal impact of imaging on clinical decision making. Given the demonstrable modest utility of imaging, the decision to undertake this path must be a carefully reasoned one.

**IMAGING RISK/BENEFIT**

The decision to proceed with any medical test or procedure should be preceded by a consideration of likely benefit weighed against risk or actual harms. Certainly there are benefits to be derived from imaging. Foremost, imaging may suggest the diagnosis of previously unsuspected systemic disease. In the patient with a radicular pain syndrome or radiculopathy that has not responded to conservative therapy, imaging may supply invaluable information that allows planning of minimally invasive or surgical procedures. Negative imaging should also have value in providing reassurance that there is no sinister disease present and in stopping further workup in appropriate circumstances. Finally, in patients with chronic pain syndromes, imaging may assist in the identification of the structural or inflammatory cause of such pain. Only when a specific pain generator is identified can a specific plan of therapeutic intervention, whether it be conservative or invasive, be developed.

There are direct harms and potential risks associated with imaging, which must be balanced against potential benefits. These include radiation dose, cost, the labeling effect, and
the downstream risk of provoking minimally invasive or surgical interventions of dubious efficacy.

Radiation dose in radiography, CT or CT/myelography, and nuclear medicine studies constitutes a direct patient harm. Radiation exposure from radiographs, CT, and nuclear medicine studies carries a cumulative risk of neoplasm induction. This risk becomes particularly problematic when serial studies are performed. The biologically effective absorbed radiation dose is measured by the Sievert (Sv); in North America, the average annual natural background exposure is approximately 3 mSv.55 A frontal and lateral chest radiograph is often considered the common currency of radiation exposure, incurring a dose of approximately 0.1 mSv. A frontal and lateral chest radiograph is often considered the common currency of radiation exposure, incurring a dose of approximately 0.1 mSv. A three-view lumbar spine radiographic series is then worth approximately 15 chest radiographs, or 1.5 mSv; cervical spine radiographs incur a dose 0.2 mSv. A dose of 6 mSv is typical for a lumbar spine CT scan, a value of 60 chest radiographs. Cervical spine CT incurs 2 mSv, or 20 chest radiographs. A technetium bone scan has a dose of 6.3 mSv. The cumulative radiation exposure creates real harm; the 2.2 million lumbar spine CT scans performed in the United States in 2007 were projected to result in 1200 future cancers.56 Although less radiation intensive, lumbar radiography is performed much more frequently than CT and contributes nearly fivefold the cumulative radiation burden to the U.S. population.57 The average annual radiation exposure from lumbar radiographs is 75 times that of chest radiography.57 Radiation risks of spine imaging are made more acute by the necessary inclusion of radiosensitive tissues, the gonadal structures in the pelvis, and the thyroid in the neck.

Imaging studies of the spine are costly. In the United States, the medical imaging community incurs more than $100 billion of societal cost per year. The 2012 Medicare reimbursements for lumbar spine imaging include radiographs: $41; noncontrast CT: $264; myelogram: $506; noncontrast MRI: $439; whole-body positron emission tomography (PET) / CT: $1183; bone scan with single-photon emission CT (SPECT): $261.18 Nominal fees are typically 3 to 5 times the Medicare reimbursements. It is easy to appreciate how quickly imaging costs can accrue.

Figure 15.1 Diminished sensitivity of low field strength upright MRI to sinister lesions. A 74-year-old female presented with bilateral lower extremity weakness and pain with a low field strength upright MRI from another institution. Sagittal T2 image (A) and axial T2 image (B) at the L4 level show degenerative spondylolisthesis at L4 with central canal compromise. She underwent an L3-L5 decompression without change in symptoms. A 1.5 Tesla MRI performed 3 weeks postoperatively demonstrated nodularity (arrows) in the cauda equina on a T2 sagittal image (C). Gadolinium-enhanced fat-saturated T1 sagittal (D) and axial (E) images demonstrate diffuse leptomeningeal metastases from breast cancer. She died in 2 months. A high-quality preoperative MRI would have likely led to the diagnosis and avoided an unnecessary operation. (From Khalil JG, Nassr A, Maus TP. Physiologic imaging of the spine. Radiol Clin North Am. 2012;50:599-611.)
The labeling effect refers to the inevitable identification of age-related change, usually described as “degenerative change,” or “degenerative disk disease” on imaging studies obtained in evaluation of back or limb pain. The patient may then perceive that he or she suffers from a degenerative spine condition; the term degenerative has only negative connotations. Fearing further damage to their “degenerative” spine, they may give up favorite activities and exercise, resulting in deconditioning and contributing to depression. These fear-avoidance behaviors can be a major impediment to recovery. In a study in which back pain patients were randomized to either receiving or being blinded to the results of their MRI imaging, those who were privy to the results (which were all benign) had a lesser sense of well-being. A study of subacute or chronic back pain patients showed that those who underwent spine radiography reported more pain, had a diminished global health state, and consumed more follow-up care than those who were not imaged. These findings emphasize the need for patient education regarding the insignificance of age-related imaging findings; imaging professionals should carefully choose descriptive language in imaging reports and avoid the use of pejorative terms such as “degenerative change.”

Finally, and most ominously, imaging may precipitate interventions that have little evidence of efficacy and expose the patient to harm. Jarvik and colleagues documented that obtaining advanced imaging (MRI) early in a patient’s spine pain syndrome leads to increased surgical interventions despite equivalent pain and disability profiles, when compared with un-imaged patients. Likewise, Lurie and colleagues examined the dramatic regional variation (12-fold) in the rate of surgical intervention for central canal stenosis. These investigators noted that the rate of surgical intervention correlated directly with the intensity of CT and MRI use. Webster and colleagues, evaluating subjects with acute job-related back pain, noted that undergoing an MRI in the first month of symptoms was associated with an eightfold increased risk for surgery and a fivefold risk for more medical care consumption than that noted for clinically matched, un-imaged subjects. Many of the interventions directed toward spine pain, both surgical and minimally invasive, have only modest, if any, evidence basis.

**IMAGING RECOMMENDATIONS**

Imaging is performed to identify sinister disease as a cause of a patient’s back or limb pain. Spine imaging has major specificity and sensitivity faults. The decision to initiate imaging must occur as a reasoned decision, weighting potential benefit against real harms and risk. The evidence is clear that there is no benefit to imaging in the acute presentation of back or limb pain in the absence of signs or symptoms of systemic disease. These principles are firmly based on evidence and have led to the imaging guidelines promulgated by several scientific societies.

These guidelines are not new. In 1994, the Agency for Health Care Policy and Research recommended against imaging patients with back pain within the first month of a pain syndrome in the absence of signs or symptoms of systemic disease. The American College of Radiology (ACR) consensus practice guidelines were restated in 2009. Imaging is not indicated in the patient who presents with acute low back pain with or without radiculopathy except in the presence of “red flag” features including the following:

- Recent significant trauma, minor trauma in a patient older than 50 years
- Unexplained weight loss
- Unexplained fever
- Immunosuppression
- History of neoplasm
- Prolonged steroid use or osteoporosis
- Age greater than 70 years
- Known intravenous drug abuse
- Progressive neurologic deficit with intractable symptoms
- Duration longer than 6 weeks

A 2007 joint recommendation from the American College of Physicians (ACP) and the American Pain Society stated that imaging should not be obtained in patients with non-specific low back pain. Imaging should only be performed when severe or progressive neurologic deficits are present or when serious underlying systemic disease is suspected. Furthermore, patients with signs or symptoms of radiculopathy or spinal stenosis should be imaged only if they are candidates for surgical or minimally invasive intervention (e.g., epidural steroid injection). In a further elaboration on these guidelines, the ACP, in its initiative to promote high-value medical care, provided more specific imaging recommendations based on clinical scenarios (Table 15.3).

There is evidence that of the small proportion of subjects with sinister disease as the cause of their back or limb pain, virtually all have risk factors that trigger imaging under these guidelines. A retrospective study of 963 patients presenting with acute low back pain noted that the 8 subjects with neoplasm all had clinical risk factors. In a prospective study of 1170 acute low back pain patients without clinical risk factors, no cases of neoplasm were found. No sinister disease was missed in the absence of clinical risk factors in a subsequent systematic review.

Despite these well-supported, evidence-based guidelines, clinical practice in the United States remains greatly divergent from this ideal. By one estimate, between one third and two thirds of all advanced spine imaging is inappropriate when measured against existing guidelines. Utilization of spine imaging is accelerating despite a complete lack of evidence of its effectiveness in improving the outcomes of back and limb pain patients. Chou and colleagues have enumerated causes of this overutilization: inappropriate patient expectations, direct and indirect financial incentives on the part of providers, defensive medicine, and provider time constraints. These issues present great challenges to imaging professionals and those who utilize imaging to improve the clinical state of their patients. Solutions will undoubtedly be multifactorial, but education of the patient, the imaging professional, and imaging consumers would seem to be at the heart of the matter. It is hoped that the evidence presented here will assist in more rational decision making regarding imaging the spine pain patient (Box 15.1).

**RADIOGRAPHS**

With the failure of clinically directed conservative care, and having made a reasoned decision to initiate imaging of
Suggestions for Initial Imaging

- Major risk factors for cancer (new onset of low back pain with history of cancer, multiple risk factors for cancer, or strong clinical suspicion for cancer)
- Risk factors for spinal infection (new onset of low back pain with fever and history of intravenous drug use or recent infection)
- Risk factors for or signs of the cauda equina syndrome (new urine retention, fecal incontinence, or saddle anesthesia)
- Severe neurologic deficits (progressive motor weakness or motor deficits at multiple neurologic levels)

Defer Imaging after a Trial of Therapy

No imaging is indicated in the acute presentation of back or limb pain in the absence of “red flag” features.

Spine Imaging Principles

- The primary role of imaging is the identification of undiagnosed systemic disease.
- Spine imaging has a significant specificity fault: a high prevalence of asymptomatic age-related “degenerative” findings.
- Significance of imaging findings depends on concordance: the imager must know the pain/dysfunction syndrome.
- Spine imaging may be insensitive to dynamic lesions.
- No imaging is indicated in the acute presentation of back or limb pain in the absence of “red flag” features.
- The decision to undertake imaging must be a reasoned harms and risk/benefit judgment.
- Imaging correlates poorly with clinical presentation and course.

identified 23 presacral segments in 3.3% of subjects and 25 in 3.3%; these anomalies of spine enumeration were not mentioned in the radiology report in nearly 70% of cases. In Carrino’s study, if one considers both anomalous number and distribution (e.g., 13 rib-bearing vertebrae + 4 lumbar type vertebrae) of thoracolumbar spine segments, 10.9% of subjects have nonclassical anatomy. For the spine interventionist, this implies these situations are in the procedure room regularly; failure of recognition virtually guarantees wrong segment procedures.

Anomalous segmentation is predicted by the presence of transitional thoracolumbar or lumbosacral vertebral bodies.
which may be a source of confusion in their own right. Thoracolumbar transitional segments have hypoplastic ribs at the lowest rib-bearing segment; they were present in 4.1% of subjects in Carrino’s study. Lumbosacral transitional segments have characteristics of both the L5 lumbar body and the superior sacral segment; their described prevalence ranges from 4% to 30%. The Castellvi classification (Fig. 15.2) describes the morphologic types, ranging from an expanded (height > 19 mm) dysplastic transverse process (type I), through a pseudoarticulation between the transverse process and sacral ala (type II), to osseous fusion between the transverse process and the sacrum (type III). Type IV denotes the presence of a type II transition on one side and a type III on the other. Unilateral (a) and bilateral (b) subtypes are also described. On lateral radiographs or sagittal MRI images, a transitional segment can be suggested in the presence of a perceived narrow S1-S2 disk, which extends for the entire anterior-posterior (AP) width of the sacral body with parallel end plates and a squared upper extends for the entire anterior-posterior (AP) width of the sacral body with parallel end plates and a squared upper.

Correlation of pain syndromes with imaging findings can be confounded in patients with transitional anatomy or anomalous segmentation. It is best to consider that, in general, radicular innervation patterns remain relatively constant when counted caudally from the skull base, but the skeletal anatomy may change about them. For example, the 26th nerve (8 cervical nerves, 12 thoracic, 5 lumbar, 1st sacral nerve) from the skull base most commonly innervates the medial head of the gastrocnemius and the soleus muscles, the basis of the S1 radicular pain pattern. In a patient with 25 presacral vertebral segments, this may exit under the pedicle of the lowest lumbar type vertebral body, creating confusion for the unwary practitioner (Fig. 15.4). There is also variation in typical innervation patterns in the presence of transitional anatomy, which may introduce further localization challenges. Only meticulous attention to spine enumeration, best provided by plain radiographs, sometimes supplemented by total spine MRI localizer images, will protect the spine pain patient and interventionalist from wrong segment invasive procedures.

When radiographs are obtained, they should be upright, weight-bearing images. Only in a physiologic posture can one assess sagittal and coronal balance (Fig. 15.5). Upright radiographs demonstrate more thoracic kyphosis and lumbar lordosis than do recumbent images. Weight-bearing images may also demonstrate instability, most commonly L4-L5 degenerative spondyloolisthesis, which would be occult on recumbent films. In spinal deformity patients, the exacerbation of spinal curves with weight bearing can be dramatic. Flexion-extension radiographs in the lumbar or cervical spine are not indicated as part of an initial imaging investigation. There is no role for oblique radiographs of the spine; in the lumbar region they double the gonadal dose and do not provide useful information that will affect clinical decision making. Cervical spine oblique views similarly serve only to irradiate sensitive tissue (thyroid, lens of the eye) without clinical benefit.

**ADVANCED IMAGING MODALITIES**

When radiographs are not explanatory of an unremitting pain syndrome or suggest underlying systemic disease, advanced imaging (CT, MRI, nuclear medicine) may be obtained. CT has undergone a revolution since the early 2000s with the advancement of multidetector technology. A data set for the lumbar spine can now be obtained in a few seconds, eliminating motion artifact and dramatically improving patient tolerance. This data set can then be reconstructed in any plane without a loss of spatial resolution or additional radiation exposure. CT provides superior imaging of cortical and trabecular bone when compared with MRI. For this reason, CT may be necessary to characterize primary bone tumors of the spine. CT also provides reasonable contrast resolution and can identify root compressive lesions such as disk herniations or characterize central canal, lateral recess, and foraminal compromise in the majority of cases. CT cannot identify intrathecal pathology and is less sensitive than MRI in the detection of early inflammatory or infectious processes, neoplasm, or paraspinal soft tissue lesions. Radiation dose must always be considered when employing CT, particularly in young patients or in serial studies. One by-product of the rapid technological advance of CT is that the literature contains no comparative studies between MRI and the latest generation of multidetector CT scanners in the detection and characterization of disk herniations.

MRI has been the dominant spine imaging modality since the 1990s, despite modest technological advancement...
in the realm of spine imaging in that time span. MRI has superior contrast resolution and thus the ability to distinguish between soft tissue types, allowing it to detect intrathecal pathology and identify subtle root compressive lesions. MRI has superior sensitivity in the detection of neoplasm and infection. With the use of gadolinium contrast, or heavily T2-weighted imaging sequences (short-tau inversion recovery [STIR] or fast spin echo T2 sequences with fat saturation), MRI can detect the physiologic parameters of edema, hyperemia, and inflammatory change. It has greater specificity than CT in characterizing the chronicity of fractures. With gadolinium enhancement, MRI can distinguish between recurrent disk herniation and scarring in the postoperative patient. MRI does not evaluate cortical bone well. Patient acceptance remains problematic because of prolonged imaging times and up to 10% examination failures.

Figure 15.3 Translational segments. Lateral radiograph (A) and sagittal T2 MRI image (B) demonstrate typical findings of a transitional segment interspace (arrows): a narrow disk space with parallel end plates and normal T2 signal intensity. Castellvi IIa transitional segment is demonstrated in frontal (C) and lateral (D) radiographs. Note right pseudoarticulation. In another patient, frontal radiograph (E) shows a left-sided pseudoarticulation, also seen on the axial CT image (arrows in [F]). Narrow, parallel end plates are visible in the transitional interspace on the lateral radiograph (G). This patient had axial pain attributed to the pseudoarticulation; this was injected (H) with relief of the index pain.
caused by claustrophobia. Open magnets have improved patient acceptance, but at the cost of image quality. A small percentage of patients are MRI incompatible due to pacemakers, spinal cord stimulators, or other implanted devices. MRI remains costly. The sensitivity challenges imposed by recumbent MRI imaging were discussed earlier; the hope is that the engineering challenges of high field strength, weight-bearing MRI imaging will be met in the near future.

CT myelography retains a problem-solving role in the lumbar spine; it will substitute for MRI in the incompatible patient. CT myelography has superior spatial resolution when compared with MRI but lacks its soft tissue contrast resolution. It can provide an exquisite demonstration of root compressive lesions and central canal, lateral recess, and foraminal compromise. In the cervical spine, the superior spatial resolution of CT myelography and its ability to discriminate between bone and soft tissue compressive lesions give it a continuing role. CT myelography is minimally invasive, expensive, operator dependent to a degree, and also requires current CT technology to be maximally useful.

Figure 15.4  The importance of segmental enumeration. This 36-year-old male who has failed conservative care presents with a left-sided L5 radicular pain pattern involving the lateral thigh, lateral calf, and dorsum of the foot. His MRI (sagittal T2 [A] and axial T1 [B] at level of dotted line) shows a subtle disk extrusion in the left lateral recess (arrow in [B]) at the penultimate interspace. The lowest-most disk appears transitional. MRI scout (C) image demonstrates 24 presacral segments. Frontal and lateral radiographs (D and E) may suggest 5 lumbar vertebrae on cursory examination; careful counting at fluoroscopy noted 11 rib-bearing vertebrae. T12 has no ribs and L5 is transitional, Castellvi type 4. The transforaminal epidural steroid injection (F and G) was performed under the pedicle bearing the dysplastic left T5 transverse process and relieved the patient’s pain.
CHAPTER 15 — RADIOLOGIC ASSESSMENT OF THE PATIENT WITH SPINE PAIN

Cone-beam CT, weight-bearing myelography holds promise for assessing position-dependent pain syndromes, at least in part defeating the sensitivity fault of recumbent advanced imaging. In this technology, arising from rotational angiography roots, the C-arm rapidly rotates about the standing patient who has had contrast introduced into the thecal sac. A flat panel fluoroscopy detector gathers a data set that can be reconstructed in any plane. Soft tissue contrast does not approach that of true CT, and the longitudinal field of view is limited to the length of the flat panel detector. Despite these limitations, the high inherent contrast among intrathecal contrast, the soft tissue structures of the spinal column, and bone allows for a very good depiction of central canal, lateral recess, and foraminal compromise. This technology will only improve (Fig. 15.6).

Nuclear medicine studies are growing in importance in spine imaging. Technetium pyrophosphate bone scans detect increased blood flow and accelerated bone metabolic activity. With the addition of SPECT and SPECT/CT image fusion, significant additional spatial localization of hyperemia and increased metabolic activity are possible. This imaging is traditionally useful in assessing the burden of metastatic disease but can also be valuable in assessing non-neoplastic inflammatory states such as spondylolysis. SPECT/CT can potentially identify inflammatory synovitis in the facet and sacroiliac joints, which might guide interventions. However, validation studies of these techniques against accepted reference standards such as comparative blocks in the facet joints or intra-articular sacroiliac blocks have not yet been done. When MRI is not technically feasible, technetium bone scanning can be used to characterize the chronicity of vertebral fractures in selecting patients for bone augmentation. The technetium bone scan, in combination with gallium scan, offers sensitivity equal to MRI in the detection of spondylodiscitis. However, these techniques provide less anatomic information and MRI may ultimately be necessary to characterize the degree of central canal compromise that may influence surgical decision making. PET or PET/CT scans have an increasing role in assessing the burden of metastatic disease and in selecting lesions for percutaneous biopsy.

Box 15.2  Spine Enumeration

- Approximately 11% of subjects will have anomalies of number or distribution of thoracolumbar vertebral bodies.
- Anomalous segmentation is predicted by the presence of transitional thoracolumbar or lumbosacral vertebral bodies.
- Ideally, vertebral numbering should occur from the skull base caudally.
- Practically, the human cervical spine is homologous and can be assumed to have seven segments.
- T1 is marked by the first upward inclined transverse process.
- Meticulous enumeration on every case will prevent wrong segment procedures.

Figure 15.4, cont’d  Note (G) the typical appearance of a transitional disk space. Careful enumeration of every case is the only way to avoid wrong segment interventions.

Figure 15.5  The effect of upright weight-bearing radiographs on balance and deformity. Recumbent radiograph (A) shows lumbar scoliosis with a rotatory component, which is significantly exacerbated in a subsequent upright radiograph (B). In another patient, the recumbent radiograph (C) underestimates the true scoliotic curve seen on an upright radiograph (D). Sagittal and coronal balance can only be assessed on upright, weight-bearing imaging.
Axial pain that may have an imaging correlate derives primarily from stimulation of nociception of the spinal articulations: the intervertebral disk, the zygapophysial or facet joints, and the sacroiliac joint. More broadly, it may include pain originating from the muscular or ligamentous structures in the supporting architecture of the spine. Axial pain is clinically characterized as constant, dull, deep, poorly localized, and aching, located primarily in the paraspinal region with inconstant referral to the proximal extremities. This is in distinction to the neuropathic pain of radicular character, which is typically sharp, electric, lancinating, and experienced in a bandlike distribution into the more distal extremities. The prevalence of axial spine pain generators has been well described by Depalma (Table 15.4). Intervertebral disk disruption (IDD) was the most common axial pain generator in this series, followed by the facet joint, the sacroiliac joint, and insufficiency fractures of the spine or pelvis. This work also emphasized the age dependence of these pain sources. Patients with diskogenic pain (IDD) were significantly

IMAGING CORRELATES OF DISKOGENIC PAIN

The imaging diagnosis of diskogenic pain is made challenging by the lack of a pathoanatomic gold standard against which to assess imaging parameters. It is not possible to evaluate a disk, either at surgery or upon histologic examination, and deem it painful. The current most stringent reference standard for the diagnosis of diskogenic pain is manometrically controlled provocation diskography with normal control levels as documented in the practice guidelines of the International Spine Intervention Society (ISIS). It is important to observe, however, that examination of the same body of evidence regarding the validity of diskography as the reference standard has resulted in diametrically opposed recommendations regarding its use by different physician societies. The ISIS, the North American Spine Society, and the International Association for the Study of Pain accept diskography as a useful diagnostic tool in back pain patients and recommend its use. The American Pain Society rejects diskography as a diagnostically useful test. A comprehensive review of diskography in the journal of the American Society of Regional Anesthesia and Pain Medicine notes that whereas CT diskography is the gold standard for the assessment of structural disk alteration, there is no convincing evidence that the use of diskography as a selection tool improves surgical outcomes. Any analysis of imaging findings in diskogenic pain patients thus remains based on a reference standard (provocation diskography) that is ultimately unproved against a pathoanatomic gold standard. This is further confounded by evolution of the criteria for a positive diskogram since the 1990s. For the purposes of this discussion, only concordant pain responses were considered to represent a positive diskogram. A significant concordant pain response without a specification of pain intensity or the use of manometry is defined as a Walsh criterion. Inclusion of the requirement for a normal control disk elevates the criteria to that of the International Association for the Study of Pain (IASP). None of the studies reviewed here meaningfully used manometric control or met the ISIS criteria for positive diskography.

Although challenging, there is motivation to make the diagnosis of diskogenic pain via noninvasive imaging. Diskography has until recently been considered a minimally invasive and nondestructive test. There is now in vitro and in vivo evidence suggesting that disk puncture or diskography may contribute to disk dysfunction. Korecki and colleagues noted that in a bovine disk model, single punctures with a 25-gauge needle resulted in biomechanical degradation of disk function with cyclic loading. Carragee and coworkers demonstrated on 10-year follow-up MR imaging that asymptomatic subjects who had undergone investigational diskography showed more degenerative phenomena than did matched control subjects. Although the clinical significance of these observations remains uncertain, noninvasive diagnosis is desirable.

The specificity fault inherent in spine imaging was previously discussed: manifestations of disk “degeneration” are ubiquitous, usually asymptomatic, and primarily represent normal age change. In a population of symptomatic patients with suspected diskogenic pain, however, are there imaging findings that correlate with positive provocation diskography? The findings evaluated in the literature include (1) loss of disk space height, (2) generalized alterations in T2 signal within the disk, (3) alterations of disk contour, (4) Modic end plate marrow changes, and (5) the presence of high intensity zones (HIZ) or fissures within the posterior disk annulus. These imaging features are examined initially as independent variables with subsequent discussion of the more limited literature in which they are combined in a multivariate analysis. A significant portion of the presented data were drawn from a systematic review of imaging and clinical markers of axial pain generators in the lumbar spine performed by Hancock and colleagues. Additional studies not included in that report or published subsequent to it have been added. A common set of measures was compiled from the many studies: sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and likelihood ratios (LRs). When imaging features were quantified (T2 signal loss in the disk was reported as normal, moderate, or severe), a threshold was used. Original data were combined and recalculated to reflect setting a detection threshold as moderate (including moderate and severe cases) or severe only. Because the diagnosis of diskogenic pain may provoke therapeutic interventions (most of which carry risk and have unproved efficacy), emphasis was placed on those measurements that inform about false-positive results: specificity (true negatives/true negatives + false positives) and PPV (true positives/true positives + false positives).
DISKOGENIC PAIN

LOSS OF DISK SPACE HEIGHT

The reports of Ito and colleagues,91 Lim and colleagues92 and O’Neill and colleagues93 studied loss of disk space height as an imaging finding that may correlate with positive provocation diskography. The studies of Ito and colleagues and O’Neill and colleagues both suggest that in a population of symptomatic patients with axial pain considered diskogenic in nature, severe disk space narrowing, although an uncommon imaging finding (approximately 10%), is strongly predictive of a painful disk. Specificity of this finding was at least 97% in these studies with PPVs of 78% and 90%, respectively. Lim’s study was less supportive. It is reasonable to conclude that in a patient with suspected diskogenic pain undergoing provocation diskography, severe loss of disk space height is a strong predictor of a positive diskogram.

NUCLEAR T2 SIGNAL LOSS

Studies addressing the correlation between MR imaging evidence of disk “degeneration,” primarily nuclear T2 signal loss, and diskogenic pain reach back to the 1990s.91-98 The challenges in this analysis are well illustrated in Table 15.5.91-100 Although disk “degeneration” definitions are inconsistent, original data have been recalculated into threshold values to provide a reasonable basis of comparison. The changes in diskography criteria over time are also noted. Despite these shortcomings, conclusions can be reasonably drawn. The NPV of disks of normal nuclear signal is uniformly high and −LRs are highly informative; disks of normal nuclear signal are rarely painful. Severe, uniform loss of T2 signal, with or without loss of disk space height, is a finding of high specificity (88% to 96% in studies using a three-part classification system) with strongly informative +LR. Disks with severe T2 signal loss are rarely nonpainful. The utility of this finding is reduced by its low prevalence (it is found in 13% to 25% of disks undergoing diskography) and low sensitivity (23%, 24%, 37%, and 70% in the studies with a three-part classification system). Disks with intermediate signal loss may be painful but with less certainty (Fig. 15.7).

DISK CONTOUR ABNORMALITY

The studies of O’Neill and colleagues92 and Kang and colleagues93 included data correlating disk contour abnormalities and diskography. Both studies showed a statistically significant correlation of disk contour abnormality with positive provocation diskography. In O’Neill and colleagues’ study, a disk bulge was the contour abnormality most predictive of a positive diskogram, with a +LR of 5.3.

MODIC END PLATE CHANGES

The functional unity of the disk and the cartilaginous end plate is manifest in signal changes within the end plate and adjacent subchondral marrow that accompany nuclear matrix degradation. End plate marrow changes were originally classified by Modic in 1988 (Fig. 15.8). Type I change represents ingrowth of vascularized granulation tissue into sub–end plate marrow; it exhibits a hypointense T1 and hyperintense T2 signal on MRI and may enhance with gadolinium. Type II change exhibits elevated T1 and T2
signal and reflects fatty infiltration of sub–end plate marrow. Type III change is hypointense on T1 and T2; it correlates with bony sclerosis. Type I change is thought to represent an active inflammatory state, with type II more quiescent and type III post-inflammatory. Ohtori and colleagues noted elevated levels of protein gene product 9.5–immunoreactive nerve fibers and TNF-α immunoreactive cells in the cartilaginous end plates of patients with Modic changes. The immunoreactive nerve ingrowth was noted exclusively in patients with diskogenic low back pain. TNF-α immunoreactive cells were more common in type I end plate changes.

Modic end plate changes do carry an association with low back pain, particularly type I change. Toyone and colleagues found that 73% of patients with type I change had low back pain as opposed to 11% of type II patients. Likewise, Albert and Manniche reported low back pain in 60% of patients with Modic changes but in only 20% of those without Modic changes. Type I change was more strongly associated with low back pain than type II change. Modic type I change may also be associated with segmental instability. Persistent type I change after fusion surgery raises concern for pseudarthrosis; patients with solid fusions more likely have either persistent type II change or resolution of all marrow abnormality.

The data in Table describe Modic-type end plate changes as predictors of diskogenic pain. The studies discussed previously suggested that type I Modic change would be more strongly correlated with positive provocation diskography than type II; that conclusion is not borne out by the data, which suggest that either type I or type II Modic change correlates with positive diskography, although not uniformly. The studies of Braithwaite and colleagues, Weishaupt and colleagues, Lei and colleagues, and O’Neill and colleagues had few false-positive results (i.e., disks with adjacent type I or type II end plate changes that were nonpainful). The specificity, PPV, and +LRs in these studies were high. The usefulness of the MR imaging findings were only hampered by their infrequency. Other studies were less supportive but may be confounded by technical flaws. The compelling results presented by Weishaupt and colleagues suggest a significant threshold for marrow change; with a threshold at 25% of vertebral body height, there were no false-positive results in this series. A reasonable conclusion is that Modic type I or II marrow change of this severity (25% of vertebral height) is an infrequent but highly specific finding, with a high PPV for diskogenic pain.

**HIGH INTENSITY ZONE (HIZ)**

In 1992, Aprill and Bogduk described the HIZ as an imaging marker of a painful disk at provocation diskography. Their definition of the HIZ is a high-intensity signal (bright white) located in the substance of the posterior annulus fibrosis, clearly dissociated from the signal of the nucleus pulposis in that it is surrounded superiorly, inferiorly, posteriorly and anteriorly by the low intensity (black) signal of the annulus fibrosis and is appreciably brighter than that of the nucleus pulposis. Page 362

This finding was identified on a midsagittal T2-weighted image; it may occur centrally in an otherwise normal
annulus, in a bulging annulus, or be located superiorly or inferiorly behind the edge of the vertebral body in a severely bulging annulus. In a series of 500 consecutive patients, the per-patient prevalence was 29%; the per-disk prevalence of an HIZ was 6%. The majority of HIZs were present at the L4 and L5 disk levels, confirmed on later studies.

The relationship of the HIZ to pain production was evaluated in a subset of 41 patients, selected for the presence of an HIZ on prediskography MR imaging. Diskography was performed with the requirement of a nonpainful control disk for a diagnosis of diskogenic pain. Pain responses were tabulated both as "exact" reproduction of pain as well as "similar" pain (Table 15.7). In all, 118 disks were tested in 41 patients; the per-disk prevalence of the HIZ was 34%, reflecting the selection bias. In detecting exact pain, the HIZ had a sensitivity of 82% and specificity of 89%, a 70% PPV, and a +LR of 7.3. When the diskographic criteria were relaxed to exact or similar pain, the specificity rose to 97% with a PPV of 95%; there were only two false-positive cases where a disk bearing an HIZ was nonpainful. The investigators postulated that the HIZ represents a complex grade 4 fissure where the nuclear material has been trapped within the lamellae of the annulus fibrosis and become inflamed, accounting for the T2 hyperintensity, brighter than that of the parent nucleus. They advanced the HIZ finding as pathognomonic of a symptomatic disk. The publication of these findings elicited considerable interest and many subsequent studies attempting to verify or refute its conclusions.

Table 15.7 demonstrates informative +LR and high specificity in most of the studies. There are dissenting voices. Carragee and colleagues evaluated the correlation of the HIZ and painful disks at provocation diskography in both symptomatic and asymptomatic subjects. In symptomatic patients, 30% of disks had an HIZ; only 9% of disks in asymptomatic subjects contained an HIZ (significant, P < 0.0001).

</table>

The statistics for the symptomatic group are presented in Table 15.7; an HIZ disk had an 84% specificity, a 73% PPV, and a +LR of 2.8 for diskogenic pain. These data are supportive of the HIZ as a useful marker for the painful disk. The investigators, however, point out that the presence of an HIZ disk was strongly predictive of a positive pain response at diskography in both the symptomatic (73%) and asymptomatic (69%) groups. The asymptomatic group had also been stratified by psychometric evaluation; in participants with either chronic pain or abnormal psychometric studies, all HIZ disks produced pain with pressurization. The investigators contend that the similar painful response rate of HIZ disks in symptomatic and asymptomatic subjects devalues the HIZ as a useful finding, because the total weight of diagnosis depends on concordance versus nonconcordance of pain response.

The study by O’Neill and associates\(^93\) stratified HIZ lesions by relative signal intensity, and expanded the definition of the HIZ to include posterolateral and lateral lesions and those that demonstrated a connection to the nuclear compartment. Original data were recalculated to establish a three-part threshold of HIZ intensity: markedly intense cases, markedly and moderately intense cases, and a combination of all three. As the threshold tightened, the specificity and +LR rose; the PPV remained high for all three threshold levels. For only markedly hyperintense HIZs, the specificity was 98%, the PPV was 86%, and the +LR was 6.8. This would support Bogduk’s comments that “low intensity zones may well occur in asymptomatic volunteers, but that when activated (ostensibly inflamed), these fissures become painful and assume a higher signal intensity” (Fig. 15.9) page 1260.\(^{114}\)

MULTIVARIATE ANALYSIS

The studies of Kang\(^94\) and O’Neill\(^93\) included multivariate analyses. O’Neill and associates showed that the disk...
structural findings—loss of disk height, loss of nuclear signal, and disk contour abnormalities—correlated strongly with each other; the inflammatory findings, HIZ, and end plate change did not, with the exception of HIZ and disk contour abnormality. The rank correlation of the MRI findings with a positive diskogram was as follows: signal abnormality > disk height > disk contour > HIZ > end plate change. Disk signal change alone was as accurate as other individual parameters or combinations thereof. This was most evident at the two extremes of the receiver operating characteristic (ROC) curve: when disk signal was normal, it was highly unlikely the disk was painful regardless of other findings, and when there was severe signal loss, the disk was highly likely to be painful. Other parameters become useful when disk signal was intermediate. Kang and colleagues\(^47\) introduced a new MRI classification system combining the findings that were previously addressed as independent variables: class 1, normal or bulging disk without an HIZ; class 2, normal or bulging disk with an HIZ; class 3, disk protrusion without HIZ; class 4, disk protrusion with HIZ. Disk extrusions and sequestrations were excluded from the analysis. Logistic regression analysis showed that class 4, disk protrusion with HIZ, had the strongest correlation with concordant pain at diskography. This combination had a specificity of 87% and a PPV of 98%. This finding had a prevalence of 13% and a sensitivity of 45%.

**IMAGING CORRELATES: CONCLUSION**

Imaging identification of diskogenic pain is challenging for a variety of reasons. (1) There is no pathologic or surgical gold standard. (2) The existing standard of comparison, diskography, is ultimately unproven, subjective in its interpretation, and has evolved over time in its criteria for a positive test. None of the studies reviewed earlier use the most current and restrictive criteria, those of ISIS. (3) The
imaging findings likely have threshold effects, where only a significant expression of the finding (intensity of an HIZ, extent of marrow change) is a useful predictor of diskogenic pain. Most studies do not account for this factor. (4) Imaging findings are likely technique dependent to an unknown degree, and imaging techniques are evolving.

From the tangle of data, useful information can emerge; the imaging correlates of diskogenic pain are summarized in Box 15.3. These imaging predictors of diskogenic pain, when applied to a select population of patients with axial back pain, in whom other pain generators have been excluded, could perhaps be used to initiate a proven therapy possessing a good safety profile. No such therapy exists. Diskography remains the reference standard for the diagnosis of diskogenic pain.

### Box 15.3 Imaging Correlates of Diskogenic Pain (IDD)

- The disk structural markers—loss of disk space height, loss of nuclear T2 signal, and disk herniation—correlate strongly with one another; loss of nuclear signal is most significant.
- Severe nuclear signal loss or severe loss of disk space height strongly predicts a painful disk.
- Normal nuclear signal virtually excludes a painful disk.
- When nuclear signal is intermediate, the inflammatory markers of the high intensity zone and end plate marrow change come into play.
- A truly high-intensity zone is infrequent but strongly predicts a painful disk.
- When an HIZ is observed in combination with a disk protrusion, it strongly predicts a painful disk.
- Marrow end plate change of type I or type II involving greater than 25% of the vertebral body is uncommon, but it strongly predicts a painful disk.

This discussion has purposely focused on the lumbar spine. The lumbar spine segment is most commonly afflicted with diskogenic pain, and the literature regarding its pathogenesis and evaluation with imaging and provocation diskography, although challenging, is of greatest depth. The cervical intervertebral disk is structurally distinct from the lumbar disk. These is no posterior annulus, and the small nuclear compartment disappears early in life; the residual fibrocartilaginous plate normally develops fissures as mere age-related change. There are no morphologic features at diskography that contribute to a diagnosis of diskogenic pain. Diagnosis is reliant entirely on the provocation of concordant pain, with the requirement of nonpainful control disks.

As in the lumbar segment, structural age changes (loss of T2 signal, loss of disk space height, contour abnormality) are ubiquitous on cervical MRI studies. The Matsumoto study cited earlier examined 2480 cervical disks in asymptomatic subjects and noted loss of T2 signal in 17% of males and 12% of females between ages 20 to 30, and 89% of males and 86% of females over 60 years of age. In another study by Okada, 89% of asymptomatic subjects (mean age 49) exhibited structural age changes on MRI; another group of patients (mean age 46) with symptomatic lumbar disk herniations but asymptomatic of neck pain showed cervical disk age-related change in 98%. There is a paucity of literature addressing the correlation of imaging findings with cervical diskography. An early study by Parfenchuck (1994) showed only a modest ability of MRI findings of T2 signal loss or disk contour abnormality to predict a positive cervical diskogram (sensitivity = 73%, specificity = 67%). Schellhas’ 1996 study suggested that MRI cannot reliably predict a positive cervical diskogram. A more recent study by Zheng again demonstrated only a modest predictive value of MRI using parameters of T2 signal loss and disk contour abnormality (sensitivity = 73%, specificity = 49%). The inflammatory disk parameters that proved to have such high specificity in the lumbar region are either unusual or little studied (Modic change) or have no anatomic existence (HIZ) in the cervical region. Occasionally foci of elevated T2 signal are observed in the posterior cervical disk, but in the absence of a posterior annulus, the anatomic correlate is unclear. Imaging identification of diskogenic pain in the cervical spine remains elusive. Cervical diskography remains the reference standard in diagnosis of cervical diskogenic pain.

The imaging investigation of diskogenic pain highlights a theme common to this chapter; physiologic parameters have greater significance in pain syndromes than purely structural alteration. To be ultimately valuable in the diagnosis of diskogenic pain, imaging must move beyond macroscopic descriptions of morphology to the realm of biochemical imaging, quantifying the change in nuclear constituents over time. In addition to characterizing biochemical nuclear matrix degradation, imaging will also need to more precisely identify inflammatory mediators in the disk and adjacent cartilaginous end plate. Perhaps then we will truly be capable of the noninvasive diagnosis of diskogenic pain.

### IMAGING OF AXIAL PAIN GENERATORS

#### ZYGAPOPHYSIAL JOINT (Z JOINT, FACET JOINT)

The supporting structure of the posterior column of the spine includes the paired facet joints with their associated capsules, the ligamentum flavum, the intraspinous and supraspinous ligaments joining the spinous processes, and the intertransverse ligaments. The inferior articular process of the facet joint faces anteriorly and is convex in configuration; on axial images the inferior articular process is the more posterior component of the joint. The superior articular process (SAP) has a concave articular surface that faces posteriorly and medially; on axial images it appears as the anterior component of the joint. In an erect standing position, the lumbar facet joints bear approximately 16% of the compressive load; in a flexed sitting position they bear essentially no load. With loss of disk space height, the lumbar facet joints will bear proportionally more axial load. The fibrous joint capsule has been demonstrated to be richly innervated by nociceptors and proprioceptive fibers. In a normal state, nociceptors such as those seen in the facet joint capsule have a high threshold and would not be expected to discharge unless loads are supraphysiologic. However, in the presence of pathologic joint inflammation, synovitis,
chemical mediators may sensitize these nociceptors and supraphysiologic levels of stress may no longer be required to stimulate pain. Such inflammatory mediators (substance P, bradykinin, phospholipase A2) have been detected in the facet joint capsule.\textsuperscript{120}

There is thus a pathoanatomic basis for facet joint-mediated pain, particularly in the presence of facet synovitis. The imaging challenge in identifying a potentially painful joint lies in the well demonstrated specificity fault, that imaging changes of morphologic facet arthrosis (subchondral sclerosis, erosions, or cyst formation, osteophytes, joint space narrowing, vacuum phenomena) are age related change and do not correlate with pain. The reference standard for facet pain is positive comparative dual medial branch blocks, as there are no reliable physical exam or historical features allowing a confident diagnosis of Z-joint pain.\textsuperscript{81} Schwarzer and colleagues semi-quantitatively scored CT finding of structural facet arthrosis and found no relationship to Z-joint pain as determined by placebo controlled medial branch blocks.\textsuperscript{121} More recently, Cohen and associates showed no association between MRI findings of structural facet arthrosis and pain relief with dual medial branch blocks and subsequent radiofrequency rhizotomy.\textsuperscript{122} These structural changes become universal by the sixth or seventh decade of life; they do not represent active inflammatory disease causal of pain.\textsuperscript{123}

Rather, imaging must look to identify physiologic, not structural, markers of active facet synovitis. Imaging techniques that may be applicable include the technetium pyrophosphate bone scan (including its technologic evolution SPECT and SPECT/CT) and the MRI physiologic imaging parameters of T2 hyperintensity and gadolinium enhancement. Technetium pyrophosphate bone scans detect hyperemia and accelerated bone turnover, which may be considered manifestations of active inflammation. Dolan and associates\textsuperscript{124} compared the response to intra-articular facet joint injection guided by clinical exam versus positive SPECT studies; there was a significantly greater short term (1- to 3-month) clinical response in the SPECT-guided injections. A similar study by Holder and colleagues, using response to uncontrolled intra-articular injections as the reference standard, identified a 100% sensitivity and 71% specificity for SPECT scans in the detection of facet joint–mediated pain.\textsuperscript{125} Pneumatoceans and colleagues prospectively studied patients undergoing intra-articular injections in three groups: injections guided by positive SPECT scans, injections in patients with negative SPECT scan guided by clinical exam, and injections in patients without SPECT studies guided by clinical exam.\textsuperscript{126} The patients whose injections were directed to SPECT-positive joints had significantly better clinical outcomes than the other two groups, as well as lower costs as fewer joints were injected. McDonald used SPECT/CT to identify joints for injection in 37 patients with clinical facet joint lumbar pain. The mean visual analog score (VAS) dropped from 7.2 to 2.8, with an average duration of benefit of 2.2 months; only 1 in 37 patients did not report benefit. The fused SPECT/CT images were useful in distinguishing the L4-5 and L5-S1 facet joints.\textsuperscript{127}

There is no correlation between the degree of morphologic facet arthrosis and the intensity of SPECT activity.\textsuperscript{124} Rather, the phase of active synovitis correlating with pain production may occur relatively early in the progressive development of structural changes of facet arthrosis. Kim and colleagues correlated MRI findings in the facet joints with SPECT; they noted that the MRI appearance of T2 hyperintensity in the synovium, intrasynovial fluid, and cartilage disruption best correlated with a positive SPECT, here used as a reference standard for active facet synovitis.\textsuperscript{128} More extensive structural manifestations of facet arthrosis did not demonstrate the physiologic finding of SPECT activity. Cervionke and colleagues have demonstrated an indirect association of T2 hyperintensity within and about the facet joint with axial pain.\textsuperscript{129} T2 hyperintensity in the adjacent pedicle has also been associated with axial pain of facet origin; this finding can also be seen in pedicle or pars stress fractures. T2 hyperintensity accompanying facet synovitis may also be seen in the surrounding multifidus muscle, occasionally sufficiently extensive as to raise concern for a sinister process. Gadolinium enhancement in and about the facet joint is also suggestive of facet synovitis. Ultimately, the physiologic parameters of edema, hyperemia and accelerated metabolic activity as detected by increased SPECT or SPECT/CT activity, and T2 hyperintensity and gadolinium enhancement on MRI must be evaluated as predictors of facet joint pain against the current reference standard, comparative medial branch blocks. Prevalence studies of these parameters in populations asymptomatic of back pain are also needed for researchers to understand the specificity of these imaging observations. Despite the lack of absolute validation, if the patient is going to undergo an MRI for evaluation of axial pain, a fat-saturated or short tau inversion recovery (STIR) sequence should be performed, as it represents the best chance of demonstrating physiologic findings (T2 hyperintensity), which may identify an axial pain generator (Fig. 15.10).

**SPACE OF OKADA**

A tissue pathway between same segment, contralateral facet joints was initially described in the cervical region by Dr. Kikuzo Okada in 1981; 80% of cervical facets demonstrated a communication between the joint capsules via a space situated dorsal to the ligamentum flavum in the axial plane and in the interlaminar space in the coronal plane.\textsuperscript{130} This communication is frequently observed in intra-articular injections of cervical facet joints that are structurally normal on imaging or exhibit only modest evidence of synovitis or structural arthrosis. In the lumbar region, this communicating pathway is commonly observed only in the face of advanced facet arthrosis; it may also be observed in the presence of defects in the pars interarticularis. This lumbar retroligamentous pathway also commonly communicates with an adventitial bursa within the interspinous ligament (i.e., Bastrup’s disease).\textsuperscript{131}

This pathway may serve as a means of transmission of infection or, more commonly, noninfectious inflammatory change between multiple joints and tissue compartments.\textsuperscript{131} In patients with lumbar axial pain and spondyloïd defects, this posterior element inflammatory complex may involve four facet joints, the bilateral pars defects, and the interspinous ligament. It may have a capacity of 4 to 6 cc of fluid in the author’s experience. It is also a potential confounding space in interlaminar epidural steroid injections. This space may provide a false loss of resistance superficial to the dorsal epidural space; contrast injection may subsequently
Figure 15.10  Imaging of facet arthrosis and synovitis. The changes of arthrosis (i.e., joint space narrowing, osteophytes, subchondral cysts, or sclerosis) as seen in the CT image (A) the T2 MRI image (B) or the radiographic image (C) do not correlate with pain. Planar bone scan image (D) of the same patient as (C) shows increased uptake near the lumbosacral junction on the left in this patient with left-sided axial pain. SPECT/CT image (E) provides better anatomic localization to the left L4-5 facet. In another patient with right-sided axial lumbar pain, T1 MRI image (F) shows low signal in right L5 pedicle, right L4-5 facet. Fat-saturated T2 sagittal image (G) demonstrates T2 hyperintensity in L4 and L5 pedicles, L4-5 facet, and adjacent soft tissues. Enhanced T1 sagittal (H) and axial (I) images also demonstrate the extensive inflammatory response in this patient with active synovitis. T2 hyperintensity or enhancement in pedicles can occur in facet synovitis or stress fractures of the pars or pedicle.
fill either facet joint at that segment level or the interspinous ligament (Fig. 15.11).

**SACROILIAC JOINT**

The sacroiliac joint is a large irregular synovial joint lined by thick hyaline cartilage on its sacral surface and thinner fibrocartilage on its iliac surface. The inferior and antero-superior aspects of the radiographically perceived joint are synovial; its superior and posterior aspect is ligamentous. The posterior surface of the joint is covered by thick interosseous and dorsal sacroiliac ligaments. There is minimal movement of the joint, except under the hormonal influences of pregnancy. This modest mobility is, however, vital to appropriate gait. The synovial portion of the joint is uniformly present in young adults, with a cartilage thickness

---

**Figure 15.11 The Space of Okada.** Frontal fluoroscopic image (A) demonstrates the space of Okada providing communication between the bilateral C6-7 facets via the right-sided injection. In another patient (B), an attempted right L4 transforaminal injection opacified the superior recess of the L4-5 facet, traversed an L5 pars defect (white arrow) to the right L5-S1 facet, and opacified the space of Okada to a left L5 pars defect (black arrow) and the left L4 and L5 facets. Subsequent CT (C, D, E, F) confirms opacification of all these structures. The space of Okada is marked by the white arrows in (D). The space of Okada may contain a small amount of fluid, which appears as T2 hyperintensity (white arrows, G, H, I). Note continuity with interspinous ligament (arrow in [H] and [I]).

Continued
of 2 to 5 mm; the synovial space may be attenuated in older adults by fibrous adhesions, but fusion across the joint is not a normal change of aging. Potential communications between the synovial space and the dorsal sacral foramina, the L5 epidural sheath, and the ventrally situated lumbar-sacral plexus have been observed. These could explain radicular pain associated with sacroiliac joint dysfunction. Although the surface area of the joint is large, its synovial space is of small volume, ranging from 1 to 2.5 cc. Innervation of the sacroiliac joint is complex and remains controversial. Consensus suggests a dominant dorsal innervation from the L5 and S1-S4 dorsal rami.

Osteoarthrosis of the sacroiliac joints may be seen in pathologic specimens of young adults, but it is not generally appreciable radiographically until middle age. Changes of cartilage degeneration are more prominent on the iliac side of the joint. Beyond age 40, many subjects have detectable narrowing of the sacroiliac joint, especially in its inferior portion. This may be accompanied by subchondral sclerosis and osteophyte formation, most prominent anteriorly and inferiorly. A vacuum phenomenon may be seen. As in the facet joint, changes of osteoarthrosis are a normal aging phenomenon and are not predictive of pain.

Evaluation of imaging features predictive of sacroiliac joint pain is yet again confounded by the lack of a pathoanatomic gold standard. Medical history and physical exam provocative maneuvers are not capable of consistently identifying painful sacroiliac (SI) joints. The reference standard for sacroiliac joint pain is relief of index pain with an intra-articular anesthetic block; this should ideally be either placebo controlled or a comparative block paradigm. Potential leakage from the joint capsule may complicate diagnostic specificity. Schwarzer studied patients with chronic low back pain experienced below the lumbosacral junction. Using response to single blocks as the diagnostic criteria for sacroiliac pain yielded a prevalence of 30%. Requiring a positive block and a ventral capsular tear on postarthrographic CT yielded a prevalence of 21%; adding pain provocation with joint distension to the criteria lowered prevalence to 16%. The Maigne study using double blocks suggested a prevalence of 18.5%. More recent work by DePalma identified a prevalence of 18%; sacroiliac joint pain increased in prevalence with age up to approximately 70 years.

Structural changes of osteoarthrosis in the sacroiliac joint are poor predictors of pain. Elgafy and colleagues scored CT features of arthrosis in SI joints and noted a sensitivity of 58% and a specificity of 69%. Physiologic imaging parameters suggesting the presence of hypervascularity, edema, or inflammation are more likely to predict pain. In the studies of Maigne and Slipman, technetium bone scans...
achieved specificities of 89.5% and 100%, although with low sensitivity, for sacroiliac pain as referenced by uncontrolled intra-articular injections. The MRI physiologic parameters of T2 hyperintensity and gadolinium enhancement have been studied primarily in the context of inflammatory spondyloarthopathies. MRI evidence of active inflammation (sacroilitis) is intrinsic to the diagnoses of spondyloarthopathies and correlates well with clinical disease activity and therapeutic response to disease modifying agents (TNFα inhibitors) (Box 15.4).

**BAASTRUP’S DISEASE**

Baasstrup’s disease, the apposition of the lumbar spinous processes resulting from hyperlordosis, segmental instability, or loss of disk space height, may degrade the interspinous ligament with formation of a pseudarthrosis or pseudobursa.141 This may be a cause of focal midline lumbar pain. Such pseudobursa may have a synovial membrane and can communicate with facet joints or pars defects via the retroligamentous space of Okada.130 The pseudobursa may extend anteriorly through a midline cleft in the ligamentum flavum and present on MRI or CT as a midline posterior epidural cyst, causing neural compression and should not be misinterpreted as metastatic disease; the distinction should be obvious when correlated with the simultaneously obtained CT images, which will show typical structural changes of arthrosis.

**BERTOLOTTI’S SYNDROME**

Bertolotti’s syndrome describes the controversial association of transitional lumbosacral segments with mechanical back pain. It does not imply a specific mechanism of pain production. Transitional lumbosacral segments occur in 4% to 30% of the general population.72 In a large study of 4000 patients, Tini found no correlation between the presence of a transitional segment and low back pain.144 The disk at the level of the transitional segment is often rudimentary, with little nuclear material; disk herniations seldom occur at this level.72 Rather, stresses may be accentuated at the supraadjacent disk level, where accelerated disk degeneration and an increased incidence of disk herniations have been reported.

Axial low back pain in the presence of an asymmetric transitional segment has also been attributed to abnormal unbalanced motion at this level, with the neoarticulation of the transverse process with the sacral ala or the contralateral facet as the specific pain generator. Jonsson reported 11 cases of mechanical pain attributed to the neoarticulation despite normal bone scans. Nine of 11 patients obtained pain relief with local anesthetic injection in the neoarticulation; a similar proportion of patients had improvement in pain with resection of the neoarticulation.145 Physiologic imaging parameters (MRI T2 fat-saturated or STIR images, SPECT/CT) are more likely to be useful than structural changes, although no systematic studies have been performed. Brault reported a case of an adolescent athlete with focal mechanical pain consistently relieved by intra-articular injection of the facet contralateral to the neoarticulation. Interestingly, bone scan showed increased uptake at the neoarticulation, but not at the contralateral facet. Surgical resection of the neoarticulation resulted in complete relief of the contralateral pain at 1 year.146 This may represent a case of pain generated by excessive facet capsular stresses caused by the asymmetric motion at this level, without detectable facet synovitis.

Transitional lumbosacral segments thus may be associated with axial pain, related to a neoarticulation, the contralateral facet at the level of an asymmetric neoarticulation, or IDD in the at-risk disk above a transitional segment. Radicular pain may be caused by a herniation in the adjacent segment disk or an extraforaminal entrapment at a neoarticulation. The presence of a transitional segment should always prompt meticulous attention to segmental enumeration, because of both its intrinsic capacity for confusion and the sevenfold increased likelihood of an anomalous number of mobile presacral segments (Fig. 15.12).72
Figure 15.12  Baastrup’s disease and Bertolotti’s syndrome as posterior element pain generators. An elderly male presents with neurogenic intermittent claudication. T2 fat-saturated sagittal image (A) and axial T2 image at the L4-5 interspace (B) demonstrate that the compressive lesion is a right paramedian dorsal cyst in continuity with the interspinous pseudobursae of Baastrup’s disease. There are also facet joint effusions. In another patient with axial pain (C), a fat-saturated, enhanced T1-weighted image shows inflammatory enhancement in the interspinous ligaments of T12-L4. Sagittal T2 (D) and T1 (E) images of another patient demonstrate a large complex midline dorsal cyst emerging from an interspinous pseudobursae at the L3-4 interspace (axial T2 image [F]). A 17-year-old female (frontal lumbar spine radiograph [G]) presented with intractable left lumbosacral junction region pain. Note left pseudoarticulation (Bertolotti’s syndrome). SPECT/CT image (H) shows markedly increased uptake at the pseudoarticulation; pain was relieved with injection into this site (fluoro image [I]; note that the patient is prone).
COCCYDYNIA

The radiographic evaluation of the sacrococcygeal region in patients with coccydynia remains controversial. This largely female pain syndrome is probably multifactorial in origin with contributions by somatic and neuropathic pain. A single lateral view of the coccyx to evaluate for destructive bony lesions is a reasonable screening study. Maigne has described a dynamic radiographic study to more fully evaluate the mobility of the coccyx. This consists of a lateral radiograph with the patient standing for 10 minutes to visualize the coccyx without load, followed by a sitting lateral view, with the patient altering the pelvic position to that which stimulates the usual pain. Maigne and colleagues have studied coccygeal mobility and suggested that a normal coccyx may undergo from 5 to 25 degrees of angulation in moving from a standing to a sitting position. Flexion of the coccyx by more than 25 degrees with sitting as well as posterior subluxation of the coccyx with sitting and reduction with standing are considered pathologic and may be the anatomic basis of coccydynia. Aggressive treatment decisions based on this evaluation are controversial. Advanced imaging has little role in this setting unless there is clinical suspicion of underlying systemic disease.

PSEUDARTHROSIS, POSTOPERATIVE AXIAL PAIN

Patients with posterior fusion instrumentation may develop pain related to pseudarthrosis, infection, implant fracture or loosening, or at the interface between the metal and the overlying soft tissue. Radiographs should be scrutinized for integrity of the implant construct, loosening of pedicle screws (which will manifest as a halo of lucency surrounding the screws), or imaging evidence of pseudarthrosis. Anesthetic injection about prominent hardware may be useful in identifying this as a pain generator.

Despite advances in surgical technique and fixation hardware, fusion remains an imperfect procedure. Pseudarthrosis is defined as the failure to achieve a solid bony fusion 1 year after attempted surgical fusion. It is manifested as persistent motion at the segment and absence of bony trabeculae bridging the vertebrae. Approximately 15% of lumbar spinal fusions result in pseudarthrosis; the range of successful reported technical and clinical outcomes spans 16% to 95%. Rates of pseudarthrosis increased with the increasing number of fused levels and with risk factors including prior surgery, instability, deficient bone graft quality and quantity, and nicotine use (Fig. 15.13).

Detection of pseudarthrosis with imaging is of significance, as it is a cause of persistent or recurrent pain following surgery. The correlation is not exact; patients with radiographic pseudarthrosis may be pain free and patients with solid fusions by all imaging techniques may have persistent pain arising from other factors. The clinical questions, therefore, are twofold: Is a pseudarthrosis present, and, if so, is it the cause of persistent or recurrent pain? The ultimate gold standard for fusion is surgical exploration; even this is not foolproof, as patients who have had hardware removal after intra-operative evaluation of stability have subsequently gone on to develop progressive deformity.

Weight-bearing radiographs are the primary tool in assessing stability and adequate fusion. In this setting, flexion-extension views likely add value. Radiographic evidence of instability includes translation of 3 mm or more at L1-L4 or 5 mm at L5-S1. Radiographic fusion may take 6 to 9 months, with ongoing remodeling for up to 2 years. Criteria for a radiographic solid interbody fusion are as follows:

- No motion, or less than 3 degrees of intersegmental motion, change on lateral flexion and extension views
- Lack of a lucent area around the implant
- Minimal loss of disk height
- No fracture of the implant, bone graft, or vertebrae
- No sclerotic change in the bone graft or adjacent vertebrae
- Visible osseous formation in or around the cage

CT will provide greater sensitivity in the detection of pseudarthrosis, which manifests as lucent fracture lines with adjacent sclerosis or fragmentation of the bone graft, and fracture or lucency about implants. Ideally, to verify solid fusion, one would like to be able to confirm the presence of continuous bony trabeculae across the site of fusion. In patients with intervertebral cage devices, bony trabeculae should be seen bridging the interspace through the cage and external to the cage.

Technetium bone scans with SPECT may be helpful. The fusion mass will be metabolically active for a prolonged period after surgery, and increased tracer uptake diffusely in the fusion mass is expected for several months. In normal healing, studies with serial bone scans have shown a steady decrease in tracer uptake after 3 months, with only minimal increased uptake at 1 year. Increased uptake within the fusion mass beyond 1 year after surgery, or new increased uptake not present on prior studies, should raise concern for pseudarthrosis. On MRI, solid bone graft should exhibit signal characteristics of normal marrow. Focal zones of T1 hypointensity, T2 hyperintensity, and gadolinium enhancement may indicate a site of pseudarthrosis with ongoing infection and inflammation. This requires careful inspection.

With disk arthroplasty, postoperative evaluation can occur by radiography or CT; radiography is more conservative of cost and radiation for serial follow-up. The implant should be centered between the pedicles on AP images without penetration of the end plates. On lateral or sagittal images, the center of rotation should be in the posterior half of the disk space, but the implant should not extend beyond the posterior vertebral line.

The clinician and imager must also be aware of symptomatic adjacent segment disease as a cause of recurrent pain in the post fusion patient. Although controversial, this likely occurs at a rate of approximately 3% per year following lumbar fusion, a similar rate has been associated with cervical fusion. The imaging findings will be those of diskogenic pain. Radiographic evidence of adjacent segment disease may or may not be clinically symptomatic.

Pseudarthrosis and adjacent segment disease are two primary causes of pain in the post-operative patient, sometimes labeled the “failed back.” Although conventionally considered a dread diagnosis, studies have shown that careful clinical evaluation, augmented by high-quality imaging and provocation and anesthetic interventions, can identify the specific cause of pain in the majority of cases. Waguespack and Slippman have each published large series of patients with so-called failed back syndrome. A specific diagnosis identifying the pain generator was achieved in over
90% of patients in both of these series. The most common diagnoses were foraminal stenosis (> 20%), diskogenic pain (20%), pseudarthroses (14%), neuropathic pain (10%), and recurrent disk herniation (7% to 12%), with lesser contributions from facet and SI joints. Each of these morphologic lesions has been individually addressed in preceding sections. The imaging challenge is to systematically evaluate each segmental level for these potential pain generators despite the confusion of the surgically altered anatomy.

**IMAGING OF RADICULAR PAIN, RADICULOPATHY, AND MYELOPATHY**

**DISK HERNIATION**

Radicular pain, or radiculopathy or myelopathy, has as its substrate neural compression and inflammation. Degradation of the nuclear matrix of the disk may occur in response to a variety of insults, including end plate infraction, genetically determined apoptotic chondrocyte cell death, diabetes mellitus, ochronosis, smoking, or infection. The nuclear compartment of the disk can no longer bear axial load, shifting its burden to the posterior annulus, which may undergo structural failure in the form of radial fissures, the anatomic basis of IDD. In addition to potentially causing axial pain, these fissures may allow herniation of nuclear material into the outer annular lamellae as a contained protrusion or breach the annulus and pass into the epidural space as an extrusion. The mechanical compression of neural tissue and an induced inflammatory response conspire to provoke radicular pain or radiculopathy.

Mixter and Barr initially described the disk herniation as the cause of sciatica in 1934; this observation, and the ability to relieve pain and neurologic dysfunction by surgical extirpation of the offending herniation, provided the basis for the first 70+ years of spine imaging. Myelography, CT, CT/myelography, and MRI were deemed useful in the patient with radicular pain or radiculopathy in the ability to first indirectly and later directly visualize the disk herniation and neural compression. The pathogenesis of radicular pain or radiculopathy is more complex than the simple
compression of neural elements; an inflammatory response is also necessary to produce pain. The evidence supporting an inflammatory component in radicular pain was summarized by Mulleman and colleagues. Neural compression in isolation produces nerve dysfunction, but not pain; exposure of compressed neural elements to the inflammatory response induced by disk nucleus pulposis results in radicular pain. This inflammatory response is mediated by phospholipase A2, interleukins 1 and 6, TNFα, and nitric oxide. The necessity of an induced inflammatory response for pain production provides a measure of understanding for the glaring specificity fault of disk herniation imaging: large disk herniations are often asymptomatic, and the severity of symptoms bears no relationship to herniation size.

The imaging description of disk herniations has historically been chaotic, with significant disparities among medical specialties and regionally. Clarity was restored by a lexicon of nomenclature produced as a cooperative venture between multiple spine societies in 2001. In this construct, spondylosis deformans describes those changes thought to be due to normal aging. Degradation of the nuclear matrix may occur without structural failure of the annulus, hence there is preservation of disk space height and normal cartilaginous end plate and subchondral marrow. Anterior and lateral osteophytes are observed. MRI imaging shows loss of the normal intranuclear cleft and mild to moderately diminished T2 signal within the disk. Small concentric and transverse annular tears may be seen in spondylosis; radial tears are not considered a normal aging phenomenon. Small amounts of gas may be present within the disk that may be detected on plain films.

In this lexicon, pathologic discovertebral change is termed intervertebral osteochondrosis. This includes the changes of IDD, radial and large circumferential fissures extending to the outer annulus. They may be accompanied by the development of posterior osteophytes that encroach on the central canal. In addition to posterior osteophytes, plain film manifestations of intervertebral osteochondrosis include large amounts of gas within the interspace, loss of disk space height, and end plate irregularity. On T2-weighted MRI images, the disk is of markedly diminished signal intensity. Disk herniations are common.

The inclusive term for displacement of disk material is herniation. A localized herniation is defined as involving less than 50% of the disk circumference; generalized disk displacement of more than 50% of the circumference is a bulging disk. Localized herniations are further subdivided: displacement of the disk over less than 25% of its circumference is called a focal herniation, and disk displacement between 25% and 50% is called a broad-based herniation. The distinction between protrusion and extrusion is one of shape (Fig. 15.14). In a protrusion, the width of displaced disk material, in any plane, does not exceed the width of its base against the normal ring apophysis. In an extrusion, the width of the displaced disk material exceeds its base in any plane. The presence of an extrusion shape suggests that there has been complete disruption of the outer annulus and disk material has entered the epidural space. Sequestration is the term for loss of continuity of a disk fragment with the parent disk from which it arose. Displacement of disk material away from the parent disk is termed migration. Migration can occur caudally or cranially. A herniated disk can further be classified as contained or uncontained. A contained disk herniation is one in which the outer annulus fibrosis is intact, whereas an uncontained herniation is one in which the annulus is completely disrupted. The shape definitions of protrusion and extrusion speak to this, but only by implication, not direct observation. CT or MRI can only rarely directly establish containment; post-CT diskography can make this distinction.

Description of displaced disk material (Fig. 15.15) in the axial plane is defined by zones: the central zone defined by the medial margins of the facets, the subarticular zone extending from the medial facet margin to the medial pedicle margin, the foraminal zone extending from the medial to lateral margins of the pedicle, and the extraforaminal zone peripheral to the lateral pedicle margin. A right-sided focal disk herniation may therefore be described as right central, right subarticular, right foraminal, or right extraforaminal. Similarly, the location in the sagittal plane (superior-inferior) is defined by levels in relationship to the vertebral end plate and pedicle margins. Extending from superior to inferior, the designations include the disk level, suprapedicular level, pedicle level, infrapedicular level, and the subsequent disk level. Although an element of subjectivity remains inherent in any usable system of terminology, careful adherence to these descriptors should allow a more coherent discussion of disk pathology.

Imaging of patients with radicular pain or radiculopathy should begin with upright radiographs of the involved spine segment. This will establish the enumeration, assess balance and stability, and act as a low-sensitivity screen for sinister disease. Advanced imaging may be needed in the setting of intractable radicular pain or progressive neurologic deficit. MRI has long been considered the primary imaging modality in the evaluation of disk herniations, but this has little basis in evidence. There are no studies comparing current generation CT with MRI technology in the detection and characterization of disk herniations. MRI remains the initial modality of choice largely because of its superior sensitivity and specificity in the detection of sinister disease causal of back or limb pain, which, it must be remembered, is the primary goal of imaging. CT myelography retains a problem-solving role in the lumbar region, but it plays a more prominent role in the cervical spine, where its ability to distinguish disk from bone may impact surgical planning.

**IMAGING RELIABILITY**

MRI has shown good reliability in the assessment of disk herniations. Lurie and colleagues analyzed MRI studies of patients with disk herniations from the Spine Patient Outcomes Research Trial (SPORT) trial; interobserver reliability was high (κ = 0.81) for disk morphology when classified as normal/bulge, protrusion, and extrusion/sequestration. There was moderate inter-observer agreement for thecal sac (κ = 0.54) and nerve root compression (κ = 0.47). Pfirrmann and colleagues proposed a grading system for nerve root compression. The authors divided the relationship of the herniated disk and the nerve root into four categories: no compromise, contact with the nerve root, deviation of the nerve root, and compression of the nerve root. The intra-observer (κ = 0.62 to 0.67) and intra-observer (κ = 0.72 to 0.77) reliability results were good. The correlation for a higher grade of nerve root involvement (compression) was better than for low-grade nerve root involvement.
Figure 15.14 Disk herniation definitions. Disk herniation definitions are depicted in the axial (A) and sagittal (B) planes. Note that the normal L1-L4 disks, shown here, are not round, but an oblate structure whose dorsal margin is convex anteriorly. The L5 disk is normally oval in configuration, convex posteriorly. The definitions are elaborated in the accompanying text.

Figure 15.15 Zones and levels of disk displacement. In the axial plane (A) the location of displaced disk material is described by zones. Moving from the midline laterally, these zones are the right or left central zone, demarcated by the medial margins of the facet joints; the subarticular zone (lateral recess), bounded by the medial aspect of the facet joint and the medial aspect of the pedicle; the foraminal zone, bounded by the medial and lateral aspects of the pedicle; and the extraforaminal or far-lateral zone, peripheral to the lateral margin of the pedicle. These zones are also illustrated in the coronal plane (B). The displacement of disk material in the cephalocaudal dimension is described by levels, as illustrated in (B) and (C).
IMAGING OBSERVATIONS

MRI T2-weighted images can well display the interface between disk herniations and the thecal sac. The herniated material may be of low T2 signal intensity comparable to the parent disk that has undergone nuclear matrix degradation, but not uncommonly extruded disk material is of higher T2 signal than its parent disk. This may in part reflect inflammatory reaction surrounding extruded material; it can make detection of extruded material in the lateral recesses or foramina challenging on Fast Spine Echo, Turbo Spin Echo (FSE, TSE) T2-weighted images in which fat is also bright. Comparison with matched T1-weighted images will identify the now dark disk material against the bright fat in the lateral recess or foramina. Occasionally, disk herniations may be associated with a small amount of hemorrhage in the epidural space, which may manifest itself as an epidural process of high T1 and variable T2 signal intensity. This hemorrhage may be related to the pathogenesis of discal cysts, relatively rare cystic lesions in the epidural space, which may present with radicular pain and be the result of prior disk extrusion and hemorrhage with incomplete resorption.161

Ninety percent of lumbar disk herniations occur at the L4 or L5 interspace levels. The vector of disk displacement in most herniations is posterolateral. In the lumbar spine, the exiting nerve passes immediately inferior to the vertebral pedicle and exits the foramen above the interspace level. Therefore, most disk herniations do not affect the exiting nerve, but rather impinge on the traversing nerve, which exits under the next lower vertebral pedicle. For example, a posterolateral L4-L5 disk herniation results in an L5 radicular pain syndrome or radiculopathy. For a lumbar disk herniation to affect the like numbered nerve, it must be an extrusion with lateral and cephalad migration of disk material into the neural foramen. The greater spatial resolution of CT myelography may identify subtle lateral recess or foraminal lesions less well seen on MRI.

Contrast material is not typically used when MRI is undertaken to evaluate for causes of radicular pain or radiculopathy except in the presence of red flag features raising concern for infection of neoplasm, or prior surgery. Unenhanced imaging can primarily detect the mechanical compression of a nerve, not the inflammatory response, which is also necessary to provoke radicular pain. T2 hyperintensity on STIR or fat-saturated images may identify this reaction. If gadolinium is given, it is often observed that the soft tissue seen on unenhanced images, thought to be herniated disk material, is largely enhancing inflammatory/granulation tissue about a small disk fragment. When confronted by a patient with clinically evident radicular pain or radiculopathy and no evidence of a neural compressive lesion on standard imaging, an enhanced exam may reveal an inflammatory process associated with a disk whose annulus is incompetent.162 This is described as chemical radiculitis. The neural compressive component of the lesion may only be present on imaging with axial load and physiologic positioning (Fig. 15.16).

POSTOPERATIVE IMAGING

Gadolinium-enhanced MRI does have a well-defined role in the evaluation of the postoperative patient. Plain films, CT, and CT myelography are relatively uninformative in the postoperative patient, as they cannot reliably distinguish recurrent disk herniation from epidural fibrosis/scar. Following diskectomy, extensive anatomic changes evolve over time, confounding imaging interpretation. Great caution must be used in interpreting MRI within 6 weeks of surgery.163 In this time frame, MRI is most useful in the evaluation for hemorrhage, pseudomeningocele, or diskitis; evaluation for recurrent disk herniation is tenuous. The diagnosis of postoperative diskitis is also complicated by the normal linear enhancement that may be observed in the postoperative disk.163 As postoperative tissue disruption and edema stabilize, MRI with gadolinium enhancement has been reported to be 96% to 100% accurate in distinguishing recurrent disk herniation from scar.163 Scar or epidural fibrosis enhances rapidly and uniformly following gadolinium administration; disk material does not enhance for the first 20 to 30 minutes. Early post-gadolinium images in the postoperative patient will show recurrent disk herniation as a nonenhancing zone; enhancing epidural fibrosis may surround this. Extensive scar or epidural fibrosis is in itself a negative prognostic sign, associated with an increased incidence of postoperative radiculopathy.164 In the postoperative setting, the thecal sac should be examined for evidence of arachnoiditis. In this condition, the roots of the cauda equina are either clumped together or adherent to the dural tube. The dural tube may even appear empty of roots, which are smoothly scarred to its wall. Roots may exhibit enhancement in this condition.

IMAGING NATURAL HISTORY

The imaging natural history of disk herniation is resolution.163 Large disk herniations, extrusions, and sequestrations, which have entered the highly vascular epidural space, are most likely to undergo resorption mediated by macrophage produced metalloproteases.166-168 This inflammatory response is integral to the profound pain these patients feel, but it will ultimately resorb the extruded disk material. If the inflammatory response can be attenuated by the targeted administration of corticosteroids, thus allowing the patient to remain functional, over time natural history will bear out with resolution of the herniated disk material and the radicular pain syndrome. Contained protrusions and bulges, with intact outer annulus shielding the herniation from the full fury of the immune system, tend not to change over time.

VALIDITY OF DISK HERNIATION IMAGING: CORRELATION WITH SYMPTOMS/SIGNS

The fundamental specificity fault of spine imaging is very evident in the imaging of disk herniations. Modic54 demonstrated that there was no relationship between herniation type, size, or change over time and patient outcome. Most of the imaging findings observed on an imaging study obtained at presentation with radicular pain will have been present at a time when the patient was asymptomatic.155 In another study by Masui, disk herniations treated conservatively were followed over 7 years.169 Clinical outcomes were unrelated to the size of the herniation or age changes in the disk. To assign causality to a disk herniation, there must be concordance, a perfect match of the patient’s pain or dysfunction syndrome, and the expected detriment caused by
an observed herniation. The imager must know the nature of the pain syndrome to identify its likely cause among the distracters of asymptomatic findings. The sensitivity fault is also evident: disk herniations that do not appear to contact neural tissue on recumbent imaging may be compressive under axial load and physiologic posture. Willén and Danielson demonstrated that significant additional information was demonstrated in 14% of sciatica patients on images obtained under extension and axial load, including accentuation of disk herniations, increasing lateral recess or foraminal stenosis, and distension of synovial cysts that contributed to root compression (Box 15.5). 

**Figure 15.16 Disk herniations.** Sagittal T2 MRI (A) and axial T2 images at L3-4 (B), L4-5 (C), and L5-S1 (D) disks demonstrate a normal L3-4 disk, a central protrusion at L4-5, and a right central extrusion with caudal migration at L5-S1. Axial T2 (E) and T1 (F) MRI images at the S1 end plate level demonstrate a left-sided sequestered disk fragment contacting the thecal sac. Fat-saturated T1 axial image (G) and sagittal image (H) show that much of the apparent disk herniation enhances and is inflammatory reaction about a small disk fragment. Enhancing Modic I change is present. Another patient with left S1 radicular pain due to an L5-S1 disk extrusion (I, J) was treated with a transforaminal epidural steroid injection with resolution of pain. He returned 4 years later with new L5 distribution pain and was reimaged (K, L). Note that the L5-S1 extrusion has completely resolved; (L) is at the identical level as (J) and a new L4-5 extrusion has developed. The natural history of disk extrusion is resolution.

**RADICULAR PAIN**

**LATERAL RECESS, FORAMINAL STENOSIS**

As the nerve root exits the common dural sac into its root sleeve, it leaves the central canal, passing caudally and laterally into the lateral recess or subarticular zone. Compromise of the lateral recess may be causal of radicular pain or radiculopathy. Lateral recess stenosis is primarily a product of facet joint arthrosis with overgrowth of the superior articular process. This encroaches on the posterior aspect of the lateral recess, impinging on the exiting nerve root. This is
The imager must know the nature of the radicular pain/radiculopathy syndrome to consider ascribing symptoms to a disk herniation. The natural history of disk herniations is resolution; larger herniations, extrusions, and sequestrations are more likely to resolve.

There is no relationship between the size, type, or change in disk herniations over time and patient outcomes.

Decisions regarding surgical intervention must be based on clinical grounds, not imaging appearance.

**Box 15.5 Disk Herniations and Radicular Pain**

- Radicular pain requires both compression of neural tissue and an inflammatory response, likely mediated by TNFα.
- Standard imaging can only detect nerve root displacement or compression, which are necessary but insufficient to cause symptoms.
- This is in part the basis of the specificity fault: many disk herniations are asymptomatic.
- Assignment of causality of symptoms to a disk herniation requires concordance: there must be a key in lock match of the lesion and the syndrome of pain and neurologic dysfunction.
- The imager must know the nature of the radicular pain/radiculopathy syndrome to consider ascribing symptoms to a disk herniation.
- The natural history of disk herniations is resolution; larger herniations, extrusions, and sequestrations are more likely to resolve.
- There is no relationship between the size, type, or change in disk herniations over time and patient outcomes.
- Decisions regarding surgical intervention must be based on clinical grounds, not imaging appearance.

Best demonstrated on axial MRI or CT myelographic images (Fig. 15.17). These images should be scrutinized to be certain that the nerve root in question is indeed entrapped within the lateral recess rather than simply displaced medially into the central canal. The minimum normal A-P dimensions of the lateral recess have been variably reported as 3 mm to 4 mm.171 The lumbar level most commonly involved with lateral recess stenosis is the L4-5 interspace level.

As the exiting nerve root continues to progress caudally and laterally under its similarly numbered lumbar pedicle, it enters the foraminal zone. The intervertebral foramen is an inverted teardrop-shaped orifice; the exiting root is situated in the larger, superior aspect of the foramen. An annular bulge or lateral protrusion may intrude into the inferior portion of the neural foramen without causing neural compression. A disk extrusion with cranial migration of disk material into the foramen may compress the exiting root. Other degenerative phenomena causing foraminal stenosis include osteophytes arising from the posterior margin of the vertebral body or superior articular process, synovial cysts, or abnormalities of vertebral alignment, including the concavity of a scoliotic curve or spondylolisthesis resulting from spondylosis or facet arthropathy. Foraminal stenosis is best demonstrated on sagittal MRI images (see Fig. 15.17).

The low signal nerve root and accompanying small veins should always be surrounded by high-signal fat on T1- or T2-weighted sagittal MRI images. Axial MRI images may also demonstrate foraminal stenosis, although to less advantage.

**SYNOVIAL CYSTS**

Synovial cysts may accompany facet osteoarthrosis and may be a cause of radicular pain, neurogenic claudication, and may be associated with axial low back pain. Synovial cysts are thought to originate with a degenerative or traumatic defect in the fibrous facet joint capsule, with subsequent herniation of the synovial membrane through the defect. Expansion of the synovial outpouching, no longer constrained by the joint capsule, results in a cystic lesion, which may impinge on adjacent neural structures or simply serve as an imaging marker of capsular pathology. Synovial cysts may retain or potentially lose their communication with the facet joint. Ganglion cysts may have a similar gross appearance but histologically lack a synovial lining; they may be indistinguishable on imaging studies.

Although relatively unusual, synovial cysts are not rare: the series of Doyle and associates172 demonstrated a prevalence of nearly 10% in a population of patients undergoing MRI for back or leg pain. In this series, anterior or intraspinous cysts, often arising from the superior recess, had a prevalence of 2.3%; posterior or extraspinal cysts were more common with a 7.3% prevalence. Synovial cysts are prevalent in an elderly population, with an average age of 63 in Metellus’ study,173 61 in Apostolaki’s174 study population, and 66 years in the large surgical series of Lyons.175 Reported male-to-female ratios are inconsistent, varying from a 1:1 ratio in the Lyons series to 1:2.1 in the Metellus series to 1:2 in the Apostolaki study; Doyle noted a female predominance in posterior cysts only. Synovial cysts are far more common in the lumbar region than in the thoracic or cervical spine. The literature has consistently shown that 60% to 70% of lumbar synovial cysts will be at L4/5 level, followed in relative order by L5/S1, L3/4, and L2/3. Anterior or intraspinal synovial cysts most commonly occur posterolateral to the thecal sac in close association to the facet joint. They may be embedded in the ligamentum flavum. Uncommonly, cysts may be located directly dorsal to the thecal sac, laterally within the neural foramen, or in a far lateral or extraforaminal site. Far lateral synovial cysts typically arise from the superior recess of the joint, which extends over the superior margin of the superior articular process; the communication with the joint will not be seen on an axial image but may be apparent on sagittal images.

Synovial cysts often arise from facet joints exhibiting significant arthrosis, with sclerosis, osteophytes, and increased joint fluid, although most joints with arthrosis do not produce cysts. Segmental hypermobility is postulated as an underlying cause of synovial cysts. This is supported by the strong association with the most mobile lumbar segment (L4/5) and the frequent (42% to 65%) association with degenerative spondylolisthesis.174 Disk age-related changes are commonly present at the level of the cyst. Metellus175 also noted that most cysts arise from joints with a predominant sagittal orientation; this orientation is also associated with segmental instability.

Synovial cysts may be detected by CT, CT myelography, or MRI; MRI is thought to be most sensitive (Fig. 15.18). Calcified cysts may rarely be seen on plain radiographs. Synovial cysts have great variation in their histology, with corresponding variety in their imaging appearance. Synovial cysts may be thin-walled collections of pure synovial fluid, or they may be complicated by varying degrees of chronic or acute hemorrhage and inflammation. Pure cysts have a high T2 signal, equal to or exceeding that of cerebrospinal fluid (CSF), with a thin, low-signal wall. With chronic hemorrhage, cyst contents may develop a high T1 signal (methemoglobin) and a variable T2 signal; the wall often enhances with gadolinium. In the presence of chronic inflammation and calcification,
Figure 15.17  Subarticular zone (lateral recess) and foraminal compromise. Axial T2 MRI image (A) at the S1 superior end plate demonstrates a widely patent central canal, but severe bilateral subarticular zone stenosis (arrows) resulting from facet hypertrophy. Consecutive CT images (B, C) at the L5 pedicle level in another patient show severe central canal stenosis, but also severe subarticular zone stenosis primarily caused by end plate osteophytes. T2 sagittal and L4-5 disk axial images (D, E) in a patient with left anterior thigh pain reveal a left foraminal disk extrusion, displacing the dorsal root ganglion (DRG) superiorly and laterally. Axial CT images (F, G) in another patient with left L4 radicular pain also demonstrate a left L4 foraminal and extraforaminal extrusion (arrows) effacing the fat about the exiting L4 DRG and ventral ramus. A final patient with L5 spondylolysis (H) demonstrates the typical S-shaped foraminal stenosis at L5-S1 seen in this setting. Note normal foramina at L3-4 and L4-5 with abundant fat surrounding the DRG and small veins.
the wall may become quite thick, with a very low T1 and T2 signal. On CT, calcification is variably observed and cyst contents range from hypodense to slightly hyperdense relative to muscle. Changes of arthrosis in the adjacent facet joint are typical, including abnormal marrow signal (T2 hyperintensity, T1 hypointensity) in the articular processes and pedicle. A direct communication with the facet joint is not always demonstrable on either CT or MRI. Synovial cysts may not be evident on recumbent CT or MRI imaging, as the synovial fluid recedes into the joint space, collapsing the

Figure 15.18 Synovial cysts. Typical bilateral L4 intraspinal synovial cysts (A) compress the thecal sac on a T2 axial image. A different patient (B) demonstrates a synovial cyst in the left L5-S1 neural foramen as well as a posterior extraspinal cyst. Another patient with right L5 radicular pain demonstrates an L4-5 synovial cyst on sagittal (C) and axial (D) T2 images. The patient underwent a right L5 transforaminal epidural steroid injection and an intra-articular injection of the facet joint/cyst. Her pain resolved. She presented 4 years later with axial pain. MRI T2 sagittal (E) and axial (F) show a new L5 compression fracture; the synovial cyst has resolved. A final patient demonstrates an irregular thick-walled cyst (arrows) arising from the left 3-4 facet (G, H, I). Note the T1 hyperintensity (H). CT (J) shows the cyst is calcified (arrow).
cyst; when the patient assumes axial load, the joint surfaces are opposed, driving the fluid into the cyst, which then exerts mass effect on neural elements. Not infrequently synovial cysts will fill when the joint is pressurized by intra-articular injection, despite no evidence of their existence on recumbent advanced imaging. The imaging differential diagnosis includes conjoined nerve root sleeves, sequestered disk fragments, cystic neural sheath tumors, and degenerative cysts of other origins, such as pseudobursae in Baasstrup’s disease.

Anterior or intraspinal synovial cysts often present as lesions causing unilateral radicular pain or contributing to neurogenic claudication. Anterior synovial cysts may cause focal neural compression in the lateral recess, foramen, or extraforaminal space, or they may contribute to central canal stenosis. Posterior cysts do not cause neural compression but may be associated with axial pain and be an imaging sign of facet capsular disease. Synovial cysts may regress spontaneously. Radicular pain resulting from synovial cysts may be treated by an injection of corticosteroid into the facet joint bearing the cyst, with a transforaminal epidural steroid injection at the same procedural setting. This strategy successfully allowed 50% of patients to avoid surgical injection in a series by Sabers and colleagues. Other nonoperative therapies have included aspiration, fenestration, or rupture of cysts under CT or fluoroscopic guidance. A large case series (n = 101) of percutaneous cyst rupture showed surgical sparing in about 50% of cases. Surgical resection of synovial cysts generally has a favorable outcome, but it may require facetectomy, laminectomy, and possible fusion.

**CERVICAL DISK HERNIATIONS**

The cervical intervertebral disks differ structurally from the lumbar disk. The cervical disks are thicker anteriorly than posteriorly and have a less well defined nuclear/annular structure. There is no discrete annulus at the posterior disk margin. The cervical disks function less to disburse axial load. They undergo maturational change with age; intradiskal T2 signal loss is a poor predictor of axial pain. Cervical radicular pain or radiculopathy is less common than lumbar symptomatology. Cervical radicular pain is most commonly caused by foraminal compromise of multifactorial origin: uncovertebral joint and facet hypertrophy, loss of disk space height, and less frequently disk herniation. In a population-based study in Rochester, Minnesota, disk herniations were causal of only 22% of cervical radiculopathies. The C6 and C7 nerves were most commonly affected. As in the lumbar region, the vector of herniation is usually posterolateral, but as the cervical nerves exit low in the foramen, a herniation will likely affect the exiting nerve, not the traversing nerve. The C6 nerve exits low in the C5-6 neural foramen; a herniation at this segment will most likely impinge on the C6 nerve.

The natural history of cervical disk herniations parallels the lumbar region. Cervical disk herniations may undergo spontaneous regression. As in the lumbar region, extrusions, migrated disk material, and laterally situated disk herniations are more likely to undergo spontaneous regression. As most lesions causing cervical radicular pain are not purely soft disk but are, at least in part, bony, overall regression of the root compressive lesion is less likely than in the lumbar region. MRI remains the primary advanced imaging modality, but CT myelography may play a larger role. It provides the best spatial resolution, critical in the narrow confines of the cervical region, and excels at discriminating bone from soft disk, which may alter the surgical approach (Fig. 15.19).

**THORACIC DISK HERNIATIONS**

Symptomatic thoracic disk herniations are rare; only 1% to 2% of all disk surgeries are performed in the thoracic segment. The expected specificity fault applies; disk age-related changes are ubiquitous, and herniations are often asymptomatic. The majority of disk herniations occur in the mid and lower thoracic region. In the surgical series of Stillerman, the T8 to T11 levels were most commonly affected. In this series, 76% of patients presented with pain, 61% with either motor or sensory dysfunction, and 24% with bladder dysfunction. Nearly two thirds of the disk herniations showed evidence of calcification on CT imaging. At surgery, 7% showed intradural extension. Thoracic disk herniations involving the conus can mimic lumbar radicular pain; MRI studies of the lumbar spine should always extend to the conus on the sagittal sequences.

Imaging of thoracic radicular pain should involve MRI or CT myelography. CT myelography has the greatest spatial resolution and may better demonstrate the presence of calcification within thoracic disks. MRI can detect signal abnormality within the cord, which may identify cord edema or venous hypertension, verifying the physiologic significance of a disk herniation. All imaging evaluation for thoracic disk disease must include careful enumeration of the segmental level involved. If a lesion that may require surgical or percutaneous intervention is detected, the imaging study should be extended to include sagittal images from the sacrum to the skull base. Communication between radiologist and surgeon or spine interventionalist is critical to avoid wrong segment interventions.

**DEGENERATIVE SPONDYLOLISTHESIS**

Spondylolisthesis refers to the abnormal anterior or posterior displacement of one vertebral body relative to another. Displacement caused by defects in the pars interarticularis (spondylolytic spondylolisthesis) will be discussed later. Degenerative anterolisthesis is the anterior displacement of a vertebral body relative to the body immediately caudal to it. The etiology of degenerative anterolisthesis is primarily facet joint arthrosis, often with a relative sagittal orientation of the facets. Disk structural failure is also necessary. Degenerative anterolisthesis may be present in 4% to 14% of elderly patients. Anterolisthesis is most frequent at the L4 level, with less common occurrence at L5, followed by L3. It is significantly more common in women than in men. Radiographic findings of degenerative anterolisthesis include the obvious displacement itself, joint space narrowing and sclerosis in the associated facets, and findings of intervertebral osteochondrosis, including a loss of disk space height, gas within the disk, and subchondral sclerosis.
Degenerative retrolisthesis describes the posterior displacement of the index vertebral body relative to that below it; the primary causative process is intervertebral osteochondrosis. As there is a loss of disk space height, the oblique orientation of the facet results in the more superior vertebral body gliding posterior relative to its inferior counterpart. Degenerative retrolisthesis is most commonly seen at the L2 interspace level, with less common occurrence at L1, followed by L3. There is no significant gender difference.

Figure 15.19  Cervical and thoracic disk herniations. A patient with prior C5-6 anterior cervical diskectomy and fusion presents with new right C7 distribution radicular pain. Sagittal T2 image (A) shows disk extrusion with caudal migration from the adjacent C6-7 segment. Note that the extruded material has higher T2 signal than parent disk, perhaps a reflection of the inflammatory response. Axial fast spine echo (FSE) T2 (B) and gradient echo (C) axial images at the C6-7 interspace well demonstrate the extrusion. In another patient with a right C6 radiculopathy axial FSE T2 images (D, E) at the C5-6 interspace suggest a disk-osteophyte complex and uncovertebral joint osteophytes compromise the right C5-6 foramen. The primary bony nature of the process is confirmed on CT images (F, G). In the cervical spine, compressive lesions are more likely to be osseous than soft disk alone. Thoracic disk extrusion in a 51-year-old woman with progressive thoracic myelopathy is shown in images H, I, and J. Sagittal T2 MR image (H) shows large T5-6 disk extrusion. Low T2 signal suggests calcification. The cord is displaced and compressed by the right-sided extrusion on T2-weighted axial MR image (I). Axial CT image (J) demonstrates coarse calcification in the disk extrusion. Note the linear defect with marginal sclerosis in the end plate, a finding often accompanying disk herniations.
Degenerative spondylolisthesis may be associated with axial low back pain. The Kauppi study showed that patients with degenerative spondylolisthesis had a higher prevalence of daily low back symptoms. There was, however, no increased disability in spondylolisthesis patients relative to controls. In this study, the overall incidence of degenerative spondylolisthesis approached 20%. Degenerative spondylolisthesis carries with it the risk of neural element compromise with secondary central canal stenosis, lateral recess stenosis, or foraminal compromise.

**SPINAL STENOSIS: LUMBAR NEUROGENIC INTERMITTENT CLAUDICATION (NIC)**

Lumbar spinal stenosis is an imaging observation; it may give rise to the clinical syndrome of NIC. NIC is the most common cause of spine surgery in patients over 65 years of age. The hallmark is the induction of gluteal and lower extremity pain with upright exercise or specific postural positions, and palliation by forward flexion, sitting, or recumbency. The most common symptoms in patients with lumbar spinal stenosis are back pain (prevalence of 95%), claudication (91%), leg pain (71%), weakness (33%), and voiding disturbances (12%). There may be a paucity of physical findings, even in the presence of symptoms.

Despite its significance, few prevalence or natural history data are available for NIC. Kalichman and colleagues utilized data from the Framingham study to establish the prevalence of congenital and acquired lumbar central canal stenosis in a community population. Using the anterior-posterior dimension of the central canal derived from CT studies (12 mm = relative stenosis, 10 mm = absolute stenosis), they noted congenital central canal narrowing of relative degree in 4.7% of the population and absolute stenosis in 2.6%. Acquired stenosis was identified in 22.5% (relative) and 7.3% (absolute) of individuals. Their review of the literature noted that the prevalence of acquired lumbar stenosis ranged from 1.7% to 13.1%. The prevalence of acquired stenosis (absolute) increased from 4% in patients younger than 40 years of age to 14.3% in patients older than 60. The North American Spine Society (NASS) 2011 evidence-based guidelines on the diagnosis and treatment of spinal stenosis suggest, in the absence of reliable evidence, that the natural history of patients with clinically mild to moderately symptomatic degenerative stenosis is favorable in one third to one half of patients. In patients with mild to moderately symptomatic stenosis, rapid or catastrophic neurologic decline is a rare phenomenon.

**PATHOPHYSIOLOGY**

The pathogenesis of NIC in lumbar spinal stenosis has been a subject of investigation for half a century. Verbiest initially described mechanical compression of the nerve roots of the cauda equina as a cause of NIC in 1954. Subsequent investigators have postulated that arterial and venous ischemia, perhaps exacerbated by restriction of CSF flow (which participates in nerve root nutrition), are contributors to the clinical syndrome. The current preponderance of evidence favors venous congestion secondary to mechanical compression. This hypothesis emphasizes the importance of multiple levels of compression and the physiologic effects of lumbar extension. Both of these observations have significant relevance to imaging.

The animal work of Takahashi and Olmarker demonstrated that two zones of modest compression in the cauda equina would dramatically reduce blood flow to the intervening nerve segment because of venous congestion; this venous congestion could precipitate neural dysfunction. Kobayashi examined cauda equina histology after the application of a modest stenosis (30% of cross-sectional area) to the dural tube. The cauda equina demonstrated congestion and dilatation of intradural veins and an inflammatory cellular infiltrate. There was disruption of the blood-nerve barrier, both at the site of the compression and also in more distant sites of Wallerian degeneration. The necrotic debris created by Wallerian degeneration stimulated macrophage activity generating inflammatory molecules such as interleukin-1 and TNFα. Macrophages stimulate cytotoxic activity by the release of nitric oxide and proteases. They are considered the chief effector cells causing an inflammatory neuritis that results in aberrant ectopic neural discharge and conduction disturbance leading to the pain and neural dysfunction of neurogenic intermittent claudication.

Multiple sites of venous congestion are key to this model of NIC; it is supported by clinical studies. Sato demonstrated that patients with two-level central canal stenosis were significantly more likely to exhibit NIC than were patients with a single level of canal compromise. In two-level stenosis, the symptomatic expression most closely matched the radicular distribution of the more caudal of the two stenotic levels; in patients with compromise at the L3 and L4 disk levels, the pain pattern matched that of the traversing L5 roots. Porter and Ward noted that the sites of compression may be either in the central canal or in the neural foramina. In their cohort of 49 patients with NIC, 94% had either multilevel central canal stenosis or central canal plus neural foraminal stenosis. The work of Morishita emphasized the importance of the neural foramen as a potential zone of compression, particularly with dynamic changes in posture. Even without demonstrable foraminal compromise by imaging in a neutral position, in lumbar extension intraforaminal pressures exceeded venous pressure and neural dysfunction was documented by electromyography (EMG). All levels of neural compromise, central, lateral recess, and foraminal, are potentially significant and must be detected by imaging.

**CONGENITAL CENTRAL CANAL STENOSIS**

A small proportion of patients with clinical NIC will have developmental narrowing of the lumbar central canal, with only modest spondylotic changes necessary to produce clinical symptoms. Singh and colleagues studied the morphologic characteristics of a cohort of surgically treated patients carrying the clinical diagnosis of congenital lumbar stenosis. They noted that these patients had a significantly shorter pedicle length and, as a result, a smaller cross-sectional spinal canal area when compared with age- and sex-matched controls. The patients with a congenitally narrowed lumbar central canal typically exhibit these morphologic characteristics over several vertebral segments,
maximal at the L3 level. This contrasts with purely acquired stenosis, which is often more focal, particularly at the L4 disk level. Congenital central canal stenosis patients tend to present at a younger age (40 to 50 years old) and with less spondyloitic change than typical.

**ACQUIRED SPINAL STENOSIS**

The great majority of patients presenting with neurogenic intermittent claudication have acquired spondyloitic change as their primary cause of central canal, lateral recess, or foraminal compromise. The changes that result in compromise of the central canal are rooted in the three-joint structure of the spine motion segment: the disk and the paired facet joints. In the anterior column, degradation of the disk nuclear matrix places excessive load on the posterior annulus, and annular failure results in posterior end plate osteophytes and disk herniation. These changes encroach on the ventral aspect of the central canal or lateral recesses. Loss of disk space height obligates narrowing of the neural foramina and contributes to increased facet load and ultimately arthrosis; facet capsular hypertrophy and superior articular process osteophytes compromise the lateral recesses. Synovial cysts, particularly at the L4 level, may contribute to central canal, lateral recess, or foraminal compromise. The reduced height of the segment and the loss of elasticity of the ligamentum flavum result in its buckling centrally as a dominant cause of the loss of cross-sectional area of the central canal. The ligamentum flavum may also thicken, although it is unclear if this represents true hypertrophy. These several anterior and posterior column phenomena conspire to narrow the central canal most commonly at the L4-5 disk level, followed by L3-4, L5-S1, and L1-2.

There are a number of measurable parameters that could quantify the degree of stenosis depicted by radiography, myelography, CT, or MRI. Verbiest, in his early descriptions of the entity of spinal stenosis, suggested that a 10- to 12-mm anterior-posterior diameter of the dural sac on conventional myelography constituted relative stenosis, with a measure of < 10 mm denoting absolute stenosis. Steurer, in a 2001 review, surveyed the numerous measurements applied between the most anterior point of the superior articular process (SAP) and the posterior vertebral body, and the LR angle is the angle formed by the posterior vertebral body and the pars interarticularis. LR stenosis is typically defined as height < 3 mm or angle < 30 degrees. Descriptors of foraminal stenosis most commonly used suggest a diameter of ≤ 2 to 3 mm as indicative of stenosis.

The multiplicity of quantitative parameters suggests that no single measurement has proven satisfactory. Indeed, the very notion of a readily quantifiable measure of stenosis may be flawed. There is a wide normal variation in central canal and dural tube diameters; an assessment of stenosis must address not simply diameter or cross-sectional area but the crowding or compression of neural tissue. The semi-quantitative criteria advanced in 2001 by Fardon and Milette simply defines reduction in expected area by less than one third as mild, by one third to two thirds as moderate, and by greater than two thirds as severe. This allows a subjective judgment of neural compression at the potential cost of reliability. Lurie and associates studied the reliability of the subjective grading of stenosis of the central canal, lateral recesses, and neural foramina and measurement of central canal and dural sac area aided by specific definitions and imaging examples of the criteria. Stenosis was subjectively rated as none, mild, moderate, and severe using the Fardon and Milette definitions; nerve root compromise in the foramen was categorized as none, touching, displacing, or compressing. Inter-reader reliability in assessing the central canal was substantial, with a $\kappa = 0.73$. There was moderate to substantial reliability for foraminal stenosis and nerve root impingement ($\kappa = 0.58$, 0.51, respectively). Reliability for subarticular stenosis was only moderate at $\kappa = 0.49$. These results emphasize the importance of a clear definition of criteria for reliably grading stenosis by subjective scales.

Other imaging observations have been employed in an attempt to identify significant stenosis. The observation of nerve root redundancy as a qualitative marker of central canal compromise dates from the original description of the entity of spinal stenosis by Verbiest. This is presumed to originate from mechanical entrapment of the root at the site of compression, with subsequent elongation of the nerve above this site under the tensile stress of physiologic flexion and extension motion. Some of these prominent structures may also represent dilated veins. Although frequently observed, this sign has been subjected to little study. Redundant nerve roots are present in 34% to 42% of surgical candidates with clinical NIC. In a 2007 study by Min and colleagues, redundant nerve roots were more commonly observed in older patients, but there was no significant association with duration of symptoms, diameter of the spinal canal, preoperative symptom intensity or surgical outcomes. There was a nonsignificant trend toward poorer surgical outcomes in patients with redundant roots.

A 2010 study by Barz described the “nerve root sedimentation sign” as a marker of symptomatic NIC. In patients without central canal compromise, the roots of cauda equina lie in the dorsal aspect of the dural sac on supine MRI imaging. A positive sedimentation sign was defined as the absence of nerve root sedimentation to the dorsal dural sac on at least one axial MRI image at a level above or below the zone of compression; the two nerve roots leaving the dural sac at the next most caudal segment are exceptions. This retrospective study utilized a total of 200 patients: 100 patients with low back pain but without clinical NIC, and a dural cross-sectional area (DSCA) of > 120 mm² and a cohort of 100 patients with clinical NIC, a maximum walking distance of less than 200 m, and a DCSA of less than 80 mm² on at least one level. There was no correlation between the smallest DCSA and patient disability as measured by the Oswestry Disability Index (ODI). The sedimentation sign, however, was identified in 94 of the patients in the NIC cohort but in none of the low back pain group. It remains to be demonstrated that this sign provides additional specificity over a quantitative measurement of the DCSA.
Given the specificity challenges of purely anatomic imaging, the more physiologic parameter of gadolinium enhancement may have a role. This is not a new observation; in 1993, Jinkins observed abnormal intrathecal nerve root enhancement at the site of stenosis on enhanced MRI in patients with NIC.198 He postulated that this represented a breakdown of the blood-nerve barrier at sites of nerve root injury with subsequent Wallerian degeneration. This has been elegantly confirmed in a canine model by the work of Kobayashi.189 Histologic examination demonstrated congestion and dilatation of intra-radicular veins and an inflammatory cellular infiltrate at sites of gadolinium enhancement. Gadolinium enhancement may provide added specificity in the correlation of imaging and the clinical symptomatology of NIC; this remains to be proven in clinical studies (Fig. 15.20).

SPECIFICITY OF IMAGING FINDINGS

The ultimate challenge in establishing the utility of diagnostic imaging in the diagnosis of NIC is the lack of a gold standard against which to measure imaging parameters. Surgical findings may be subjective. Clinical outcomes are highly dependent on the technical success of the instituted surgical therapy and the outcome instruments used in any such measurement.

The specificity fault in imaging of central canal stenosis can be seen in studies of asymptomatic volunteers. Boden and associates noted significant central canal stenosis on MRI in 21% of asymptomatic subjects over the age of 60.18 Jarvik and colleagues demonstrated that asymptomatic stenosis on MRI increases in prevalence with age: moderate to severe central canal stenosis was observed in 7% of subjects < 45; in 6% of subjects age 45 to 55; in 11% of subjects age 55 to 65, and in 21% of subjects over age 65.

Against this background of asymptomatic central canal narrowing, numerous conflicting studies have attempted to establish a relationship between imaging quantitation of central canal or dural size and clinical expression of NIC. For example, Hamanishi and colleagues showed that a decrease in the DCSA to less than 100 mm² at more than two of three lumbar levels (L2-3, L3-4, L4-5) was highly associated with the presence of clinical NIC.199 For each study showing such an association, several others refute it. Sirvanci examined patients undergoing decompressive surgery for NIC.200 Morphologic stenosis was assessed by DCSA (> 100 mm²: normal; 76 to 100 mm²: moderately stenotic; < 76 mm²: severely stenotic) and a 4-point grading of subarticular and foraminal stenosis. There was no correlation between any of the measured parameters in any spine compartment and patient disability as measured by the Oswestry Disability Index (ODI). This applied both to patients with multilevel central stenosis and to a subset with degenerative spondylolisthesis. The NASS guidelines185 conclude that there is insufficient evidence to recommend for or against a correlation between clinical symptoms or function and the presence of anatomic narrowing of the spinal canal on cross-sectional imaging.

SENSITIVITY OF IMAGING FINDINGS

There is also a basic sensitivity flaw in advanced imaging. NIC is by definition intermittent; most patients with NIC report exacerbation of symptoms with extension and weight bearing. It is well known that the cross-sectional area of the central spinal canal, subarticular zone or lateral recess, and neural foramina is maximized with flexion positioning; the dimensions of these structures diminish with extension and axial load. Intradiskal pressures are significantly lower when one is in a recumbent position than when sitting or standing. A 2009 study by Hansson and associates identified the ligamentum flavum as the greatest dynamic contributor to central canal compromise with axial load and extension.39 The average cross-sectional area of the central canal diminished by 23 mm² at the L3 disk level and 14 mm² at the L4 level under load. The ligamentum flavum was responsible for 50% of the reduction at the L3 level and 85% of the reduction at the L4 level. Madsen and associates attempted to distinguish between the effects of axial load and extension; their work suggested that lumbar spine extension is the dominant cause of reduction in DCSA in the standing patient.40 Mechanisms circumventing this flaw include upright axial loading devices, the technologically immature upright MRI, and cone beam CT myelography (Box 15.6).

THORACIC SPINAL STENOSIS

Symptomatic central spinal stenosis in the thoracic segment of the spine resulting from age-related change is far less common than in the cervical and lumbar regions, likely because of the added mechanical stability imparted by the rib cage. Systemic disease accounts for a correspondingly greater proportion of cases. Systemic processes leading to thoracic central canal compromise include achondroplasia, osteochondrodystrophy, Scheuermann’s disease, diffuse idiopathic skeletal hyperostosis (DISH), and Paget’s disease.

Compromise of the thoracic spinal canal may be manifest clinically as myelopathy, radiculopathy, or a mixed presentation. The segmental level of canal compromise is most commonly reported to be in the lower thoracic region. Thoracic spine mobility, particularly flexion-extension motion, is greatest near the thoracolumbar junction, likely the biomechanical underpinning to this distribution of age-related pathology. Posterior element age-related changes play a greater role in the genesis of thoracic central canal compromise. This takes the form primarily of unilateral or bilateral facet joint hypertrophy. Thoracic disk herniations or disk-osteophyte complexes may also contribute. Both the ventral and dorsal contributions to thoracic central canal compromise are clearly visible on CT, CT/myelography, and MRI.

Other causes of thoracic central canal stenosis include ossification of the thoracic ligamentum flavum (OLF), a well-recognized cause of thoracic stenosis in an Asian population, but rare among Caucasian subjects. Epidural lipo-omatosis is a rare cause of central canal compromise in the thoracic or lumbar spine. It may be idiopathic or secondary to endogenous or exogenous steroid excess. Obesity is a common factor in both groups. Excess epidural fat acts as a mass compressing the dural sac, most commonly from a dorsal vector in the thoracic region; it is more likely to be circumferential in the lumbar region.
Figure 15.20  Central canal stenosis manifest as neurogenic intermittent claudication (NIC). A 24-year-old male presents with incapacitating leg pain with walking and recent voiding disturbance. Lateral radiograph (A) demonstrates short pedicles throughout the lumbar spine. Sagittal CT image (B) and axial images at L3-4 (C), L4-5 (D), and L5-S1 (E) demonstrate the developmentally narrow spinal canal with superimposed disk herniations at L4-5 and L5-S1. There is severe central canal compromise at L4-5 and L5-S1. The L3-4 disk has a broad bulge without canal compromise. A 62-year-old male has classic symptoms of NIC; a sagittal T2 MRI image (F) demonstrates mild loss of disk space height and annular bulges at L2-3 and L3-4; the dominant element constricting the spinal canal is the ligamentum flavum. Axial T2 images at L1-2 to L4-5 (G, H, I, J, respectively) confirm the severe central canal compromise at L2-3 and L3-4 primarily because of ligamentum flavum thickening. A 68-year-old male has severe NIC with a walking tolerance of 10 to 20 m. A T2 sagittal image (K) shows severe stenosis at L4-5 and an L1-2 herniation. T1 unenhanced (L) and fat-saturated, T1-enhanced (M) images show intrathecal enhancement at L4-5 consistent with breakdown of blood-nerve barrier and Wallerian degeneration. Note also enhancing Modic I change and disk herniation at L1-2.
Cervical spondylotic myelopathy (CSM) is the most common cause of spinal cord dysfunction in patients over 55 years of age. Stookey originally described cervical spondylotic myelopathy in 1928. Although its pathophysiology remains incompletely understood, it is widely acknowledged to involve static factors causing stenosis of the cervical canal and dynamic factors causing repetitive cord injury. These mechanical factors both directly injure neural tissue and initiate secondary ischemia, inflammation, and apoptosis. The histologic characteristics in the cord in CSM include cystic cavitation and gliosis of the central gray matter and demyelination of the medial portions of the white matter long tracks. There is Wallerian degeneration in the posterior columns and posterolateral tracts cephalad to the site of compression. Loss of anterior horn cells and corticospinal tract degeneration are visible at and caudal to the site of compression.

The developmentally narrow spinal canal is a more universal substrate for CSM than is the case with NIC in the lumbar region. The sagittal diameter of the adult spinal cord is nearly constant, measuring about 8 mm from C3-C7; the cervical canal enlargement occurs primarily in the transverse plane. The normal cervical spinal canal sagittal diameter (posterior vertebral body to spinolaminar line) is 17 to 18 mm (C3-C7) in a Caucasian population; these subjects rarely develop sufficient age-related change to provoke CSM. Edwards and LaRocca observed that patients with developmentally narrowed midcervical sagittal diameters of < 10 mm were often myelopathic, patients with canals of 10 to 13 mm were at risk for CSM, canals of 13 to 17 mm were noted in patients with symptomatic spondylosis but rarely myelopathy, and subjects with canals > 17 mm were not prone to develop spondylosis. Morishita studied the kinematics of subjects with congenitally narrowed canals; there is hypermobility in the lower cervical region, providing a biomechanical explanation for the significantly greater age-related change seen in this setting. Hence, the individual with a congenitally narrowed canal is at risk because of both the limited space available for the cord and a greater propensity to age-related spondylotic change.

Acquired cervical central canal stenosis encompasses age-related spondylotic change (most common), ossification of the posterior longitudinal ligament (OPLL), and OLIF. Disk degradation results in a loss of disk space height, excess loading of the uncovertebral joints with osteophyte formation, excess facet loading causing hypertrophy, and central buckling of the ligamentum flavum. These processes circumferentially narrow the canal and directly compress the cord, exiting nerves, and the anterior spinal artery. The most common levels of compromise were C3-4 (27%), C4-5 (37%), and C5-6 (29%) in a surgical series. This series included patients with spondylosis only and those with OPLL. It is also known that the cross-sectional area of the cervical canal diminishes in both extension and flexion, with greater effects during extension. Ventral compression of the cord compromises flow through the arterioles arising from the anterior spinal artery in the ventral sulcus of the cervical cord; dorsal compression reduces perfusion to the central gray matter. Oligodendrocytes are extremely sensitive to ischemic injury; resultant apoptotic cell death may cause the demyelination characteristically observed in CSM. Animal evidence further supports the role of an inflammatory cascade in apoptotic cell death.

**IMAGING**

Historically, radiographic assessment of cervical anatomic stenosis relied on the anterior-posterior dimension of the central canal as measured from the posterior vertebral body to the spinolaminar line. The normal sagittal diameter from C3 through C7 is considered to be 17 to 18 mm; Edwards and LaRocca noted that a cervical canal with a sagittal diameter of less than 13 mm was at risk for myelopathy; absolute stenosis was defined as being less than 10 mm. The advent of cross-sectional imaging has allowed us to directly measure the diameters and cross-sectional areas of the cervical spinal canal and the cervical cord. MRI has also given us the ability to evaluate physiologic parameters: T2 hyperintensity, T1 hypointensity, gadolinium enhancement, and, with diffusion tensor imaging (DTI), fractional anisotropy (FA), and apparent diffusion coefficient (ADC).

A 2010 study by Naganawa and associates demonstrated good intra- and inter-observer reliability in evaluation of the cross sections of the cervical canal and spinal cord with both CT/myelography and MRI. They noted that dural sac diameter and cross-sectional area measurements were slightly but significantly larger with CT/myelography than fast spin echo T2-weighted MRI; conversely, the diameters and cross-sectional areas of the spinal cord were slightly but significantly larger with MRI. MRI graded the stenosis as slightly, but significantly, more severe than CT/myelography. A 2009 study by Song and associates found no significant difference in inter-observer or intra-observer reliability between CT/myelography and MRI. With its superior spatial resolution, CT/myelography was somewhat better in assessing foraminal stenosis and much better in discriminating bony versus soft tissue lesions. MRI was more reliable in identifying direct nerve root compression (Fig. 15.21).
Figure 15.21  Cervical central canal compromise manifest as cervical spondylotic myelography (CSM). A 36-year-old female presents with very subtle bilateral hand incoordination, neck pain, and left arm symptoms. Her lateral radiograph (A) shows no lamina posterior to the articular pillar. Compare to a normal lateral radiograph (B). Sagittal T2 (C) and T1 (D) images show effacement of CSF and cord compression from the C4-C6 interspaces with subtle T2 hyperintensity in the cord at the C5-6 interspace level. Note that no dorsal epidural fat is visible above the C7-T1 level, a typical finding.

A 48-year-old female had intractable upper extremity pain and dysesthesia involving the right lateral forearm. There were also long tract signs. Sagittal T2 (E) and T2 with fat saturation (F) demonstrate cord deformity at the C6-C7 interspace level, with focal T2 hyperintensity in the right side of the cord, as seen on the axial FSE image (G). Postgadolinium sagittal T1-weighted image with fat saturation (H) shows enhancement at the site of T2 hyperintensity, a negative prognostic sign.

A 77-year-old Caucasian male has slowly progressive myelopathy on clinical examination. Lateral radiograph (I) demonstrates OPLL in the upper cervical spine; note the coexistent manifestations of DISH. CT sagittal reconstruction (J) and sagittal T2 (K) images better depict the severe cord deformity at C2.
IMAGING SPECIFICITY

The significant prevalence of asymptomatic cervical central canal stenosis was noted earlier in this chapter. When a population of patients with a clinical diagnosis of CSM is studied, the correlations appear more favorable. The transverse area of the spinal cord as measured by MRI correlates well with the severity of myelopathy and the pathologic changes observed in the cord in CSM.209 The physiologic parameters of T2 hyperintensity or T1 hypointensity have provided further insight into the evolution of CSM. The several studies addressing these correlates are explored in a review.210 From these studies we can conclude the following:

1. Intramedullary T2 hyperintensity represents a range of reversible (edema) and irreversible (demyelination, gliosis, cystic necrosis) pathology.
2. Faint and indistinct T2 hyperintensity is more likely to reflect reversible edema.
3. Very intense and well-defined T2 hyperintensity more likely represents fixed gliosis or cystic necrotic change.
4. Intramedullary T1 hypointensity represents irreversible necrosis and myelomalacia.

A 2010 study by Ozawa211 and a 2011 study by Cho212 compared CSM patients who exhibited gadolinium enhancement with a nonenhancing control group. The zone of enhancement was always within and smaller than a zone of T2 hyperintensity at the site of maximal compression, with extension caudally. It was typically observed in the posterior or posterolateral cord. There was no correlation of enhancement with preoperative clinical symptoms. Enhancement disappeared in most patients within 1 year of surgical decompression; patients who exhibited preoperative enhancement had a poorer postoperative prognosis than those who did not. Floeth studied 20 CSM patients with FDG-PET in the setting of a single level stenosis at C3/C4 or C4/C5.213 All the CSM patients showed a significant decrease in 18F-FDG uptake in the lower cord below the stenosis, relative to normal controls. A cohort of these patients also exhibited increased uptake at the level of the stenosis. The patients with increased 18F-FDG uptake at the stenosis had a significantly shorter duration of symptoms, a more precipitous decline in function in the 3 months prior to decompression, and ultimately exhibited significant improvement after decompression. Patients without increased uptake at the stenotic zone did not recover neurologic function after decompression.

Early reports suggest that diffusion tensor imaging may offer greater accuracy in the identification of symptomatic cord compromise than T2 hyperintensity or T1 hypointensity. The measured parameters are fractional anisotropy (FA), mean diffusivity (MD), or apparent diffusion coefficient (ADC). The ADC or MD values reflect overall diffusivity in the tissue irrespective of directional dependence. Anisotropy (directional dependence) of diffusion in white matter tracts results from oriented membrane structures (i.e., axons and myelin). Diminished FA values may reflect loss of directionally oriented membrane structures, increased extracellular edema, or both. Several studies210 suggest diminished FA is more sensitive in the detection of early cord injury than intramedullary T2 hyperintensity and is better correlated with symptoms. This may assist in the selection of patients for surgical decompression, although additional work remains to be done.

IMAGING CORRELATES WITH DECOMPRESSION PROGNOSIS

The ultimate goal of imaging must be to improve the clinical outcomes of patients. In the CSM population, this currently implies the timely and appropriate selection of patients for therapeutic interventions, primarily surgical decompression. There is a large body of literature210 that has examined the role of imaging in predicting clinical response to surgical decompression; imaging parameters under consideration include the cross-sectional area of the cord, intramedullary T2 hyperintensity, including its degree of intensity and multifocality, intramedullary T1 hypointensity, change or stabilization of intramedullary signal after decompression, recovery of cord cross-sectional area after decompression, and intramedullary gadolinium enhancement. These are summarized in Box 15.7. Utilization of these findings should assist in the selection and counseling of CSM patients regarding surgical decompression.

Box 15.7 Cervical Spondylotic Myelopathy: Prognostic Factors for Surgical Decompression

1. Intramedullary T2 hyperintensity diminishes prognosis relative to normal signal.
   a. Intense, focal T2 hyperintensity is a more negative prognostic sign than ill-defined hyperintensity.
   b. Multilevel T2 hyperintensity is a more negative prognostic sign than single level change.
   c. Resolution of T2 hyperintensity postoperatively improves prognosis.
   d. Expansion of T2 hyperintensity postoperatively diminishes prognosis.

2. Intramedullary T1 hypointensity greatly diminishes prognosis.
   a. Evolution of T1 hypointensity postoperatively diminishes prognosis.

3. Intramedullary gadolinium enhancement greatly diminishes prognosis.

4. Increased metabolic activity at the site of compression on 18F-FDG PET improves prognosis over no increased activity.

5. Postoperative residual compression and failure of re-expansion of the cord cross section are negative prognostic signs.

OSSIFICATION OF THE POSTERIOR LONGITUDINAL LIGAMENT (OPLL)

Ossification of the posterior longitudinal ligament (OPLL) is a multifactorial disease, whose genetic basis is a defect in the nucleotide pyrophosphatase (NPPS) gene.201 The prevalence is 1.9 to 4.3% of the Japanese population and approximately 3% of the populations of Korea and Taiwan. It is
implied in up to 25% of North American and Japanese cases of CSM. It has a significant association (up to 50%) with DISH, and some consider it a subtype of DISH. Like age-related causes of structural central canal narrowing, it is often asymptomatic. The ossification is most common in the cervical region, where it causes static narrowing of the canal; repeated impact of the ventral cord on the bony mass contributes to myelopathic injury. Patients may present in their 40s and 50s with pain, chronic myelopathy, or acute neurologic injury after modest trauma. The natural history of the ossification is progression. Close clinical follow-up is warranted.

The ligamentous ossification may be identified on radiographs, CT, and MRI. On lateral radiographs, reduction of the sagittal canal diameter available for the cord by > 60% correlates strongly with myelopathy. The ossification is located from C2-4 in 70% of cases, T1-4 in 15%, and L1-3 in 15%. On CT, the ossification may be classified as segmental (posterior to individual vertebrae, 39%), continuous (bridging across vertebra, 27%), mixed type (29%), and other (ossification posterior to disks, variable sagittal extension, 5%). In addition to documenting the degree of central canal compromise, the CT characteristics of OPLL can suggest dural penetration. CSF leaks are a significant risk in anterior decompression surgery, particularly when the dura is ossified or inseparable from the bony ligamentous mass. On MRI, mature ligamentous ossification is of diminished signal intensity on all sequences; early OPLL may have inhomogeneous signal and exhibit slight enhancement. When mature, there is no enhancement, allowing differentiation from epidural fibrosis. The secondary signal alterations in the cord were described earlier in the chapter.

**SYSTEMIC DISEASE CAUSAL OF SPINE/LIMB PAIN**

In the context of the very low prevalence of systemic disease as causal of spine or limb pain, this chapter has focused on the mechanical and inflammatory processes involving the articulations of the spine that most commonly provoke axial or radicular pain syndromes and syndromes of neurologic dysfunction. It must be remembered, however, that detection of undiagnosed systemic disease—including stress fractures, infection, spondyloarthritis, neoplasm, and dural fistula—is the primary role of spine imaging.

**STRESS FRACTURES**

Stress fractures encompass fatigue fractures, in which normal osseous architecture is subjected to sustained supraphysiologic loads, and insufficiency fractures, in which deficient osseous structure fails under normal load conditions. Insufficiency (osteoporotic) fractures are the most common manifestation of systemic disease to present as back pain. In 2005, an estimated 2 million osteoporotic fractures occurred in the United States in patients > 50 years of age; 27% were vertebral body fractures. This is an underestimate of prevalence, as many vertebral fractures remain asymptomatic. Each vertebral wedge configuration fracture accentuates load on the anterior aspect or adjacent vertebra and increases the annual risk of additional fractures fivefold.

Imaging of vertebral compression fractures begins with weight-bearing radiographs, which provide a low-cost means of assessing change over time with serial images but are relatively insensitive in fracture detection. Radiographic findings include a wedge deformity, most commonly of the superior end plate, which may be accompanied by increased density in the involved end plate in the acute or subacute phase. Chronic deformities often demonstrate remodeled osteophytes. MRI or bone scan are much more sensitive in fracture detection and can better assess acuity. The presence and extent of a narrow edema pattern (T1 hypointense, T2 hyperintense, most conspicuous on STIR or fat-saturated images) can provide an estimate of acuity. The signal abnormality in the marrow tends to be bandlike, paralleling the involved end plate; it may be traversed by a low signal line, adding further confidence to the diagnosis of fracture.

A primary role of imaging in this setting is the characterization of a vertebral fracture as benign or malignant. Malignant lesions are much more likely to exhibit diminished T1 signal throughout the vertebral body. Extension of diminished T1 signal to the vertebral pedicles or posterior elements is relatively specific for malignancy. Paravertebral or epidural mass associated with a fracture is more common in malignant lesions. Posterior bowing of the vertebral body strongly suggests malignancy. Gadolinium enhancement to a level greater than that noted in normal marrow suggests a malignant lesion. Associated disk rupture and retropulsion of a bony fragment without bowing of the posterior margin of the vertebral body suggest a benign lesion. Discrete linear zones of T2 hyperintensity similar to CSF adjacent to the fractured end plate (the fluid sign) are visible in 40% of osteoporotic compression fractures and are a finding of high specificity for a benign fracture. Advanced MRI techniques, such as diffusion sequences or chemical shift imaging, may play a problem-solving role.

In the non-MRI compatible patient, CT can aid in characterization of fractures but is less sensitive to narrow abnormality than MRI. Trabecular preservation within the vertebral body outside the fracture zone suggests a benign process. The ability of CT to display cortical or trabecular destruction or an adjacent soft tissue mass can aid in the diagnosis of a malignant lesion. The fluid sign noted earlier is occasionally visible as a vacuum cleft containing gas under the fractured end plate, marking a benign osteoporotic compression. Bone scans are highly sensitive in fracture detection, but they are of poor specificity in characterization.

Pelvic insufficiency fractures are increasingly recognized as a cause of axial and somatic referred pain experienced in the low back, pelvis, groin, and proximal lower extremities. Postmenopausal osteoporosis is the dominant risk factor, along with pelvic radiation, corticosteroid use, rheumatoid arthritis, and osteomalacia. The role of osteoporosis is emphasized by the marked female predominance of these lesions, with a reported female-to-male ratio of 9:1. Patients are typically in their sixth decade or older. There is often significant morbidity associated with insufficiency fractures. Taillandier and colleagues noted that 50% of their patients did not recover their former level of independence, and in 25% the insufficiency fracture precipitated institutionalization in their elderly study population. Sacral insufficiency fractures are the most common expression of this
condition; pubic ramus fractures, parasymphysial fractures, and para-acetabular fractures have also been described. Sacral insufficiency fractures were first described by Lourie in 1982. Plain radiographs of the pelvis are relatively insensitive. The most common radiographic finding is a vertical sclerotic band in the sacral ala paralleling the SI joint, representing trabecular compression and callous formation.

Less commonly one may see cortical disruption at the superior or inferior margins of the sacrum or directly visualize a fracture line. These are difficult findings to appreciate in the setting of osteoporotic bone and overlying bowel gas. In Grangier’s series, only 25% of patients had typical plain film findings. CT is more sensitive in detecting cortical disruption and the sclerotic margins of the fracture. Axial CT demonstrates the vertical component of the fracture. There is often a horizontal fracture line extending through the sacral body; this may be missed on axial images and will be better identified on coronal CT images. A vacuum phenomenon may also be observed within the fracture.

Technetium bone scan also represents a sensitive means of insufficiency fracture detection. The classic finding is the so-called Honda sign. Increased metabolic activity in bilateral vertical sacral ala fracture lines are bridged by a horizontal line representing a fracture through the sacral body, resulting in a representation of the letter H. In Fuji’s series, 63% of patients with sacral insufficiency fractures exhibited this sign in toto, with 35% showing a variant thereof such as two vertical lines without a crossbar or a single vertical and horizontal line. In this series, the Honda sign taken with its variants had a 96% sensitivity and 92% positive predictive value for sacral insufficiency fracture.

MRI is more sensitive than CT in the early detection of insufficiency fractures; it will reveal marrow edema (low T1, high T2 signal with gadolinium enhancement) in a pattern typical of insufficiency fracture (Honda sign) before sclerosis or a fracture line can be visualized with CT. Imaging in the coronal plane is preferred; fat-saturated or STIR sequences are mandatory. In Grangier’s series, marrow edema was observed in all cases as early as 18 days after symptom onset. Over time, the fracture line will become visible within the zone of marrow edema as a line of diminished signal. Fluid (very high, homogeneous T2 signal) may be detected within insufficiency fractures. The confidence in the diagnosis of sacral insufficiency fracture will be increased by the presence of similar bone lesions in the pubic rami, immediately about the pubic symphysis, and in the para-acetabular region, also typical sites of insufficiency fracture.

**SPONDYLOLYSIS**

Spondylolysis, or isthmic spondylolisthesis, describes a defect in the pars interarticularis, which may be unilateral or bilateral. It is considered a fatigue fracture occurring within a vulnerable pars; the vulnerability may be related to the distribution of ossification centers within the posterior neural arch, not a defect in bone quality. Spondylolysis has a familial predisposition. There is a 2:4:1 male-to-female predominance. The incidence of spondylolysis has been estimated at 7% in the U.S. population. Spondylolysis is frequently asymptomatic, but it is a particular clinical issue in adolescent athletes. A retrospective study of lumbar radiographs in more than 4000 athletes demonstrated a 13.9% rate of spondylolysis with concomitant spondylolisthesis in 47%. Spondylolysis occurs most commonly at the L5 level (67%), followed by the L4 level (15% to 20%), and L3 (1% to 2%). It is unusual in the cervical region, where it most often occurs at the C6 level. Spondylolysis is extremely rare in the infant population but appears to develop in childhood or adolescence, with no significant change in its incidence beyond age 20.

Although considered a fatigue fracture, it is unusual in that there is seldom an effective healing response, and the bony defect is persistent. The pars defect is frequently a synovial-lined pseudoarthrosis. Shipley demonstrated that injection of the facet immediately superior to a pars defect showed communication with the pars defect cavity in 30 of 32 facets, with communication to the next most inferior facet in 20 of 32 facets. The presence of synovial fluid in the defect likely contributes to its diminished capacity to heal.

Radiographic findings of spondylolysis are often evident on lateral plain films where a radiolucent band can be directly visualized across the pars interarticularis, with or without a sclerotic margin; there is no role for oblique radiographs. Spondylolisthesis refers to the anterior translation of the vertebral body bearing the spondylolytic defects in relation to the vertebral body below (Fig. 15.22). The degree of spondylolisthesis is graded from I to V based on the percentage of anterior translation relative to the anterior-posterior dimension of the vertebrae: grade I, 0% to 25%; grade II, 26% to 50%; grade III, 51% to 75%; grade IV, 76% to 100%; and grade V, > 100% (spondylolisthesis). Most cases of spondylolisthesis are of grade I. A trapezoidal appearance of L5 with a dome-shaped superior end plate of S1 can be observed in chronic spondylolysis with spondylolisthesis.

Computed tomography allows direct visualization of the pars defect interposed between the adjacent facet joints on axial images. Sagittal reconstructions make the defect more obvious. Care must be taken to distinguish between a true pars defect and severe facet arthrosis. CT will also help distinguish between a stress response (sclerosis, hypertrophy) in the contralateral pedicle or pars in a unilateral spondylolysis, and an osteoid osteoma. CT allows characterization of the process as a stress response (sclerosis), an incomplete fracture, or a completed fracture. Fuji and colleagues categorized these types as early, progressive, and terminal.

The early stage consists of a narrow fissure with sharp margins; the progressive stage consists of a narrow fissure with less well-defined, rounder margins; and the terminal stage consists of a wide defect with rounded, sclerotic margins. Early stage lesions healed with conservative care, including bracing, more frequently than progressive lesions; no terminal stage lesions healed (see Fig. 15.22).

The defect in the pars interarticularis can be directly visualized on sagittal MRI images. Several ancillary signs have been described on MRI including (1) an increase in the sagittal diameter of the central canal at the level of the pars defect, (2) reactive marrow changes (hypointense T1, hyperintense T2) within the adjacent pedicle, and (3) wedging of the posterior aspect of the associated vertebral body, usually L5. Reactive marrow changes in a vertebral pedicle are not specific for the presence of spondylolysis and may be observed in the presence of adjacent facet arthrosis or synovitis. Hollenberg and colleagues developed an MRI
classification of spondylolysis (Table 15.8). A subsequent study comparing CT staging and MRI findings noted that CT-defined early stage lesions all exhibited T2 hyperintensity in the ipsilateral pedicle; terminal stage lesions never exhibited T2 hyperintensity in the pedicle. Nearly 80% of lesions with T2 hyperintensity in the pedicle healed with conservative care.

Spondylolysis has also been assessed with SPECT/CT, although at the cost of radiation dose to a typically young population. Gregory and colleagues assessed the diagnostic value of combining SPECT with CT in the evaluation of spondylolysis. They described four categories of patients: group A: (+) SPECT and (+) CT findings for spondylolysis; group B: (+) SPECT and (-) CT findings for spondylolysis; group C: (-) SPECT and (+) CT findings for spondylolysis; and group D: (-) SPECT and (-) CT findings for spondylolysis. Group A and B patients were felt to have a healing potential with early fatigue fractures or stress responses; group C patients had terminal lesions without healing potential, and group D patients had other pain generators, often the disk. Although adult spondylolysis is often asymptomatic, there is a tendency to develop significant disk failure at the level of the pars defect, which may result in late progression of the degree of vertebral displacement and neural element compromise resulting from foraminal stenosis, which is well demonstrated on sagittal MRI. Spondylolysis patients may then experience axial pain caused by the inflammatory change about the pars defect, diskogenic pain from the failed disk, and radicular pain from secondary foraminal compromise.

Characterization of pars defects sufficient for therapeutic planning requires assessment of both morphologic and physiologic parameters. A stress response in the pars, or an incomplete fracture, may respond to conservative therapy with healing; completed chronic fractures seldom heal and are often asymptomatic. Persistent symptoms in the face of a chronic completed fracture may reflect secondary phenomena of diskogenic pain or radicular pain from foraminal stenosis. The combined morphologic and physiologic characterization can be performed with SPECT/CT or MRI. The interested reader is referred to a far more complete review by Murthy.

### Figure 15.22 Spondylolisthesis, modified Meyerding classification

Modified Meyerding classification of spondylolisthesis: grade I, 0% to 25%; grade II, 26% to 50%; grade III, 51% to 75%; grade IV, 76% to 100%; grade V, greater than 100% (spondyloptosis [falling off]). (From Murthy NS. Imaging of stress fractures of the spine. Radiol Clin North Am. 2012;50:799-821.)

### SPINE INFECTION

Extradural spinal infections are primarily the result of arterial seeding. In children, the disk and end plate have a rich blood supply; infection occurs initially in the disk itself. In the adult, the disk is avascular; an infection develops in the anterior subchondral vertebral body with secondary spread to the disk, adjacent vertebrae, and subligamentous (deep to the anterior longitudinal ligament) space. Most disk space...
infections involve two adjacent lumbar vertebrae. Spread from contiguous infection or direct inoculation of the disk (surgery, injections, diskography) is much less common.

Pyogenic disk space infection involves men much more commonly than women (2:3:1) in the fifth to seventh decades of life.\textsuperscript{231} Infection is usually unimicrobial, \textit{Staphylococcus aureus} is the most common pathogen, and urinary tract infections are the most common source of seeding.\textsuperscript{232} Clinical symptoms may precede radiographic findings by 1 to 8 weeks. Clinical signs of elevated sedimentation rate, white cell count, and C-reactive protein are usually present. Plain films reveal early rarefaction of anterior subchondral bone, followed by a loss of disk space height (at 1 to 3 weeks) with subsequent destructive changes in the vertebral end plates. Late changes include variable amounts of sclerosis, kyphotic deformity from vertebral collapse, and ankylosis. CT in pyogenic diskitis shows early hypodensity in the disk, moth-eaten destruction of the vertebral end plates, inflammatory changes in paravertebral soft tissues, and epidural mass. Scattered gas formation may be observed as well. Extensive gas formation in the central portion of the disk is typical of noninfectious disk degeneration; the disappearance of such a vacuum disk sign may herald infection.

MRI is the preferred imaging modality for the evaluation of diskitis, with a greater than 90% sensitivity and specificity in disease detection.\textsuperscript{231,232} It also provides critical anatomic information. Early marrow changes are elevated T2 signal (best observed with fat saturation or STIR), diminished T1 signal, and gadolinium enhancement (Fig. 15.23). There is loss of the crisp dark cortical line of the vertebral end plate. Within the disk, the intranuclear cleft is lost and foci of elevated T2 signal and gadolinium enhancement develop. The paravertebral and epidural soft tissues show diffuse enhancement (phlegmon) or frank abscess formation with zones of hypo-enhancement and increased T2 signal where liquid purulent material is present. The imaging differential diagnosis consists of a Modic type I degenerative change, atypical cartilaginous (Schmorl’s) nodes, adjacent metastatic lesions, osteomalacia secondary to osteodystrophy, and pseudoarthroses in patients with ankylosing spondylitis or a Charcot spine. Discrimination from a Modic type I end plate change can be particularly vexing; differential points are presented in Table 15.9. In challenging cases, image-guided biopsy and culture are appropriate.

MRI abnormalities lag behind the clinical syndrome. Imaging may be minimally abnormal early in the disease process and remain quite dramatic even after a gratifying clinical response to antibiotics. In following the short-term efficacy of antibiotic therapy, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and white cell count will be more useful than repeated imaging. Follow-up imaging should be reserved for patients in whom there is a clinical concern for continued infection with central canal compromise. Persistently elevated or increasing ESR or CRP at week 4 of antibiotic therapy predicts treatment failure.\textsuperscript{233}

Nuclear medicine scans using gallium-67 citrate and technitium-99m diphosphonate are complementary in the evaluation for suspected spondylodiscitis. A series by Hadjipavlou and colleagues demonstrated 100% sensitivity, specificity, and accuracy for the combination of gallium and technetium scans when compared with surgical biopsy results.\textsuperscript{234} Gallium may be useful in following resolution of the infection. All nuclear medicine techniques lack anatomic information; they are unable to define the extent of epidural or paraspinal disease or central canal compromise.

Pyogenic epidural abscesses may arise from the contiguous spread of adjacent spondylodiscitis or facet joint infection, but they are most commonly primary, because of the hematogenous dissemination or direct inoculation of the epidural space. \textit{S. aureus} is the most common pathogen; immune compromise, especially diabetes, is common.\textsuperscript{231} Emergent MRI is the imaging modality of choice. This will demonstrate a T1 hypointense, T2 hyperintense epidural process with peripheral or heterogenous enhancement, depending on the physical state of abscess versus phlegmon. The midline ventral epidural septum may be violated; most neoplasms respect this structure. Compression of the dural sac is common; severe compromise with neurologic deficit precipitates emergent decompression. Imaging resolution of an epidural abscess more closely parallels the clinical state than in spondylodiscitis.

Pyogenic facet joint infection is uncommon; it is usually the result of hematogenous dissemination, although direct inoculation caused by invasive procedures is reported. Clinical presentation may resemble spondylodiscitis, although most commonly with lateralizing symptoms; the lumbar spine segment is most frequently affected. Bilateral involvement may occur via the space of Okada.\textsuperscript{130} CT will demonstrate an erosive process centered on the joint with inflammatory change in adjacent multifidus muscle. MRI will demonstrate marrow edema in the articular processes, a joint effusion, and edematous changes in the multifidus; enhancement in the joint with peripheral enhancement about an adjacent paraspinal or epidural abscess or uniform heterogeneous enhancement within a phlegmon may be noted.

Tuberculosis (TB) remains the most common cause of spinal infection worldwide, and it is of increasing incidence in industrialized societies. Clinical symptoms are usually insidious. Whereas 90% to 100% of patients will have back pain, only 50% will have constitutional symptoms or fever. Tuberculous spondylitis (Pott’s disease) arises from hematogenous (arterial) spread of tuberculous bacilli, usually from a pulmonary source. This initially lodges in the anterior subchondral bone. There is early anterior subligamentous extension and then spread to adjacent vertebrae, often multiple, as well as spread across the disk. Neurologic deficit occurs in a moderate number of patients due to epidural extension. Posterior elements tend to be spared. Extensive anterior column destruction with gibbus deformity is characteristic.

Tuberculous spondylitis with diskitis shows disk space narrowing, vertebral osteolysis with collapse, and gibbus deformity on plain films. The thoracolumbar junction is most frequently affected, with less frequent involvement as one ascends the thoracic or descends the lumbar spine.\textsuperscript{231} Plain films may not be abnormal until 2 to 5 months after the onset of infection. Paraspinal soft tissue masses caused by subligamentous spread, particularly with calcification, are characteristic. CT will demonstrate the osteolytic changes of spinal tuberculosis earlier than plain films will. It more readily demonstrates epidural involvement, particularly when...
calcification or bone fragments are visible in the epidural space. Paraspinal involvement is also well demonstrated.

MRI is the primary imaging procedure for the detection of spinal TB. Early changes of tuberculous spondylitis with diskitis are very similar to pyogenic disk space infection, with marrow and disk inflammatory changes consisting of elevated T2 signal, diminished T1 signal, and enhancement. Extensive subligamentous spread of disease suggests TB. Paraspinal abscesses, granulomas, and epidural involvement are common. Epidural involvement may be observed in 60% to 80% of cases.\(^{231}\)

Figure 15.23  Stress fractures. Spondylolysis at L5 is visible on flexion (A) and extension (B) radiographs. Although there is no translation of L5 on S1, the degree of rotation (12 degrees) qualifies this as unstable. In unilateral spondylolysis, the contralateral pars often shows hypertrophy and sclerosis (C). CT can be used to stage pars fractures as early stage (D) with a narrow, sharply marginated fissure; progressive stage (E) with a narrow fissure having slightly rounded margins; and terminal stage (F) with a wide fissure with rounded margins and sclerosis. Typical sacral stress fracture (arrows) demonstrates a low signal fracture line on a coronal T1 image (G), a linear zone of T2 hyperintensity on a STIR image (H), whereas CT demonstrates a linear zone of sclerosis (I). The integrity of the neural foramina is better defined on CT. (From Murthy NS. Imaging of stress fractures of the spine. Radiol Clin North Am. 2012;50:799-821.)
tissue sampling. Caliber bone cutting needles can provide minimally invasive Image-guided percutaneous aspiration/biopsy with large therapy require tissue sampling for histology and culture. The MRI findings remain unspecific, however, and accurate diagnosis and staging before destructive changes have evolved. The MRI findings may suggest tuberculosis, allowing this to be suggested as a likely diagnosis.

Noninfectious inflammatory disease of the spine includes rheumatoid arthritis (RA) and the seronegative spondyloarthropathies (SpA), of which ankylosing spondylitis is the prototype. These diverse entities have spine involvement in common and may present with axial spine pain.

INFLAMMATORY SPONDYLOARTHROPATHY

Rheumatoid arthritis is most common in the cervical spine, sometimes referred to as the fifth limb in RA patients. Symptoms and signs of cervical spine involvement are present in 60% to 80% of RA patients. The most frequent site of involvement is the atlantoaxial articulation. Inflammatory pannus may be seen on MRI as a low T1, high T2 signal-enhancing mass posterior to the dens. This may cause compression of the cervical medullary junction. The inflammatory change may destroy the transverse and alar ligaments, resulting in atlantoaxial instability in 20% to 25% of RA patients. A distance of greater than 4 mm between the posterior arch of C1 and the cortical surface of the dens on radiographs is abnormal and is most evident in flexion views. The destruction of supporting structures at the cranio cervical junction may also result in cranial settling, a vertical migration of the dens into the foramen magnum, with possible compression of the C1 and C2 cranial nerves, the medulla, and vertebral arteries.

The cervical spine below the C1-2 articulations demonstrates erosive arthritis in the uncovertebral and facet joints in RA patients. The inflammatory change can be demonstrated on MRI as increased T2 signal on STIR sequences and gadolinium enhancement on fat-saturated T1 sequences. This results in multilevel instability, with anterior subluxation of successive vertebral bodies in flexion, the so-called step ladder cervical spine, noted in up to 30% of RA patients. Disk space narrowing and end plate sclerosis are common, but this may be a secondary phenomenon to the posterior element instability.

Involvement of the thoracic and lumbar spine in RA is uncommon. Synovitis and erosive change may be present in the facet and costovertebral joints but is inconsistent and not well demonstrated. Discovertebral changes may be present.

| Table 15.9 Differentiating Spondylodiscitis from Modic Type I End Plate Changes |
|-----------------------------------------------|-----------------------------------------------|-----------------------------------------------|
| Favoring Spondylodiscitis | Favoring Modic Type I End Plate Changes | Pitfall/Comments |
| Disk Space Signal | T2 hyperintensity | T2 hypointensity or lack of T2 hyperintensity | Severely degenerated disks rarely can be T2 hyperintense (even fluid signal) Rarely absent in infection; rarely present in Modic I |
| Disk Space Enhancement | Present | Absent | Gas may be present early in infection, in rare gas-forming bacterial infection, or in rare fistulas with the gastrointestinal tract |
| Disk Space Vacuum Sign | Absent, or only scattered | Often present; large amount of confluent gas on radiographs virtually exclude infection | Modic I can have end plate irregularity; CT is very useful here |
| Vertebral Body End Plates | End plate destruction | Lack of end plate destruction | Peripherally enhancing disk herniation can be confused for abscesses Both spondylodiscitis and Modic I are often along entire end plate |
| Paraspinal, Epidural Spaces | Inflammation or abscess | Absent | Fever is only variably present in spondylodiscitis; inflammatory markers are nonspecific |
| Location | Anteriorly eccentric | Laterally eccentric: at point of biomechanical stress (e.g., inner aspect of curve) | If remote comparison images are available, even Modic I can show significant progression |
| Fever, Elevated Inflammatory Markers | Present | Absent | |
| Short-Term Follow-up | Progression | Stability | |

Fever, raised erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are generally elevated in patients with RA. The ESR typically is increased before the CRP, and both tests are usually elevated in patients with active arthritis. The ESR often is a better indicator of acute inflammation than CRP. A normal ESR and CRP in a patient with inflammatory symptoms should suggest a differential diagnosis, such as an infection. Short-term follow-up is not practical, since it is not possible to prove that a patient will not progress.
but it is again unclear if these are primary inflammatory lesions or a response to facet instability. The sacroiliac joints may show inflammatory change, but with much less frequency and severity than in ankylosing spondylitis patients.

The seronegative spondyloarthropathies are a group of rheumatoid factor negative inflammatory disease processes affecting the spine and sacroiliac joints, with a unique predilection for entheses. Historically these have included ankylosing spondylitis, psoriatic arthritis, reactive arthritis (formerly known as Reiter’s syndrome), and the arthritis associated with inflammatory bowel disease. The categorization of these diseases has evolved, most recently in 2009 with the designation of axial spondylarthropathy (formerly known as ankylosing spondylitis) as a unique disease entity with axial dominance. Axial spondylarthropathy requires active sacroiliitis on MRI plus one or more features of spondylarthropathy, or human leukocyte antigen B27 (HLA-B27) positivity with two or more features of spondylarthropathy. This discussion only encompasses the axial imaging features of the classically defined processes (Fig. 15.24).

MRI is the necessary imaging modality for the assessment of disease activity in the SI joints and spine articulations. MRI or CT can demonstrate the aftermath of disease: joint space narrowing, subchondral erosions, reactive sclerosis, or periarticular fat deposition (a Modic II analog); only MRI can assess active inflammation with T2 hyperintensity (STIR or fat-saturated images) and gadolinium enhancement on fat-saturated T1 images.

Figure 15.24 Spondylodiscitis. A lateral radiograph (A) demonstrates early pyogenic spondylodiscitis manifest as subtle destruction of the anterior inferior aspect of the L3 vertebrae. In another patient, a sagittal CT reconstruction (B), sagittal T1-unenhanced (C) and enhanced (D) and axial T1-enhanced MRI images (E) of a patient with L2-3 pyogenic diskitis. Note loss of disk space height, end plate destruction, low T1 signal and extensive vertebral, epidural, and paraspinal enhancement.

Sagittal T2-weighted MRI (F) of a back pain patient without myelopathy demonstrates vertebral destruction with kyphotic deformity; this is tuberculous spondylodiscitis. Coronal T1-enhanced MRI (G) in the same patient demonstrates the extensive paraspinal disease typical of Pott’s disease. A sagittal T2-weighted MRI (H) in another patient with tuberculous spondylodiscitis; note the multiple vertebral lesions with sparing of the disks. This can be confused with metastatic disease. Tissue sampling is essential. (From Maus T. Imaging the back pain patient. Phys Med Rehabil Clin N Am. 2010;21:725-766.)
Ankylosing spondylitis (AS) is the prototypical seronegative spondyloarthropathy; active disease in the SI joints by MRI criteria is integral to its diagnosis. AS has a prevalence of up to 0.1% in the general population; a very high percentage will be HLA B27 positive. Males dominate by 4:1. The disease involves synovial and cartilaginous joints and entheses (ligament and tendon insertions on bone) with a strong predilection for the axial skeleton. The most common presentation is low back pain with inflammatory features (Calin criteria, 4 out of 5 of insidious onset, age < 40, 3 months persistence, morning stiffness, and pain improved by exercise). Radiating pain mimicking sciatica may be observed in up to 50% of patients.

Imaging findings in AS include sacroiliitis, ultimately bilaterally symmetric and multiple manifestations of spondylitis (see Fig. 15.24). Sacroiliitis is the uniform initial imaging finding. Early plain film findings of sacroiliitis are blurring of the subchondral cortex by small erosions, predominantly on the iliac side of the joint. As the erosions coalesce, the joint space appears widened and ill defined; sclerotic reaction develops in the trabecular bone about both sides of the joint. Over time the joint undergoes ankylosis via direct bony bridging; the joint space is no longer visible and the sclerosis resolves. MRI can detect inflammation in the SI joint in symptomatic patients with normal plain films. Inflammation can be reliably identified with low interobserver variability as high T2 signal on STIR sequences or gadolinium enhancement on fat-saturated T1 images. In patients with recent onset axial low back pain with inflammatory clinical characteristics, SI joint inflammation may be detected by MRI in one third of patients and structural changes in one sixth of patients. Inflammation is initially observed in the iliac side of the joint at its caudal and dorsal aspects, and in the adjacent dorsal entheses.

Spine findings in AS are present in 50% of patients and include osteitis, syndesmophyte formation, discovertebral lesions, and inflammation leading to ankylosis of facet and costovertebral joints. Osteitis is observed at the anterior margins of the discovertebral junction, termed the Romanus lesion. On plain films, sclerosis at these sites leads to increased density of the anterior corners of the vertebra, termed the shiny corners sign. Remodeling of the anterior margin of the vertebral body as a result of osteitis straightens the normally concave anterior vertebral margin, referred to as “squaring” of the vertebra. These findings are most evident in the lumbar region. MRI is more sensitive to the early detection of osteitis, recognized as diminished T1 and increased T2 signal and enhancement at the anterior vertebral corners. Osteitis at the margins of the discovertebral junctions leads to reactive bone formation in the outer annulus fibrosis, which ultimately bridges the margins of adjacent vertebrae. These vertically oriented bony struts are syndesmophytes. They are distinguished from osteophytes by their vertical orientation and gracile nature; osteophytes are oriented in the horizontal plane and are bulkier. Syndesmophytes are most common at the anterior and lateral aspects of the vertebral body; when long standing, ossification may involve the anterior longitudinal ligament.

Erosions at the discovertebral junction are termed Anderson lesions; this inflammatory destruction of the vertebral end plate with intravertebral disk displacement can progress to pseudarthrosis. End plate destruction is visible on plain films; MRI demonstrates structural and inflammatory change. The inflammatory change will undergo evolution reminiscent of the progression from Modic type 1 to Modic type 2. Over time there is sclerosis and transdiskal ossification leading to ankylosis. The facet and costovertebral joints show similar findings, with initial periarticular erosions followed by sclerosis and ankylosis. Enthesitis of the posterior interspinous and supraspinous ligament attachments ultimately leads to ossification of these structures, visible as a vertical midline bony band on frontal radiographs, the so-called dagger sign. The inflammatory spinal lesions are most common in the mid-thoracic spine (T7-T8) and in the midlumbar region (L2-3).

AS may also produce changes at the atlanto-axial articulation. Synovitis may result in erosive changes in the dens, although the extent of inflammatory change seldom reaches that noted in RA. Atlanto-axial subluxation may be present. The extensive ankylosis observed in patients with longstanding AS leads to flattening of the lumbar lordosis and exaggeration of the thoracic kyphosis. The rigidity places these patients at risk for catastrophic fracture-dislocations with modest trauma, most commonly with a hyperextension mechanism. The cervical spine is most frequently involved; neurologic deficits are common. Plain film evaluation is difficult because of the osteopenia typical of these patients; the three-column nature of these fractures is best appreciated with CT or MRI. The threshold for use of advanced imaging in the AS patient with trauma should be low. Three-column fractures that do not cause acute neurologic injury or go undetected may be a cause of chronic focal pain as a pseudarthrosis. MRI will show a linear zone of inflammatory change, often through a disk space with extension through the posterior elements. The cortical disruption may be best appreciated on CT. Finally, some AS patients will have findings of dural ectasia (see Fig. 15.24). The thecal sac will be abnormally capacious with diverticular-like outpouchings; there is associated bony erosion in the posterior elements, medial margins of the pedicles, and the posterior vertebral body. These patients may present with a cauda equina syndrome, perhaps related to arachnoiditis.

Psoriatic arthritis (PA) is far less common than AS; it affects 7% of patients with cutaneous psoriasis. Approximately 10% to 25% of patients with moderate to severe skin disease will have abnormal SI joint radiographs. Spondylitis is present in a roughly similar proportion but may or may not coexist with sacroiliitis. Males and females are equally affected. The sacroiliitis is usually bilateral but asymmetric, with a lesser tendency to progress to bony ankylosis. Erosions and foci of reactive sclerosis tend to be larger and more discrete than in AS. The spondylitis in psoriatic arthritis is characterized by asymmetric, coarse paravertebral ossification more resembling osteophytes than syndesmophytes. Vertebral squaring and shiny corners are absent. Facet involvement is infrequent.

Reactive spondylarthritis describes an inflammatory arthropathy, preferentially affecting the heel and large peripheral joints. Sacroiliitis is very common, affecting up to 45% of patients. It is more commonly unilateral or asymmetric than in AS; ankylosis is rare. Spine involvement may be identical to that of PA but more common; the lumbar spine is involved in 30% of RS patients. In the setting of a triggering infection (often chlamydia) and the triad of urethritis, uveitis, and arthritis, the term Reiter’s syndrome may be applied.
Enteropathic arthritis may also be observed in association with ulcerative colitis or Crohn’s disease. The initial presentation of back pain may precede symptoms of gastrointestinal disease. The spondylitis and sacroiliitis noted in association with these conditions are indistinguishable from classic ankylosing spondylitis. Sacroiliitis is usually bilaterally symmetric progressing to ankylosis; spondylitic findings of vertebral squaring, discovertebral lesions, syndesmophytes, and involvement of the facet joints are typical.

**SPINE NEOPLASM**

Spinal neoplasms are classified by the anatomic compartment from which they arise: extradural, intradural-extramedullary, or intramedullary. Extradural neoplasms arise from the vertebral bodies, within the paravertebral soft tissues, or within the epidural space. These include metastatic lesions, hematologic malignancies, and primary osseous or cartilaginous tumors. Intradural-extramedullary lesions arise within the dural tube but are extrinsic to the spinal cord itself. Lesions in this category include meningiomas, Schwannomas, neurofibromas, and leptomeningeal metastatic disease. Intradural-vascular lesions are those that arise primarily from the spinal cord or filum terminale. Astrocytomas, ependymomas, and hemangioblastomas make up the majority of these lesions.

Extradural neoplasms are common. MRI provides the best combination of lesion detection, morphologic characterization, and assessment of neural compromise. Nuclear medicine techniques such as technetium bone scan and PET scanning provide high sensitivity to lesion detection and excellent body wide assessment of tumor burden (Fig. 15.25). Nuclear medicine studies will not provide anatomic information regarding compression of neural elements. CT is less sensitive than MRI in lesion detection; plain films are far less sensitive.

Extradural neoplasms may narrow the subarachnoid space (cerebrospinal fluid) as they extrinsically intrude into the spinal canal. They exhibit diminished T1 signal, elevated T2 signal, and gadolinium enhancement on MRI. The unenhanced T1 image is the mainstay of lesion detection; normal adult marrow should be brighter than the intervertebral disks. Fat-saturated T2-weighted images and STIR images provide high sensitivity to lesion detection. Fat-saturated postgadolinium images will also display extradural neoplasm with high sensitivity. On axial images, compression of the thecal sac or exiting nerve roots can be directly displayed. CT and plain films play a role in characterizing primary bone and cartilaginous tumors including malignant lesions such as osteosarcoma, chondrosarcoma, chordoma, and the benign tumors, including hemangioma, osteoid osteoma, giant cell tumor, and aneurysmal bone cyst.

Metastases are the most common extradural spine tumor, and the spinal column is the most common site of osseous metastases. An overwhelming majority of spine metastases are due to prostate, lung, and breast cancer. The thoracic spine is most commonly involved (70%), followed by the lumbar and cervical segments. Involvement of the vertebral body is most common (85%), with less frequent spread to the paravertebral tissues or epidural space. The disks, dura, and the anterior longitudinal ligament are resistant to invasion by metastatic tumor; the posterior longitudinal ligament is more readily involved, as it is penetrated by numerous venous channels. Vertebral body metastases may be blastic (bone forming), lytic (destructive), or mixed. Blastic lesions are observed as ill-defined areas of increased density on plain films or CT; on MRI, blastic lesions will have low T1 and T2 signal with enhancement. Common primary tumors are prostate, carcinoid, or bladder cancer. Lytic metastases show destruction on plain films and CT; and low T1 and variable T2 signal with enhancement on MRI. Lytic metastases are most commonly produced by breast, lung, renal, and thyroid neoplasms. Mixed lytic and blastic lesions are visible in lung, breast, cervical, and ovarian primaries.

Hemangiomas are the most common spine tumor, present in up to 10% to 12% of adults. They are frequently multiple. Typical hemangiomas are benign and of no clinical significance; they are identified by their fatty content on MRI (high T1 and T2 signal) and a corduroy appearance on plain films or CT. This is due to sparse, thickened trabeculae surrounded by fat; on axial images this results in a polka dot appearance.

Osteoid osteomas occur in patients under the age of 30, and they typically present with pain, often nocturnal. Aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) can usually relieve pain. The lesion consists of a small nidus, less than 1.5 cm in diameter, surrounded by a larger zone of sclerotic reaction or soft tissue inflammation, visible on plain films or CT. The nidus is intensely enhancing on CT, MRI, or bone scan. Ten percent of osteoid osteomas occur in the spine, almost exclusively in the posterior neural arch. The lumbar spine is involved in 59% of spinal osteoid osteomas, the cervical region in 22%, and the thoracic spine in 12%. Lesions larger than 1.5 cm are considered osteoblastomas.

Myloma is the most common malignant primary tumor of bone; it presents with bone pain in 75% of patients. It is often widespread at presentation. Its imaging appearance can range from discrete destructive lesions to diffuse loss of bone density indistinguishable from osteoporosis on plain films. CT is better able to resolve the discrete destructive lesions in trabecular or cortical bone. The MRI appearance is variable, with diminished T1 marrow signal and gadolinium enhancement in a multifocal or diffuse pattern. Compression fractures are common and they may be indistinguishable from benign osteoporotic fractures. Single focal lesions (plasmacytomas) are expansile and lytic on imaging.

Leukemia may present with spine pain in the setting of diffuse marrow involvement and associated compression fractures. The most common imaging finding is that of diffuse marrow replacement, with osteopenia on plain films and CT, and generalized loss of the normal T1 marrow signal. Normal marrow should always be brighter than disk signal on T1 images. Focal extra-osseous soft tissue masses of leukemic tissue may be present and are termed chloromas.

Lymphoma is the great mimic. It can present in the spine as vertebral lesions indistinguishable from metastases, as an epidural soft tissue mass without bone involvement, as a diffuse leptomeningeal process, and as a primary intramedullary lesion.

Intradural-extramedullary neoplasms are situated within the dural sac, widening the subarachnoid space as they displace the cord or cauda equina. Meningiomas typically exhibit a broad base against the dural surface and enhance uniformly. Schwannomas and neurofibromas are indistinguishable on imaging. They may enhance uniformly
Figure 15.25  Spondyloarthopathy. Changes of sacroiliitis are detectable on radiographs (A) as irregularity, erosions, and sclerosis, dominant on the iliac side of the joint. In the end stage of ankylosing spondylitis (AS), the sacroiliac joints are fused and the sclerosis resolves (B); this radiograph also depicts the dagger sign, as the fused spinous processes make a continuous sclerotic structure in the midline. CT (C) is more sensitive in the detection of erosions and early sclerotic reaction in AS; this structural change may simply reflect prior disease. Only MRI can detect disease activity (D) as demonstrated by the T2 hyperintensity in and about both SI joints in this AS patient. The gracile vertical syndesmophytes bridging lumbar vertebrae and the fused posterior elements are well seen on CT (E); the spine in AS is rendered vulnerable to three-column unstable fractures with modest trauma (F). These situations deserve CT imaging. The spondyloarthopathy of inflammatory bowel disease may present as back pain (T2 sagittal [G] and enhanced T1 fat-saturated sagittal [H]) with evidence of multifocal inflammatory spondyloarthopathy. The differential diagnosis here is multilevel spondylodiscitis, especially Pott's disease (tuberculosis). Changes of sacroiliitis in inflammatory bowel disease (I) may be indistinguishable from AS. Asymmetric sacroiliitis (T1-enhanced, fat-saturated coronal MRI [J]) is typical of reactive spondylarthritis (formerly Reiter's syndrome).
or show central zones of cystic degeneration. The classic “dumb-bell” neurofibroma may issue through and widen a neural foramen. They may also occur entirely within the dural sac or in a paravertebral location. Leptomeningeal metastatic disease is most typically seen as enhancement on the surface of the cord or within the roots of the cauda equina. In some cases more discrete small masses may be observed within the cauda equina. CSF cytology remains more sensitive than MRI in the detection of leptomeningeal metastatic disease.

Intramedullary neoplasms are rare entities, but they may present with pain or dysfunction that can mimic degenerative disease. Ependymomas arise from the ependymal cells lining the central canal of the cord. Ependymomas are the most common intramedullary tumor in adults; they are most frequently located in the conus medullaris and filum terminale (myxopapillary ependymoma). Because of their slow growth, they may cause bony erosion and scalloped enlargement of the central canal. MRI demonstrates an enlarged cord if the filum terminale with an elevated T2 signal and heterogenous enhancement. Small cysts or hemorrhage are frequent. Astrocytomas are typically low-grade neoplasms, more commonly noted in young patients and in the cervical region. They typically extend over multiple vertebral segments within the cord with poorly defined margins. The cord is enlarged with heterogenous enhancement. The entire cross section of the cord is typically involved. Considerable edema within the white matter of the cord extends cephalad and caudal to the enhancing neoplasm itself. Peritumoral cysts may be present. Hemangioblastomas are rare lesions that typically occur in the cervical and thoracic spine. An intensely enhancing vascular nodule adjacent to the pial surface, often associated with an intramedullary cyst, is typical. About one third of patients with hemangioblastomas will have Von Hippel Lindau syndrome.

**SPINAL DURAL ARTERIOVENOUS FISTULA (AVF)**

Spinal dural AVFs are the most common form of vascular malformation involving the spine. This lesion merits description in that it may present with pain and progressive neurologic deficit, mimicking neurogenic intermittent claudication; it frequently remains undiagnosed for prolonged periods. In Atkinson’s series, the mean delay from symptom onset to diagnosis was 23 months. Patients are frequently subjected to misdirected interventions, including decompressive surgery. When diagnosed, it is treatable with arrest of the progressive neurologic deficit.

Spinal dural AVFs are an acquired lesion, with a fistulous communication within the dura of a root sleeve and intrathecal venous drainage to the venous plexus surrounding the cord. This results in venous hypertension within the cord and ultimately cord dysfunction. The fistula is most commonly in the low thoracic or lumbar spine. It is a lesion of elderly males. Gilbertson’s series had a mean age of 62, with a range from 37 to 81; Atkinson’s series reported a 4:1 male predominance. Pain was a reported symptom in 53% of patients; many of these patients described a burning, dysesthetic pain in the lower extremities; 15% had low back pain when erect, which worsened with use of the lower extremities. This is typically accompanied by a slowly progressive or stepwise worsening myelopathy, manifest as lower extremity fatigue and weakness. Atkinson’s series reported that 69% of patients had upper and lower motor neuron signs; 30% had only lower motor neuron signs.

Imaging findings of dural AVFs have been well described. On CT myelography, abnormally prominent tortuous vessels are present in 100% of cases; this may give the cauda equina a beaded appearance. On MRI, there will be T2 hyperintensity in the cord in nearly 100% of cases (Fig. 15.26). This typically extends over multiple vertebral segments and may be accompanied by cord enlargement in 45% of cases. There may be patchy cord enhancement; these findings may raise a concern for tumor. A differentiating finding is the presence of prominent flow voids or intravascular enhancement caused by the dilated veins, particularly on the dorsal surface of the cord. The T2 hyperintensity in the cord usually involves the low thoracic cord and conus; this does not predict the site of the fistula. Magnetic resonance angiography (MRA) is useful in predicting the site of the fistula (Fig. 15.27) and reducing the scope of spinal angiography, which provides the definitive diagnosis. The fistula may be disconnected surgically or by an endovascular approach.

The goal of diagnosis and therapy is primarily to arrest the progression of the neurologic deficit and possibly improve the current disability. After successful occlusion of the fistula, either surgically or by endovascular embolic techniques, gait improvement was noted in 67% to 80% of patients. Bowel/bladder dysfunction or pain is relieved in only a minority of patients. Worsening of motor symptoms should prompt an imaging investigation for recanalization of the fistula. After successful fistula occlusion, cord enlargement, enhancement, and T2 hyperintensity and the prominent veins about the conus will slowly resolve; T2 hyperintensity and enhancement may persist for up to a year.

**CONCLUSION**

As a synopsis of the imaging assessment of the patient with spine or limb pain, this chapter has ranged widely over large swaths of pathology and imaging technology. There are enduring themes. The primary role of imaging is to detect systemic disease causal of the patient’s pain or neurologic dysfunction; such disease is uncommon. Imaging is currently overutilized to the detriment of patients and society. It has no value in the initial presentation of the patient in the absence of red flag features suggesting systemic disease. The decision to begin imaging should be a reasoned one, considering benefits of improved outcomes versus real risks and harms. The ACR and the ACP have promulgated evidence-based guidelines for imaging use; they should be respected. When imaging occurs, it must be done with a full appreciation of its inherent specificity and sensitivity faults. There is a high prevalence of asymptomatic, age-related change evident on all types of spine imaging; loss of T2 signal in the disk nucleus, anterior and lateral vertebral osteophytes, disk protrusions, and facet and sacroiliac joint arthrosis do not correlate with pain. Imaging performed without axial load and physiologic posture may be insensitive to dynamic lesions.
Figure 15.26 Spine neoplasm. Sagittal T2 (A) and T1 (B) images show a lesion in the L2 vertebral body characterized by increased signal intensity on both sequences, typical of hemangioma, the most common benign spinal extradural neoplasm. A CT image in another patient (C) demonstrates the classic CT features of hemangioma: thickened trabeculae surrounding increased marrow fat, resulting in a polka dot appearance. Blastic metastases (D) have increased bone density; CT is more sensitive than radiographs (E), particularly in the detection of lytic metastases (F). Myeloma can be challenging to detect on radiographs, mimicking osteoporosis (G); MRI in the same patient (H) identifies the myriad of tiny destructive lesions. The MRI T1 sagittal sequence (I) typically reveals metastatic disease as focal hypointense lesions, as in this patient with prostate cancer, as the bright signal of normal marrow fat is replaced. When marrow replacement is diffuse, this can be difficult to detect. Normal marrow should always be brighter than adjacent disks. Note that normal marrow in (J) is completely replaced 2 years later by leukemia (K) when this patient presented with back pain. Osteoid osteoma is a posterior element benign neoplasm causal of pain, often nocturnal and relieved by salicylates. It is visible as a small nidus (arrow in [L]) with surrounding sclerotic reaction (M). Leptomeningeal metastases or lymphoma may be imaged as diffuse enhancing tissue coating the cord and cauda equina (N).
Structural alterations detected by imaging are of less significance than physiologic parameters of edema, hyperemia, disruption of blood-nerve barrier, or accelerated metabolism noted with T2 hyperintensity (STIR or fat-saturated images), gadolinium enhancement, or nuclear medicine techniques. Always treat the patient, not the images.

**KEY POINTS**

- The primary role of imaging is to identify systemic disease; no imaging is indicated in the acute presentation of back or limb pain without “red flag” features.
- All spine imaging has a significant specificity fault: a high prevalence of asymptomatic age-related findings, including disk “degeneration” and facet arthrosis.
- Spine imaging performed without physiologic positioning and axial load may be insensitive to dynamic lesions.
- Imaging correlates poorly with clinical presentation and course.
- Meticulous enumeration of spine segmentation from the skull base caudally is necessary to avoid wrong segment procedures.
- Magnetic resonance imaging (MRI) findings can reasonably predict positive lumbar diskography; the high intensity zone and significant expression of Modic end plate change have high specificity but low sensitivity.
- Imaging cannot identify cervical diskogenic pain.
- Findings of structural arthrosis of the facet or sacroiliac joints (osteofytes, joint space narrowing, sclerosis) have no relationship to pain; physiologic findings (positive bone scan, MRI T2 hyperintensity) may predict pain but have not been tested against an appropriate reference standard.

**KEY POINTS—cont’d**

- Radicular pain requires both neural compression and an inflammatory response; standard imaging detects only the neural compression.
- There is no relationship among the size, type, or change in disk herniations over time and patient outcomes.
- The imaging natural history of disk herniation is resolution.
- Neurogenic intermittent claudication requires compression at multiple segmental levels or in multiple compartments (central, lateral recess, foraminal) for clinical expression.
- MRI signal changes in the cervical cord can provide prognostic guidance for decompression in the cervical spondylotic myelopathy patient.

Psychological and Behavioral Assessment

Elizabeth Seng | Robert D. Kerns | Alicia Heapy

Chronic pain presents two broad challenges to proper assessment: the inherently subjective nature of pain complaints and the wide-ranging influence of chronic pain on patients’ functioning. These challenges necessitate a systematic approach that involves standardized assessment of multiple domains of functioning through the use of several assessment techniques, including questionnaires, behavioral observation, psychophysiological measurement, diary data, and reports of significant others. This chapter begins with a brief discussion of the clinical goals of psychological and behavioral assessment of patients with persistent pain, provides a rationale and context for the use of psychological assessment in the practice of pain management, articulates recommendations for the core domains of assessment, and provides an overview of the psychological assessment process. The remainder of the chapter provides specific information about some of the most commonly used psychological and behavioral assessment strategies for general use across chronic pain conditions. Disease-specific measures may also be of interest to clinicians but are not specifically covered in this chapter. Examples include the Oswestry Disability Questionnaire\(^1\) (lower back pain), Western Ontario and McMaster Universities Osteoarthritis Index\(^2\) (osteoarthritis), and the Neuropathic Pain Scale (neuropathic pain).\(^3\)

**CLINICAL OBJECTIVES**

Psychological and behavioral assessment of pain serves several clinical goals. First, data gathered in the assessment process provide important information about a patient’s pain experiences, pain treatment history, current and past emotional and physical functioning, and beliefs about pain. Thorough assessment of the multidimensional nature of a patient’s pain experiences not only informs clinicians’ treatment planning by identifying problems and intervention targets but also reinforces the multidimensional nature of pain to the patient, which may enhance engagement in future treatment modalities. Second, assessment allows the clinician to identify a patient’s strengths and weaknesses and the factors that contribute to the development and maintenance of problems in physical, social, and emotional functioning. This information can direct selection of the treatment modality most likely to correspond to the patient’s strengths and the intervention targets most related to the patient’s specific functional deficits. Third, assessment allows the clinician to identify comorbid psychiatric or behavioral conditions that may interfere with pain coping and overall adjustment. Fourth, assessment can determine whether the patient is psychologically appropriate and likely to benefit from surgical or invasive procedure if medically indicated. Finally, thorough assessment of a patient’s pain complaint and functioning at baseline provides an important benchmark against which the efficacy of future treatments can be measured. Assessment should not stop after the initial visit but should be ongoing throughout the treatment process. This allows identification of new problems, quantifies progress across domains, and facilitates refinement or revision of treatment if necessary. Post-treatment assessment is imperative to evaluate the overall success of the treatment, as well as the differential success of the treatment across various domains of function such as pain intensity and social, emotional, and physical functioning.

**USE OF PSYCHOLOGICAL AND BEHAVIORAL ASSESSMENT IN THE PRACTICE OF PAIN MANAGEMENT**

Multidimensional psychological and behavioral assessment of a patient with pain can assist a multidisciplinary pain team or treating clinician in several ways. Multidimensional assessment serves as a foundation for planning treatment and subsequent evaluation of treatment outcomes. Psychological and behavioral assessment may also reveal the need for adjunctive psychological treatment of preexisting or emerging psychosocial difficulties that may interfere with medical treatment of the patient’s painful condition. Psychological assessment can provide information about the patient’s motivation and readiness to engage in treatment, as well as treatment preferences. Finally, psychological assessment can provide data about a patient’s suitability for surgical or other invasive procedures under consideration.

When making a request for a psychological and behavioral assessment it is necessary to explicitly state the reasons for the request or pose a question to be answered about the patient or the patient’s treatment. It is helpful for the psychologist or behavioral specialist to understand the specific question that the clinician or team is trying to answer about a patient to perform a thorough evaluation and provide meaningful feedback. Although any psychological or behavioral assessment should be multidimensional and include all relevant domains of function, the specific measures used and the areas of most intense focus differ depending on the consultation question.
OVERVIEW OF THE PSYCHOLOGICAL AND BEHAVIORAL ASSESSMENT PROCESS

Ideally, psychological and behavioral assessment of a patient with chronic pain should follow an approach in which hypotheses are generated and tested. The assessment should begin broadly; as problems are identified, the clinician can hypothesize contributing and maintaining mechanisms. The assessment process will be increasingly focused and behaviorally oriented as the hypothesized mechanisms are investigated. Generally, the assessment process begins with a standardized interview that assesses the pain complaint, as well as the patient’s physical, emotional, social, and occupational functioning. This allows assessment of the patient’s past and present level of functioning and the temporal association of any changes in functioning to the pain complaint. In addition to the information gained in the interview, questionnaires, diaries, behavioral observations, reports by significant others, and medical record information may be used as adjunctive sources of information. Use of multiple adjunctive measures helps avoid the biases or error associated with reliance on a single assessment strategy. Hypotheses about the factors that initiated and maintain problems in adjustment and functioning are generated and refined throughout the assessment process. Ultimately, the validity of hypotheses is tested by examining the patient’s response to treatment. For example, anxiety and fear of pain have been shown to contribute to unfavorable outcomes in persons with chronic pain complaints. Significant functional disability can be associated with fear of pain and further injury, such as behavioral avoidance, muscle deconditioning as a result of reduced activity, muscle hyperreactivity in response to stress, negative and distorted cognitions about the adverse effects of activity, and psychological distress secondary to restricted access to pleasant and rewarding activities. Thus, when an initial interview provides evidence of a significant decline in physical functioning and the presence of anxiety, the process just described becomes a reasonable hypothesis and avenue for more targeted assessment through the use of specific questionnaires, diaries, or reports by significant others. Ultimately, the assessment process should result in a model that describes the patient’s specific pain experience; explicate how that patient’s beliefs, experiences, strengths, and weaknesses have resulted in the current level of functioning across domains; and provide an individualized treatment plan that uses these hypotheses to target specific factors for intervention.

DOMAINS OF FUNCTIONING

The multidimensional nature of chronic pain necessitates a broad assessment of multiple domains of functioning to provide a valid snapshot of the patient’s unique pain experience and meaningfully guide intervention strategies. A useful guide for the assessment process is the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) group consensus statement regarding the core outcome domains that should be assessed, as well as recommended instruments for measuring these domains, when evaluating the efficacy of a pain treatment. These recommendations, though originally generated to aid researchers in increasing comparability across randomized controlled studies of pain treatments, can be useful to the clinician in guiding assessment. The IMMPACT group, which consists of recognized experts drawn from academia, government agencies, and the pharmaceutical industry, recommends assessing the following chronic pain domains: pain, physical functioning, emotional functioning, patient ratings of improvement and satisfaction with treatment, treatment-related symptoms and adverse events, and patient disposition. Additionally, through literature review and expert consensus the group has provided recommendations regarding specific assessment instruments within each domain that are applicable across a diverse range of pain complaints. Most recently, this same group has provided recommendations for the future development of patient-oriented outcome measures that may provide more sensitive and efficient assessment of the key outcome domains relevant to a comprehensive assessment of patients with pain. To date, however, there are no prospective data to support the routine application of such measures in clinical care settings.

OVERVIEW OF ASSESSMENT STRATEGIES

Multiple assessment strategies such as interviews, standardized questionnaires, diaries, behavioral observation, psychophysiologic evaluation, and assessment of family members and significant others are commonly used to investigate and quantify the pain experience and concomitant physical and emotional functioning. The use of multiple, standardized assessment measures is encouraged to obtain comprehensive, valid, and reliable information.

A well-conducted clinical interview can be a rich source of information on a patient’s pain and pain treatment history, as well as the resulting physical, emotional, behavioral, and cognitive responses. The interview also provides an opportunity for clinicians to interact with the patient, establish rapport, and develop an impression of the patient’s receptivity to rehabilitation and treatment efforts. Interviews may be standardized or unstandardized. Even when conducting an unstandardized interview it is useful to systematically investigate a prespecified set of domains (Box 16.1 is an example of an interview structure used in the author’s [RK] comprehensive pain management clinic).

Questionnaires and inventories provide opportunities for focused assessment of specific domains of functioning and quantifying patient responses. Because published questionnaires have typically met standards for reliability and validity, greater confidence can be placed in the information provided by these measures. Questionnaires typically permit quantification of important dimensions of the experience of pain and allow evaluation of within-person change over time. Concurrent administration of measures of multiple domains of functioning can assist in the identification of a patient’s relative strengths and weaknesses across these domains, such as identification of patients who report low levels of disability and distress despite an apparently severe level of pain intensity. Questionnaires with normative data offer the added benefit of providing a comparison point for evaluating the status of the respondent relative to others with
similar painful conditions or within similar demographic groups (i.e., age, race/ethnicity, gender). Ultimately, they may provide a more efficient and cost-effective option to more intensive and time-consuming interviews. Following this brief overview of psychological and behavioral assessment strategies, a number of questionnaires and inventories that are frequently used for the assessment of patients with pain in the clinical setting are reviewed.

</table>

#### 1. LOCATION OF PAIN
- Head/face
- Neck
- Shoulder
- Arm
- Hand
- Stomach/abdomen
- Upper back
- Lower back
- Hip
- Leg
- Knee
- Foot
- Ankle
- Genital
- Whole body
- Other sites (specify)

#### 2. INTENSITY OF PAIN
Patients rate their average level of pain over the past week as follows:

- No Pain
- Worst Possible Pain

Worst pain gets: Best pain gets: Average pain rating:

#### 3. QUALITY OF PAIN (Do not prompt; use the patient’s own words when possible.)
- Dull
- Stabbing
- Hot-burning
- Shooting
- Aching
- Piercing
- Tingling
- Numb
- Squeezing
- Throbbing
- Pulling
- Sharp
- Cramping
- Gnawing
- Heavy
- Tender
- Radiating
- Deep
- Other (specify)

#### 4. ONSET/DURATION
Approximate time the pain started:

#### 5. VARIATIONS/PATTERNS/RHYTHMS
The pain is constant, intermittent, episodic/recurring, other (specify)

#### 6. WHAT RELIEVES THE PAIN?
- Sitting
- Lying down
- Standing
- Heat
- Cold
- Rest
- Exercising
- Other (specify)

#### 7. WHAT CAUSES OR INCREASES THE PAIN?
- Sitting
- Lying down
- Standing
- Heat
- Cold
- Rest
- Exercising
- Movement
- Other (specify)

#### 8. EFFECTS OF PAIN
Other associated symptoms: nausea, vomiting, dyspnea
- Confusion
- Weakness
- Numbness
- Other (specify)

The pain affect the patient’s
- Sleep
- Movement
- Energy
- Lifestyle
- Personal relationships
- Work
- Emotions
- Concentration
- Appetite
- Motivation
- ADLs
- IADLs
- Other (specify)

#### 9. PATIENT’S PAIN GOAL (Check any appropriate boxes, if appropriate, and add brief descriptors of the patient’s goals regarding reduced level of pain intensity and goals related to function, ADLs, quality of life, etc.)
- Sleep comfortably
- Comfort at rest
- Comfort with movement
- Stay alert
- Perform activity (specify)
- Other (specify)

Acceptable level of pain (0 to 10 scale):

#### 10. PAIN MEDICATIONS (During the interview, determine the current use, dosage, and general effectiveness of pain medications to determine the patient’s perception of effectiveness.)
- Physical therapy
- Surgical interventions
- Psychotherapy
- Relaxation
- Biofeedback
- Manual treatments
- TENS
- Heat application
- Cold application
- Occupational therapy
- Distraction
- Exercises
- Stretching
- Other (specify)

#### Relevant Medical History
Significant recent medical history

#### Psychosocial History and Present Status
Significant mental health and substance abuse history
Current employment status, current living arrangements

ADLs, activities of daily living; CPMC, Chronic Pain Management Clinic; IADLs, instrumental activities of daily living; TENS, transcutaneous electrical nerve stimulation.

---

Diaries offer two advantages over other assessment methods. They allow recording of prospective, day-to-day, or even more frequent information about pain, sleep, and physical and emotional function, thereby eliminating the distortion associated with memory and retrospective recall. Additionally, diaries allow recording of the temporal association between pain and other factors. For example, many sleep diaries collect information about pain intensity scores before
sleep, as well as sleep quality and duration.11 This allows investigation of the relationship between pain and functioning as opposed to examining either factor in isolation. The composition of diaries can vary from those designed to assess a single domain, such as pain intensity, to those that are much more comprehensive and multidimensional. The use of innovative technologies such mobile telephone applications, web-based diaries, and interactive voice response systems is increasingly being promoted as a more efficient strategy for collection of prospective information.12

Although pain is a private, subjective experience, it is possible to observe signs that a patient is experiencing pain by direct behavioral observation. Patients can communicate that they are experiencing pain and the intensity of their pain through facial expressions, crying, moaning, limping, guarding, and rubbing affected areas. Behavioral observation of patients with chronic pain can provide valuable adjunctive information beyond that gathered with a self-report format and is crucial to the evaluation of those with cognitive or physical limitations that interfere with verbal communication. Behavioral observation methods have been developed for the assessment of patients with a range of painful medical conditions, including cancer pain,13 rheumatoid arthritis,14 osteoarthritis,15 and low back pain.16 Prkachin and colleagues17 reported on a method for assessment of pain behavior in the context of clinical evaluation of patients with low back pain. These methods have also been developed and used in studies of pain-relevant communication in partner dyads.18 To obtain reliable and valid behavioral observation data it is necessary to have a systematic plan for behavioral observation, coding, and interpretation of the data; accordingly, use of these methods requires considerable technological sophistication and expense.19 The use of behavioral observation methods is commonly limited to the clinical research setting because of the time-intensive and costly nature of these methods.

Reports of families and significant others in the assessment of pain have been strongly encouraged in contemporary models of pain, particularly Fordyce’s operant conditioning model20 and Turk’s cognitive-behavioral model,21 which have specifically encouraged this focus given the hypothesized roles of social contingencies in the perpetuation, if not etiology, of persistent pain and disability and awareness of the frequent negative impact of persistent pain on significant others. In particular, the role of solicitousness in the development and maintenance of pain-related disability has been a topic of a great deal of research. Operant principles specify that when spouses provide solicitous responses to pain behavior, the pain behavior is more likely to occur in the future, even in the absence of continued nociception. Positive or solicitous responses from spouses and family members, contingent on pain behavior, may serve to reinforce the maladaptive behavior and encourage the development and maintenance of pain and pain-related disability. Examples of solicitous behavior examined in the literature include expressions of sympathy or concern for the spouse, physical assistance or performance of a task, and encouraging rest and discouraging activity. A 2006 review summarized the evidence for relationships between marital functioning and chronic pain.22 In general, spouse solicitousness is significantly related to greater pain intensity, greater frequency of pain behavior, higher levels of disability,22-24 and increased help-seeking behavior.23,24 Distracting responses from significant others, meaning responses that are intended to cue engagement in other behavior in an effort to distract from pain, have been found to be positively related to poor outcomes despite the probable intent of these responses to encourage adaptive coping with pain.22 In addition to global measures of family and marital relationships, numerous questionnaires and inventories,25-27 diaries,28 and behavioral observation methods18 have been developed specifically for the assessment of pain-relevant communication and the impact of pain on family members and significant others.

Psychophysical measures are used primarily to demonstrate the influence of psychological factors on the initiation and maintenance of pain symptoms.29 For clinicians, psychophysical measures provide evidence that psychological factors are influencing biologic reactions in an individual patient and provide information on the utility of certain types of interventions (e.g., biofeedback). For the patient, evidence that psychological factors are influencing physical responses related to pain can provide direct feedback regarding the successful use of behavioral strategies to manage a pain disorder and increase confidence to engage in these behavioral strategies.30

The most common clinical use of psychophysical measures in the treatment of pain occurs primarily during biofeedback treatments. Biofeedback treatments use psychophysical measures to train patients in voluntary modifications of bodily reactions through provision of feedback of physiologic processes.29 Surface electromyographic (EMG) recordings are the most widely used psychophysical measure in biofeedback for pain disorders because muscle tension is implicated in the majority of musculoskeletal pain disorders. EMG readings typically target specific muscle groups associated with the patient’s pain disorder (e.g., trapezius muscle for patients with upper back pain and the erector spinae muscle for patients with lower back pain). Additionally, blood flow is linked to several chronically painful conditions, including migraine headaches and Raynaud’s disease. For these conditions, measures of blood flow and peripheral skin temperature (a proxy for peripheral circulation) can be used in biofeedback treatments. Other types of biofeedback include heart rate variability and skin conductance, but more research is required to determine the relationship of these measures to chronic pain disorders and their utility in biofeedback treatment of chronic pain.

### SPECIFIC PSYCHOLOGICAL AND BEHAVIORAL ASSESSMENT STRATEGIES

Standardized assessment instruments, often in the form of questionnaires or inventories, are used frequently in the assessment of patients with pain (Table 16.1).31-54 Questionnaires allow a focused examination of a specific domain such as pain intensity, physical and emotional functioning, or coping beliefs and provide quantitative data that can be used to understand the patient’s functioning relative to the general population or other patients experiencing pain.

### PAIN INTENSITY

A primary objective in assessing patients experiencing pain is to determine their level of pain intensity. Change in pain...

Continued on following page
intensity from baseline to after treatment is often the primary outcome measure used in evaluating the efficacy of a given pain treatment. The following measures attempt to quantify the private experience of perceived pain. The numerical rating scale (NRS), the verbal rating scale (VRS), and the visual analog scale (VAS) are the most frequently used measures of pain intensity.31

The NRS is a single-item rating scale of pain intensity that can be administered in an oral or written format. Patients are asked to specify their pain on a scale from 0 to 10, with 0 representing “no pain” and 10 representing “the worst pain imaginable” or extreme pain. Although a 0 to 10 scale is most commonly used, ranges of 0 to 20 or 0 to 100 are also used. Farrar and colleagues55 suggested that a 2-point decrease in the 0 to 10 NRS may be indicative of a clinically important change in pain intensity. Advantages of the NRS include ease of administration and scoring and high rates of completion by respondents.31,56

The VRS contains a list of pain descriptors that typically range in intensity from “no pain” to “severe pain.” Patients select the descriptor that best characterizes their level of pain from a list that ranges from 4 to 15 descriptors. The descriptors are then assigned a number value based on the intensity level (i.e., no pain = 0, mild = 1, moderate = 2, and severe = 3).31 Like the NRS, the VRS has demonstrated validity through significant correlations with other measures of pain intensity.31,56 Although the VRS is an attractive option because it is easy to administer, patients with limited vocabulary or command of English may have difficulty discriminating among the descriptor words, and the selection of descriptors may not adequately describe a respondent’s pain, especially when a four_DESCRIPTOR format is used.31

The VAS uses a 10-cm-long line with end points denoting the absence of pain (e.g., “no pain”) at one end and extreme pain at the other. Respondents place a mark on the line at the point that best characterizes their pain intensity relative to the end points. Calculation of a pain intensity score is based on the distance from the “no pain” end point to the respondent’s mark.

A review by Jensen and Karoly found that all the aforementioned measures demonstrated validity through significant correlations with other pain intensity measures and have comparable responsiveness to changes in pain in the context of pain treatment.31 Evidence suggests that respondents may

*Measure was selected by the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) panel as the preferred measure within a domain.

NIH, National Institutes of Health.
prefer VRS and NRS instruments over the VAS and that VAS instruments are more likely than NRS measures to result in missing or incomplete data, possibly because of cognitive or motor disabilities. For these reasons, the consensus statement of the IMMPACT committee’s review of core measures for chronic pain clinical trials recommends using an 11-point NRS scale to assess pain intensity and the VRS as an adjunct. Although these recommendations were developed for use by clinical researchers, the importance of consistent use of valid, reliable, and understandable measures in clinical practice should not be ignored, and the guidelines provide valuable information for all users of these measures.

The McGill Pain Questionnaire (MPQ) is a more lengthy measure designed to assess the quality and affective component of the pain experience, not simply pain intensity. Respondents choose pain descriptors from a list of 78 potential descriptors that fall into 20 pain categories. These descriptors assess four pain domains: sensory, affective, evaluative, and miscellaneous. Within each category the individual descriptors reflect varying degrees of intensity and are assigned corresponding numerical values that reflect this difference. Respondents also highlight the location of their pain on a figure drawing and provide information about the factors that alleviate and aggravate their pain intensity. The MPQ generates three scores: (1) the Pain Rating Index, which is the sum of all words chosen in the available categories (the sum of the value of each subclass can also be obtained); (2) the number of words chosen, a score that reflects the number of words chosen from each of the four categories; and (3) the present pain intensity, a rating of current pain on a scale from 0 (no pain) to 5 (excruciating).

The MPQ has been widely used in a variety of pain-focused research and has been translated into a variety of languages, although not all new versions of the scale have been subjected to adequate clinimetric or psychometric testing. A 15-item short-version of the MPQ (SF-MPQ) is also available.

Strengths of the MPQ include demonstrated validity of its subscales through their association with perceived quality of life, ability to discriminate among pain conditions, pain medication use, and sensitivity to the effects of pain treatment. The MPQ scale scores have not shown a consistent association with pain intensity ratings, and a review concluded that the MPQ scales may not measure the same construct as other pain intensity measures do and may be less sensitive than “pure” measures of pain intensity such as the NRS and VRS. The SF-MPQ demonstrated high correlation with the Pain Rating Index of the MPQ and was sensitive to changes produced by pain medications in patients with pain. The IMMPACT committee recommended use of the SF-MPQ as a measure of pain quality and the affective component of pain because these aspects of the pain experience may respond differently to treatment than pain intensity does.

PERSONALITY

The Minnesota Multiphasic Personality Inventory (MMPI) is by far the most commonly used objective measure of personality, and it is similarly the most commonly used measure for the evaluation of psychological functioning of patients with pain. A recently revised version, known as the MMPI-2-RF, consists of 338 true-false items that are used to derive scores on: 3 higher-order scales; 9 restructured clinical scales; 8 validity scales; 14 somatic/cognitive and internalizing scales; 11 externalizing, interpersonal, and interest scales; and 5 personality psychopathology scales. The most recent version of the MMPI has several advantages over previous versions: it is based on more modern views of psychopathology, it has fewer items and therefore lower patient burden, and its normative sample is more representative of the U.S. population. Additionally, the restructured clinical scales have reduced intercorrelations with respect to the original scales and have demonstrated validity in predicting pathology with more accuracy while using fewer items than the original scales. However, the MMPI-2-RF has not been examined in patients with chronic pain.

Significant concerns have been raised about the appropriateness of the previous versions of the MMPI (MMPI or MMPI-2) for use in the assessment of patients with chronic pain. Differences observed on the clinical scales between pain and nonpain samples have been demonstrated to more likely reflect disease status than psychological functioning. An extensive research effort has focused on the identification of reliable subgroups of patients with chronic pain based on their MMPI profiles. The sum of this literature suggests that even though reliable subgroups can be identified despite evidence that the subgroups differ in terms of behavioral correlates of the experience of pain, it has yet to be demonstrated in a compelling fashion that the MMPI has value in characterizing patterns of coping with chronic pain over and above data derived from pain-specific measures. No information is available to indicate whether these issues have been alleviated (or exacerbated) by the significant revisions of the MMPI-2-RF. Results in patients with chronic pain should be interpreted with caution until further studies are able to validate the MMPI-2-RF in chronic pain populations.

The Millon Behavioral Health Inventory (MBHI) was developed to assess the psychological functioning of patients with medical conditions. This 150-item measure contains eight scales designed to assess the respondent’s interaction style (e.g., cooperation), six scales that assess the respondent’s response to illness (e.g., pain treatment responsibility), and six scales that assess the presence of psychosocial stressors (e.g., social alienation). Questions are posed in a true/false format. A respondent’s answers are scored by comparison with the base rate in the normative sample, which consisted of patients with a variety of medical illnesses.

The MBHI has been demonstrated to have substantial reliability and validity indices. It may have advantages relative to the MMPI-2-RF for use in the assessment of patients with pain conditions as a function of its relative brevity and the fact that it was developed and normed on medical as opposed to psychiatric populations. However, to date, studies have failed to demonstrate the predictive validity of the scale in studies of psychological interventions, surgical interventions, or multidisciplinary treatment of patients with chronic pain.

ASSESSMENT OF PSYCHOSOCIAL IMPACT

The West Haven–Yale Multidimensional Pain Inventory (WHYMPI) is designed to measure the psychosocial and behavioral aspects of chronic pain and is useful across
a variety of pain complaints. It is a 52-item multidimensional self-report instrument that uses 7-point Likert scales. The instrument consists of three sections. Section one includes six scales measuring pain-related interference across several domains, including work and leisure activities, as well as interpersonal relationships, perceived support from spouse or significant other, pain severity and suffering, perceived life control, and negative mood. Section two assesses patient perception of significant others’ responses to overt expressions of pain by classifying responses as solicitous, distracting, or negative. Section three measures the frequency with which the patient engages in four clusters of everyday activities, including household chores, social activities, outdoor work, and activities away from home. The WHYMPI takes approximately 10 to 15 minutes to complete and is written at a fifth-grade reading level. Test-retest reliability over 2 weeks ranges from 0.62 to 0.91, and internal reliability coefficients range from 0.70 to 0.90. Several investigative teams have generally replicated the factor structure and psychometric properties of the WHYMPI. Turk and colleagues proposed an empirically derived taxonomy of the WHYMPI that includes three reliable profiles of patients with persistent pain labeled as dysfunctional, interpersonally distressed, and adaptive copers, and these investigators and several other groups have replicated these findings in numerous samples of patients with various pain conditions. The measure has been used in many empirical studies, including clinical trials of psychological and pharmacologic interventions, studies of the psychosocial impact of pain, and studies examining the role of psychosocial factors as contributors to the development and maintenance of persistent pain. The IMMPACT group recommended use of the interference scale of the WHYMPI as an outcome measure in pain clinical trials. The second section of the measures that focus on responses of significant others has been particularly valuable in evaluating the role of such responses as predictors of the severity of pain and pain-related disability and distress.

Three additions to the original version of the scale have enhanced its overall reliability, validity, and clinical utility. Rudy added two items to the life control and interference scales, Okifuji and colleagues proposed alternative instructions for the significant other response section to reduce missing observations, and Bruehl and colleagues developed a scale to detect random responding and malinger. A significant other version of the measure has also been published.

The National Institutes of Health Patient-Reported Outcomes Measurement Information System (PROMIS) is a standardized item bank developed by a cooperative group for the purpose of developing psychometrically sound standardized measures to assess patient-reported outcomes. These measures provide information on the domains of physical, mental, and social health across a variety of medical illnesses. Measures for pain currently available in the PROMIS assessment center include “pain-interference” and “pain-behaviors.” The pain-interference item bank includes 41 items, with 4 short forms consisting of 4 to 8 items. The pain-behaviors item bank includes 39 items with a single short form consisting of 7 items. Both measures have demonstrated reliability and validity in psychometric evaluation, were related to other measures of pain-related outcomes, and discriminated among groups of patients with different self-reported health, number of chronic conditions, and number of disabling conditions. Further studies have demonstrated that pain-related measures are higher and global scores of quality of life are lower in clinical pain samples than in samples from the general population. The PROMIS pain-interference and pain-behaviors scales have recently been developed and therefore have only a small body of evidence regarding reliability and validity. Available studies suggest that these scales provide comprehensive, sophisticated, and psychometrically sound measures for pain-related patient-reported outcomes.

The Sickness Impact Profile (SIP) measures the degree of disability across 12 domains of functioning. One hundred thirty-six items are used to derive measures of sleep and rest, eating, work, home management, recreation and pastimes, ambulation, mobility, body care and movement, social interaction, alertness behavior, emotional behavior, and communication. These domain scores are combined to produce physical, psychosocial, and total disability scores. The SIP can be self-administered or administered by an interviewer in about 20 to 30 minutes.

An extensive period of development and testing and reports on these efforts support the reliability and validity of the measure. The SIP has been found to be responsive to change during treatment of chronic pain. A brief version consisting of 24 items, called the Roland-Morris Disability Questionnaire, has been developed specifically for use in patients with chronic low back pain. This measure has also been shown to have strong evidence of reliability, validity, and responsiveness to change as a function of psychological interventions and is recommended by the IMMPACT group as the preferred measure of physical functioning for evaluating persons with back pain.

**PHYSICAL AND SOCIAL ROLE FUNCTIONING**

Assessment of physical functioning has been recommended as a core outcome domain in pain clinical trials, and others have suggested that it should perhaps be considered the primary outcome in such trials. Measurement of physical and social role functioning represents a challenge to the field given the broad range of levels of functioning, for example, the range of activities of daily living to the broader domain of health-related quality of life. A variety of strategies have been developed to assess these varying dimensions, and selection of the appropriate measure in the research or clinical setting should take into account the specific population being assessed (e.g., unexplained chronic low back pain, frail elderly) and the purpose of the assessment (e.g., responsivity to change during treatment, comparison to population norms). Three of the most commonly used measures of this domain for the assessment of patients with painful medical conditions are briefly reviewed.

The Pain Disability Index (PDI) is a brief measure of pain-related interference in role functioning. The PDI includes seven items assessing perceived disability in each of seven areas of functioning: family/home responsibilities, recreation, social activity, occupation, sexual behavior, self-care, and life support activity. Each item is rated on a 10-point Likert scale (0 = no disability to 10 = worst disability).
The PDI has demonstrated internal consistency values of 0.85 to 0.86 and excellent test-retest reliability. Validity has been demonstrated through its association with the Oswestry Disability Questionnaire (focused specifically on chronic lower back pain), physical functioning tests, and measures of pain intensity.

The Brief Pain Inventory (BPI) was originally developed to measure pain intensity and interference in patients with cancer pain, but it has been widely used to assess non–cancer-related pain. A short-form of the BPI containing 15 items is also available. The short form of the BPI has been found to have high internal consistency scores ranging from 0.82 to 0.95 for the severity and interference scales in a sample of patients with arthritis and lower back pain. Demonstration of its reliability and validity and its availability in multiple languages have contributed to its being recommended by the IMMPACT group for use as a measure of physical functioning in pain clinical trials.

The PEG is an ultra-brief version of the BPI that consists of three items: (P) pain intensity, (E) enjoyment of life, and (G) general activity. Development studies demonstrated reliability and validity of the PEG comparable to that of the longer BPI.

EMOTIONAL FUNCTIONING

Assessment of the emotional functioning of patients experiencing chronic pain should be conducted in the context of any pain-relevant intervention. The high prevalence of emotional distress in patients with chronic pain conditions, the negative effects of emotional distress on pain and pain-related disability, the inflated health care cost associated with emotional distress in patients with chronic pain, and the influence of emotional distress on participation in pain treatment provide the rationale for this recommendation.

The Beck Depression Inventory (BDI) was developed to measure the behavioral manifestations of depression in adolescents and adults and to standardize the assessment of depressive symptom severity for monitoring change over time. In its original form, the BDI consisted of 21 groups of four to five statements describing symptoms in each cluster from low to high. Respondents were instructed to endorse the single item in each group that best describes how they were feeling “right now.” The original version was designed to be used in an interview format, but subsequent versions have more commonly been used in a self-report, questionnaire format. In 1978 the full scale was revised to eliminate redundancy among some of the items, and the time frame for assessment was altered to “during the last week, including today.” Only four possible responses for each symptom cluster are now included, so scores on the measure range from 0 to 63. In 1996 the BDI-II was published and included revisions of some items and the time frame for assessment to be consistent with the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV). Although the BDI-II has advantages in terms of the content of the items and consistency with current diagnostic nomenclature, concerns have been raised about its sensitivity to change during brief periods of time. The 21-item version of the BDI takes about 5 to 10 minutes to complete.

The reliability and several dimensions of validity of the measure have been extensively reported. In a review of 25 years of research with the BDI, Beck and colleagues reported on 25 studies that assessed the internal consistency of the measure. Across psychiatric, healthy, and medically ill samples, indices of internal consistency (alphas) ranged from 0.75 to 0.95. Stability estimates (i.e., test-retest correlations) have consistently been high as well, typically varying in the 0.80 to 0.90 range, depending on the assessment interval and sample. Estimates of validity for psychiatric patients have been assessed by examining the correlation between BDI scores and clinical ratings of depression (e.g., by using the Hamilton Rating Scale for Depression), with validity averaging about 0.72. For nonpsychiatric patients, the average estimate of validity is 0.60. In a review of eight studies of sensitivity to change, Moran and Lambert found that the BDI was sensitive to change as a function of psychotherapy and pharmacotherapy outcome studies. Some evidence suggests a reporting bias for certain populations, including women, adolescents, and elderly persons, although the robustness of these observations is not clear.

The BDI has been used extensively in studies designed to evaluate the efficacy of pharmacologic and nonpharmacologic treatments of chronic pain, and there is ample evidence of its sensitivity to change. The results of most studies provide compelling support for use of the BDI in assessing improvements in depressive symptom severity as a function of pain treatment, and it has been recommended as one of the core outcome measures for assessment in pain clinical trials.

The Center for Epidemiologic Studies Depression Scale (CES-D) was developed to screen for the presence of depressive illness and to measure levels of symptoms of depression in community samples. The scale’s 20 items were selected from existing scales (e.g., BDI, MMPI depression scale, Zung Self-Rating Depression Scale) to represent the major components of depression on the basis of clinical and empirical studies. Respondents are asked to rate the frequency of a given symptom on a 0 (rarely or none of the time) to 3 (most or all of the time) scale with reference to the past week. Four items are worded in the positive direction to partially control for response bias. The CES-D takes about 5 minutes to complete.

Indices of internal consistency (Cronbach’s alpha) have been reported to be 0.85 in community samples and 0.90 in psychiatric samples. Split-half reliabilities are also high and range from 0.77 to 0.92. Test-retest correlations over a 6- to 8-week period range from 0.51 to 0.67. Roberts reported that studies of African American and Mexican American respondents revealed similar reliability estimates. The reliability and validity of the measure have also been examined in numerous ethnic populations, and it has been translated into several languages. Overall, high levels of internal consistency have been reported across numerous samples from the general population and patient samples, irrespective of age, gender, race, and geographic location. In a sample of chronic pain patients, the level of internal consistency was found to be 0.90. Indices of criterion-related validity have generally been reported to be moderate to high. For example, correlations between the CES-D and the depression scale of the Symptom Checklist—Revised in samples
of psychiatric patients have been reported to range from 0.73 to 0.90. Correlations with the Hamilton Rating Scale for Depression in similar samples have ranged from 0.49 to 0.85. Studies of elderly samples have revealed somewhat lower validity estimates.

Investigators have challenged the diagnostic sensitivity of the CES-D. Investigators in the pain field have called for modifications of the measure in terms of item content or scale cutoffs for the diagnosis of depression. Ultimately, it is fair to say that the measure lacks the sensitivity and specificity for supporting its use in clinical diagnosis without the concurrent use of a psychiatric interview. The CES-D has increasingly been used for the assessment of outcome following pain interventions, and in numerous cases the measure has been demonstrated to be sensitive to change.

The Geriatric Depression Scale (GDS) was specifically designed to identify and quantify both situational anxiety and depression-dejection, anger-hostility, fatigue-inertia, vigor-activity, and confusion-bewildermert. The POMS requires only 3 to 5 minutes to administer. It has been recommended for use in pain clinical trials because of its capacity for briefly assessing the multiple dimensions of emotional functioning of patients with pain; its strong psychometric properties, including evidence of its responsiveness to change, especially in analgesic medication trials; and its availability in multiple languages.

Indices of internal consistency (alphas) for the six mood scales ranged from 0.84 for confusion-bewildermert to 0.95 for depression-dejection. Stability estimates (test-retest reliability correlations) ranged from 0.65 for vigor-activity to 0.74 for depression-dejection. Regarding validity, correlations between scales of the POMS and analogous scales from the MMPI-2 were largely in the expected direction and significant, with coefficients ranging from −0.58 to 0.69. The POMS has been used extensively in the pain treatment literature and has been shown to be sensitive to change as a function of pain treatment. Advantages of the POMS include its ease of administration, its brevity, its development on nonpsychiatric populations, and its design to capture both the negative and positive dimensions of emotional functioning. In particular, since the POMS has scales for three of the most important dimensions of emotional distress in patients with pain (anxiety, depression, and anger), the scale has an explicit advantage over any alternative scale. Within each of these three negative emotions, some items also have an intuitive appeal for capturing the construct in patients with chronic pain. For example, the tension-anxiety scale incorporates items that reflect both somatic and cognitive distress. The depression-dejection scale includes mood descriptors other than sadness that have been observed to be present in a large proportion of patients with chronic pain who meet the criteria for current major depressive disorder but who otherwise deny feelings of depression. Inclusion of an anger-hostility scale is particularly novel and potentially an advantage of the POMS relative to any other comparable instrument. The vigor-activity scale represents a relatively unique opportunity to assess improvements in this key dimension of emotional functioning rather than relying on a reduction in negative mood and symptoms of emotional distress. The fatigue-inertia scale provides an opportunity to measure this common comitant of the experience of chronic pain, especially when assessing pain treatment in patients with clinical pain conditions in which fatigue is particularly prevalent (e.g., pain in multiple sclerosis). The opportunity to discriminate the effects of a pain intervention on fatigue and anergia, on the one hand, and from “not at all” to “very much so” in terms of both their present state (state version) and their frequency over time (trait version). There is high concordance between pain and anxiety as measured by the STAI, and it has been widely used in the pain literature. It has acceptable psychometric properties and is sensitive to change in anxiety as a function of pain treatment. The Profile of Mood States (POMS) is a self-report measure composed of a list of 65 mood-related adjectives that requires respondents to report the degree to which each feeling or mood state has applied to them over the past week via a 0 (not at all) to 4 (extremely) Likert scale. The scale assesses six dimensions of mood: tension-anxiety, depression-dejection, anger-hostility, fatigue-inertia, vigor-activity, and confusion-bewildermert. The POMS requires only 3 to 5 minutes to administer. It has been recommended for use in pain clinical trials because of its capacity for briefly assessing the multiple dimensions of emotional functioning of patients with pain; its strong psychometric properties, including evidence of its responsiveness to change, especially in analgesic medication trials; and its availability in multiple languages.

Indices of internal consistency (alphas) for the six mood scales ranged from 0.84 for confusion-bewildermert to 0.95 for depression-dejection. Stability estimates (test-retest reliability correlations) ranged from 0.65 for vigor-activity to 0.74 for depression-dejection. Regarding validity, correlations between scales of the POMS and analogous scales from the MMPI-2 were largely in the expected direction and significant, with coefficients ranging from −0.58 to 0.69. The POMS has been used extensively in the pain treatment literature and has been shown to be sensitive to change as a function of pain treatment. Advantages of the POMS include its ease of administration, its brevity, its development on nonpsychiatric populations, and its design to capture both the negative and positive dimensions of emotional functioning. In particular, since the POMS has scales for three of the most important dimensions of emotional distress in patients with pain (anxiety, depression, and anger), the scale has an explicit advantage over any alternative scale. Within each of these three negative emotions, some items also have an intuitive appeal for capturing the construct in patients with chronic pain. For example, the tension-anxiety scale incorporates items that reflect both somatic and cognitive distress. The depression-dejection scale includes mood descriptors other than sadness that have been observed to be present in a large proportion of patients with chronic pain who meet the criteria for current major depressive disorder but who otherwise deny feelings of depression. Inclusion of an anger-hostility scale is particularly novel and potentially an advantage of the POMS relative to any other comparable instrument. The vigor-activity scale represents a relatively unique opportunity to assess improvements in this key dimension of emotional functioning rather than relying on a reduction in negative mood and symptoms of emotional distress. The fatigue-inertia scale provides an opportunity to measure this common concomitant of the experience of chronic pain, especially when assessing pain treatment in patients with clinical pain conditions in which fatigue is particularly prevalent (e.g., pain in multiple sclerosis). The opportunity to discriminate the effects of a pain intervention on fatigue and anergia, on the one hand, and
other symptoms of emotional distress on the other may have particular utility in certain cases. Finally, given concerns about the effects of certain pain medications on cognitive functioning, the bewildermint-confusion scale may also have some benefit.

The Symptom Checklist—90 Revised (SCL-90R) requires respondents to rate the extent to which they have been bothered by each of 90 physical or mental health symptoms in the past week. Responses are used to derive nine standardized indices of psychological disturbance labeled somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism. A global severity index may also be derived. The reliability and validity of the SCL-90R for the evaluation of psychiatric patients have been extensively reported in a manual for the instrument and elsewhere.

Numerous researchers have criticized the appropriateness of this measure for use in the assessment of patients with chronic pain. For example, Shute and colleagues were able to identify only five rather than nine reliable factors from the SCL-90R in a sample of chronic pain patients. These investigators also challenged the validity of evaluating patients with chronic pain by using norms developed from samples of psychiatric patients. On the other hand, Jamison and colleagues identified three reliable subgroups of patients with chronic pain by using the SCL-90R. These investigators demonstrated that patients with elevations in the subscales of the measure, relative to those who have a profile consistent with normative data, reported significantly higher levels of disability, sleep disturbance, and emotional distress. Several other investigators have largely replicated these findings. Unfortunately, no data have been published in support of the ability of these subgroups or the individual scales to predict response to pain treatment. Finally, the sensitivity of the SCL-90R to change as a function of treatment has not been adequately demonstrated.

The Medical Outcomes Study Short-Form Health Survey (SF-36) was developed as a general measure of perceived health status and is typically self-administered. The measure contains 36 items that are combined to form eight scales: physical functioning, physical role functioning, bodily pain, general health, vitality, social functioning, emotional role functioning, and mental health. Respondents use “yes-no” or 5- or 6-point scales to endorse the presence or degree of specific symptoms, problems, and concerns. Scores on the scales range from 0 to 100, with higher scores indicating better health status and functioning. The measure takes about 10 to 15 minutes to complete. The SF-36 has been extensively validated with large samples from the general population and across several demographic subgroups, including samples of healthy persons older than 65.

Estimates of internal consistency (alphas) for most samples range from 0.62 to 0.94 for the subscales, with most estimates ranging over 0.80. Test-retest coefficients ranged from 0.43 to 0.81 for a 6-month period and from 0.60 to 0.81 for a 2-week period. The SF-36 has been shown to correlate reasonably well with other criterion measures, measures of ability to work, utilization of health care resources, and other clinically meaningful criteria such as "burden of care." Factor analysis studies have supported the presence of two distinct factors labeled physical health and mental health functioning, which account for 82% of the measure’s variance.

In one multisite trial of cognitive-behavioral therapy, exercise, and their combination in patients with Gulf War illness that included chronic, diffuse musculoskeletal pain as a primary feature, each of these treatments was found to be associated with improvements in the mental health–functioning component score. On a more negative note, Rogers and colleagues reported that the SF-36 lacked reliability in the assessment of outcomes following multidisciplinary pain treatment, and they questioned aspects of the measure’s validity in discriminating dimensions of functional limitations. Similar concerns about the sensitivity of the SF-36 to change have also been raised. Continued examination of the sensitivity of the SF-36 mental health–functioning component to change as a function of pain interventions is indicated.

PAIN BELIEFS AND COPING

The Survey of Pain Attitudes (SOPA) was developed to measure beliefs about chronic pain and included five domains: perceived ability to control pain, perceived level of pain-related disability, belief in medical cures for pain, belief that others should be solicitous toward them when they are in pain, and the importance of medication as a treatment of pain. The measure was later expanded to include two new dimensions: belief in the influence of emotions on pain and belief that pain indicates underlying physical damage that necessitates limitation of physical activity. The final version of the SOPA has 57 items and uses a 0 (this is very untrue for me) to 4 (this is very true for me) response scale. The SOPA is grounded in cognitive-behavioral theory, which specifies that patients’ beliefs about their pain influence important pain-related outcomes, including emotional and physical functioning. A 30-item brief form of the SOPA (the SOPA-B) and a 35-item short version (SOPA-R) are also available.

Internal consistency alphas for the 57-item SOPA scales are good and range from 0.71 (control) to 0.81 (disability), and test-retest stability ranged from 0.65 to 0.68. The shorter version of the SOPA, the SOPA-B, has demonstrated a seven-factor structure consistent with the original measure, adequate internal consistency (ranging from 0.56 [medication] to 0.83 [solicitude]), and strong correlations with the corresponding SOPA scales (0.79 to 0.97). The original factor structure of the SOPA-R has largely been confirmed by other investigators, and the measure has demonstrated good internal consistency (0.65 to 0.84) with the exception of the medication scale (0.49).

The main strength of the various versions of the SOPA is their correlation with clinical treatment outcomes. The disability scale of the SOPA (higher scores indicate higher beliefs that one is disabled) has demonstrated significant correlations with physical and emotional functioning. The harm scale showed a significant association with reported physical disability, and the medication scale was associated with treatment utilization.

The most frequently used measure of the construct of “pain readiness to change” is the Pain Stages of Change Questionnaire (PSOCQ). The PSOCQ measures beliefs about the degree of a patient’s personal responsibility for pain control and interest in making behavioral changes to cope with pain. The PSOCQ is a 30-item self-report measure
composed of four distinct scales. The precontemplation scale measures the degree to which a patient endorses little personal responsibility for pain control and no interest in making behavioral changes. Contemplation represents an increasing recognition of personal responsibility for pain control and interest in behavioral changes that support pain management. The action scale measures the extent to which patients believe that they are actively learning pain management skills. The maintenance scale quantifies patients’ degree of commitment to using self-management strategies in their daily life and a high degree of personal responsibility for pain management.

A review of the empirical literature documents the reliability and criterion and concurrent validity of the measure. Internal consistencies of the four scales range from 0.77 to 0.86, and stability indices range from 0.74 to 0.88. The utility of the PSOCQ, however, hinges on its ability to predict important treatment process variables. Thus far, research has been encouraging. For example, the PSOCQ subscales (i.e., precontemplation, contemplation, action, and maintenance) predict completion of self-management treatment programs and improvements in pain coping during treatment. Furthermore, changes in the PSOCQ during treatment consistent with increased readiness to change, or “forward stage movement,” are associated with improvements in pain and physical and emotional functioning. The readiness-to-change model, however, has not been without critics. For example, Strong and colleagues challenged the external validity of the PSOCQ and demonstrated that a measure of self-efficacy had greater predictive validity than the PSOCQ.

The Chronic Pain Coping Inventory (CPCI) is a 64-item questionnaire designed to assess a patient’s use of pain-coping strategies. The questions contained in the scale fall into three broad categories and include eight subscales: wellness-focused or positive coping strategies (exercise, relaxation, task persistence, coping self-statements), illness-focused or negative coping strategies (guarding, asking for assistance, resting) and neutral coping strategies (seeking social support). Respondents report the number of days in the last week that they used each strategy.

In the initial validation, the CPCI subscales demonstrated good internal consistency (0.74 to 0.91) and test-retest reliability (0.65 to 0.90). Spouse report of patient disability and coping skills use was strongly associated with CPCI scales. Other studies have largely confirmed the initially specified eight-subscale factor structure.

Studies have found various associations between the CPCI subscales and patient adjustment and outcomes, but overall, illness-focused coping strategies were found to be significantly associated with poorer patient adjustment and outcomes, and wellness-focused strategies were significantly associated with better patient adjustment and outcomes. An exception is relaxation, with some studies showing a counterintuitive association between relaxation and higher affective distress and lower pain control and another showing no associations between relaxation and any patient adjustment or outcome variable examined. Importantly, even after controlling for pain severity and demographic factors, the CPCI subscales were significant predictors of patient-reported physical functioning, mood, disability, and activity level. A 6-month longitudinal study of patients with low back pain following a work accident demonstrated that higher guarding scores were predictive of prolonged leave from work.

The Pain Catastrophizing Scale (PCS) is a 13-item instrument designed to measure the extent to which patients engage in catastrophic thinking regarding their pain. Catastrophic thinking is characterized by thoughts that the pain is horrible and unbearable and that the worst possible outcome of the patient’s pain will be manifested. Patients record the frequency with which they experience thoughts and feelings described by items on a 5-point Likert-type scale ranging from 0 (not at all) to 4 (all the time).

Initial scale development used an undergraduate sample; however, the PCS has demonstrated reliability and validity in both nonclinical and clinical samples. Factor analyses tend to identify three subscales: magnification, rumination, and helplessness. These factors have demonstrated gender invariance; however, evidence from a single study suggests that particularly for African Americans, two subscales of rumination and magnification/helplessness might be more appropriate. Internal consistency coefficients range from 0.60 to 0.91 for subscales and from 0.87 to 0.95 for the full scale. The PCS has demonstrated validity through its association with catastrophic thought patterns identified through clinical interview, pain severity, pain interference, pain-related disability, and mood and anxiety symptoms. Furthermore, the PCS has demonstrated discriminant validity from affect and psychological disturbance.

The PCS has demonstrated responsiveness to cognitive, behavioral, and physical activity pain treatments and is considered an important mechanism of changes in these treatments. The PCS has also been translated into several languages.

The Chronic Pain Acceptance Questionnaire (CPAQ) is a 20-item scale designed to measure chronic pain acceptance, or the extent to which a patient accepts the inevitability of chronic pain and engages in activities despite experiencing pain. The recent interest in acceptance and commitment therapy as an effective psychological intervention for chronic pain has precipitated widespread use of the CPAQ. Patients respond to statements of acceptance-related pain beliefs by using a 7-item Likert scale ranging from 1 (never true) to 6 (always true).

The CPAQ has two subscales: engagement in activities and willingness to experience pain. Additional factor analyses have confirmed these two subscales with the scale as published or with minor revision. Internal consistency coefficients of the total scale range from 0.72 to 0.91. Regarding validity, the CPAQ has been associated with lower pain severity and pain-related disability, less health care and medication use, lower self-reported depressive symptoms, less pain-related anxiety and pain catastrophizing, higher self-efficacy, and lower dysfunctional pain coping and social support interaction styles. The CPAQ has also demonstrated responsiveness to acceptance-based and cognitive-behavioral pain treatment, as well as to a yoga-based pain treatment.

The CPAQ is available in an adolescent version and in multiple languages. An eight-item version of the CPAQ has demonstrated reasonable reliability (internal consistency coefficients of 0.77 to 0.89) and validity, as evidenced...
by relationships with pain severity and interference, pain treatment seeking, and depressive and anxious symptoms.

QUALITY OF CARE

The quality of pain care offered to patients can differ substantially by institution, clinician, and individual patient experience. High-quality pain care is thought to improve outcomes of pain treatment through a high-quality patient-provider relationship and faithful administration of validated treatments. Any effort to improve the quality of pain care across a system must first begin with measurement. For this reason, the American Pain Society produced its first Patient Outcome Questionnaire (POQ) to assess multiple domains of the quality of patient care. The most recent version of the POQ is a 12-item scale that assesses pain severity; the impact of pain on affect, sleep, and activity; side effects; satisfaction with information provided about pain treatment; shared decision making; and use of nonpharmacologic strategies. Patients circle or check the statement that best applies to their pain management care (e.g., “Were you allowed to participate in decisions about your pain treatment as much as you wanted to?” with responses ranging from 0 [not at all] to 10 [very much so]). In the initial development study, inpatients who had been in the hospital for less than 72 hours were administered the POQ orally to evaluate the first 24 hours of their hospital stay. Overall internal consistency was 0.86. Factor analysis identified five subscales that corresponded with the domains described above, with alphas of 0.63 to 0.83. As with previous versions of the POQ, higher pain severity was associated with higher interference in activities, adverse effects from pain treatments, and affective distress, as well as with lower satisfaction with pain care, thereby providing preliminary evidence for validity. Although initial analyses looked promising, criterion validity analyses were restricted to intercorrelations among POQ subscales. Thus, further evaluation of the validity of the POQ is warranted.

CONCLUSION

This chapter provides an overview of the role of psychological and behavioral assessment in the context of the provision of comprehensive and integrative care to patients with painful medical conditions. Discussion of more general principles that can be used to guide decisions regarding psychological assessment of pain in the clinical setting was followed by a more detailed consideration of some of the most commonly used standardized psychological assessment strategies. This review is designed to serve as a general guide to clinicians who are compelled by the value of more thorough consideration of psychosocial factors in the assessment of patients with pain that may be used to guide and evaluate pain care. Having acknowledged the potential value of such an approach, several relevant issues that may serve as cautionary notes and targets for future research and clinical investigation may be highlighted.

Of particular note are the overall limitations of this field with regard to consideration of the influence of cultural, racial, ethnic, and other aspects of diverse society on the reliability and validity of existing psychological and behavioral assessment methods. Few standardized measures have been evaluated for their use in specific populations. Given a growing awareness and empirical evidence of reliable differences in the experience of pain in patients of different racial/ethnic backgrounds, gender, and age, among other relevant variables, caution is encouraged when using most of the reviewed assessment strategies, and specific consideration of culturally specific norms for the measures is important.

Already emphasized throughout this chapter is the fact that several measures that are frequently used in this field were not originally developed for use in patients with painful conditions, and as a result, the validity of these methods is still subject to concern. The continued development and evaluation of psychological and assessment methods designed specifically for patients with painful conditions and further evaluation of the psychometric properties of these measures are clearly indicated. With increasing appreciation of differences in the experience of pain and its impact on patients with different conditions, specific examination of the psychometric properties in patients with similar disorders is encouraged. Consistent with this observation, the IMMPACT group, for example, though providing recommendations for the use of specific measures to assess the effects of pain treatment, has encouraged the selection of measures that were developed and normed for a specific population (e.g., osteoarthritis patients) when such instruments are available.

Another area for continued work is the importance of developing patient-oriented outcome measures. One example is work that helped identify the types of pain-coping strategies that are commonly used by older patients living in the community. Using a more qualitative approach, these investigators have collected information that may be useful in developing an age-appropriate quantitative measure of pain coping that may be more valid than existing coping measures for this population. Several other investigator groups are currently working on the development and validation of more comprehensive measures for assessing patient-oriented outcomes, and the future availability of these methods promises to provide alternatives to existing methods that may have increased sensitivity to important and meaningful changes in pain and its impact, at least from a patient’s perspectives.

One particularly challenging area of ongoing research is the development of reliable and valid strategies for the assessment of pain in patients who are significantly cognitively impaired or otherwise unable to communicate. In the absence of existing reliable methods, clinical scholars have encouraged the use of an array of methods, including reliance on systematic observation and reports from significant others. With a growing population of older patients with significant dementia and younger patients with significant brain injuries, efforts designed to develop reliable and valid strategies for pain assessment in patients with cognitive impairment will continue to be a high priority for clinical investigation.

Clinicians must consider pragmatic issues related to the use of existing methods and measures for the psychological and behavioral assessment of patients with pain in the clinical setting. Response burden is an important factor to consider when selecting measures for use in the clinical setting. Clinicians are encouraged to consider specific objectives of the assessment and the importance of reaching a balance.
between the desire for more thorough assessment and patient burden. Clinicians should also consider measurement precision, brevity, and cost of the assessment process in making decisions about the use of psychological assessment strategies. As already emphasized, the clinical interview and examination remain the core method for clinical assessment and should not be displaced by the use of questionnaires, diaries, and other methods. Finally, managed care reimbursement methodologies are, of course, critical to consider in most clinical settings.

In closing, the potential value of incorporating assessment methods that permit a more comprehensive evaluation of the psychological and behavioral aspects of the experience of pain has been emphasized. As in most similar contexts, the “devil is in the details,” and clinicians and investigators alike are encouraged to consider a range of important issues when designing an assessment approach consistent with their goals and objectives.

**KEY POINTS**

- Chronic pain is challenging to assess because pain complaints are inherently subjective and pain has a wide-ranging influence on patient functioning.
- Psychological and behavioral assessment of pain serves several clinical goals: (1) providing information about a patient’s pain experiences, treatment history, current and past emotional and physical functioning, and beliefs about pain; (2) identifying the patient’s strengths and weaknesses; (3) identifying factors that contribute to the development and maintenance of problems in physical, social, and emotional functioning; (4) identifying comorbid psychiatric or behavioral conditions that may interfere with pain treatment; (5) determining whether the patient is psychologically appropriate and likely to benefit from surgery or invasive procedure; and (6) providing a benchmark of the patient’s pain and functioning against which the efficacy of treatments can be measured.
- Because of the wide range of clinical goals for psychological and behavioral assessment of pain, when making a request for psychological and behavioral assessment it is necessary to explicitly state the reasons for the request or pose a question to be answered about the patient or the patient’s treatment.
- A useful guide for assessment of the multidimensional nature of pain is the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMPACT) group consensus statement on the core outcome domains that should be assessed when evaluating the efficacy of a pain treatment and recommended instruments for measuring these domains. The group has encouraged the selection of measures that were developed and normed for a specific population (e.g., low back pain patients) when such instruments are available.

INTRODUCTION

Physicians dealing with the evaluation and treatment of patients with chronic painful and disabling conditions can expect to be called on from time to time to formally assess the disability of their patients. Recent estimates indicate that more than 40 to 50 million persons are currently living with potentially disabling conditions,1 and these numbers are likely to increase in the next few decades with our aging generation of baby boomers. Continued advancements in medical and surgical technologies enable increased survival after catastrophic injuries and illnesses and may help mitigate the disabling consequences of the same, as well as allow an increased prevalence of disability within our society. As the face of our disabled population changes, treating physicians can adapt their practice to better address the needs of patients associated with these changes by gaining greater familiarity with and understanding of the concepts and terminology of disablement and the practices of impairment rating and disability evaluation.

This chapter is intended to provide pain specialists with a practical vocabulary of the terminology and definitions unique to the emerging field of disability medicine, to provide a brief historical and conceptual overview of models of disablement and U.S. disability systems, to familiarize pain specialists with the processes and tools available for impairment rating and disability determination, and to examine the medical-legal pitfalls and ramifications of these clinical activities.

WORKING TERMINOLOGY AND DEFINITIONS

The following terms and definitions are frequently applied to the evaluation and reporting of disablement:

**Aggravation:** A circumstance or event that permanently worsens a preexisting or underlying and susceptible condition.

**Exacerbation:** A circumstance or event that temporarily worsens a preexisting or underlying and susceptible condition.

**Apportionment:** A determination of the percentage of impairment directly attributable to preexisting or resulting conditions and directly contributing to the total impairment rating derived.

**Causality:** An association between a given cause (an event capable of producing an effect) and effect (a condition that can result from a specific cause) within a reasonable degree of medical probability. Causality requires determining that:

- An event took place.
- The claimant experiencing the event has the condition (i.e., pathology, impairment).
- The event could cause the condition (biologic plausibility, etc.).
- Within medical probability the event did cause the condition.

**Impairment:** A significant deviation, loss, or loss of use of any body structure or function in an individual with a health condition, disorder, or disease.

**Maximum medical improvement (MMI):** The point at which a condition (impairment) has stabilized and is unlikely to change (improve or worsen) substantially in the next year with or without treatment. MMI is thought to occur when the following criteria have been satisfied:

- A sufficient healing period has transpired (usually based on an analysis that includes consideration of the natural course of disease for the specific pathology, which in some cases may be days, months, or rarely even years.
- The medical condition (impairment) has fully resolved or has reached a static and stable status (plateau), after which no further reasonable progress occurs or is expected to occur in the next 12 months toward resolution of the pathology.

MMI does not preclude any deterioration of a condition that is expected to occur with the passage of time (i.e., beyond 12 months), nor does it preclude allowances for ongoing follow-up or maintenance medical care should such care be indicated based on current evidence-based practice generally accepted by the scientific community.

MODELS AND CLASSIFICATION OF DISABLEMENT

MODELS OF DISABILITY

The “medical model” of disability was the paradigm for understanding disablement throughout much of the 19th and 20th centuries, during which causation of disability was directly viewed in terms of the underlying pathology (impairment) arising through illness or disease. Management of disability was closely linked to diagnosis and treatment of the underlying pathology, long considered the purview of the physician examiner, who then became empowered to rate, as well as to diagnose and treat, the disabling condition (impairment).

Anatomic and physiologic objectivity is the conceptual lynchpin of the medical model of disability. This model worked well for conditions in which the diagnosis was unambiguous and the pathology was well understood and in which treatment strategies and end points were often well established and also clearly understood. Today, the medical model still serves as the basis for Social Security disability determinations (see later).
The “social model” of disability grew out of the disability advocacy movement of the 1970s and 1980s and was founded on the notion that society imposes disability on individuals with impairments by failing to address their special needs in terms of priority awareness, environmental access, and infrastructural accommodation for major life activities. The resulting disability was viewed in terms of restrictions imposed on the impaired individual ranging from individual and institutional prejudicial thinking and discrimination, architectural and other physical barriers to access and transportation, educational segregation, and lack of accommodation in the workplace. An understanding of the social model has helped foster strategies to better neutralize social barriers to individuals with impairments, thereby enabling them and minimizing their disability.

The “biopsychosocial model” of disability is now widely accepted as the preferred conceptual model of disablement. It simultaneously recognizes the contributions of medical, social, personal, and psychological determinants of disability. The biologic component refers to the physical and mental aspects of an individual’s health condition, the psychological component recognizes personal and psychological factors that are affecting that individual’s functioning, and the social component recognizes contextual and environmental factors that may also have an impact on functioning in each particular case.

**CLASSIFICATIONS OF DISABLEMENT**

The most commonly used, contemporary, internationally accepted definitions, terminology, and classification of disablement have been created by the World Health Organization, the origins of which can be traced to the work of Bertillon’s *Classification of Causes of Death* (1893), which later was expanded into the *International Statistical Classification of Diseases, Injuries and Causes of Death* (ICD). In 1948 the World Health Organization took over this effort, which ultimately led to creation of the *International Classification of Impairments, Disabilities and Handicaps (ICIDH)* in 1980. This system applied a model of disablement with four ordinal domains linked in a linear relationship as follows (Fig. 17.1):

**Pathology**—“a disease or trauma acting at a tissue anatomical or physiological level to potentially alter the structure and/or function of an organ.”

**Impairment**—“any loss or abnormality of psychological, physiological or anatomical structure or function and resulting from a pathology.” Impairment occurs at an organ system level.

**Disability**—“any restriction or lack (resulting from impairment) of ability to perform an activity in the manner or within the range considered normal for a human being.” Disability is commonly conceptualized in terms of limitations in activities within one’s personal sphere, including mobility (transfers and ambulation) and self-care (activities of daily living [ADLs]).

**Handicap**—“a disadvantage for an individual that limits or prevents fulfillment of a role that is normal (depending on age, sex, social and cultural factors) for that individual.”

There were several shortcomings of the ICIDH system. It was rooted in the medical model of disease, whose limitations are described above. The linearity of the system implies a unidirectional and causal relationship among its elements, which may not always be the case. It inadequately accounted for various modifiers (e.g., personal, environmental) that could influence the magnitude of disability; for example, other work showed that environmental factors play a key role in determining outcomes of disability, which could be studied independently. Subsequent work by the Institute of Medicine (IOM) and the National Center for Medical Rehabilitation Research (NCMRR) expanded on the view that the resulting disability was the product of the individual with an impairment interacting with the environment in each specific case. Additional attention was given to the role of personal modifiers (e.g., lifestyle choices, belief systems, entitlement, and coping abilities) affecting the outcomes of disability for individual cases.

The *International Classification of Functioning, Disabilities and Health: ICF* is depicted in Figure 17.2. The ICF has replaced the ICIDH and portrays an interactive (as opposed to linear) association between an individual with a health condition, the functional consequences of the impairment, and contextual factors of a personal and environmental nature. The ICF classification system embraces the biopsychosocial model of disease described earlier by taking into account environmental and personal modifiers of functional outcomes in any given case.
The components of disablement according to the ICF classification system include the following:

- **Body functions and body structures**: physiologic functions and body parts, respectively
- **Activity**: execution of a task or action by an individual (typically within that person’s personal sphere)
- **Participation**: involvement in a life situation (typically within a social sphere)
- **Impairments**: problems in body function or structure such as a significant deviation or loss
- **Activity limitations**: difficulties that an individual may have in executing activities
- **Participation restrictions**: problems that an individual may experience in involvement in life situations

Within this conceptual framework the disabling consequences of impairment may be amplified or mitigated by factors unique to the individual with a health condition, by interaction with the environment, and by personal choice. To illustrate the importance of environmental factors, consider Vignette 1:

**Vignette 1**

A farmer in rural Iowa suffers a unilateral medium-length transradial amputation of the forearm in a combine accident. He would probably have immediate access to level 1 trauma services on an emergency basis and receive timely and appropriate surgical and medical care to repair and heal the residual limb. He would benefit from rehabilitation and most likely from fitting with a body-powered upper limb prosthesis with an appropriate industrial-grade terminal hook device. With proper training and motivation, he could recapture the majority of his “baseline” functional activities—indeed ADLs, household activity, community activity, and work (with some limitations). If need be, he might also be fitted with a myoelectric or cosmetic hand, or both, thereby maximizing his full functional potential. Alternatively, a similar clinical scenario in a “third world” country could have a significantly less favorable functional outcome. Consider a transradial amputation in a local Haitian resident following the devastating earthquake in 2009, where the availability of timely medical and surgical care was compromised by local destruction of the existing medical infrastructure and access to rehabilitative care and adaptive technology was scarce or nonexistent. In such a scenario the less fortunate individual might be left with one functioning upper limb and be destined to manage ADLs with one-handed techniques indefinitely.

To illustrate the importance of personal choice, consider Vignette 2:

**Vignette 2**

A long-term smoker with advanced chronic obstructive disease has measurable pulmonary impairment as noted by a significant reduction in forced expiratory volume in 1 second (FEV₁) on pulmonary function testing. The probability of the symptoms worsening and a further decline in FEV₁ over time is directly linked to the amount and duration of continued smoking, and consequently, the impairment can be substantially mitigated or worsened simply by making a personal choice to adopt or reject permanent smoking cessation.

Despite its superiority as a classification system, shortcomings of the ICF can be noted. The distinctions between activities and participations are often blurred, and inadequate attention has thus far been given to measures of quality of life (QOL) (e.g., life satisfaction, burden of care) in the model itself.

### MEASURING DISABILITY FOR COMPENSATION PURPOSES

Social justice requires that individual group members contribute productively to the common good of the whole. Provisions must be made, however, to exempt this requirement and to support members who are incapable of such productivity by virtue of age, illness, or disability. A related expectation is that individuals who incur loss or disablement as a result of illness or injury are thereby entitled to some compensation for their loss.

Within our social system there exist a number of different disability systems (see later) designed to compensate individuals for such loss. They share a common conceptual and operational platform in which the initial estimate of physical or psychological loss (or both) can be translated into an estimate of functional and economic loss expressed in monetary terms.

By convention, the severity of physical and psychological loss is operationally defined and measured in terms of a *medical impairment rating* at an organ system level that is typically expressed as a percentage of regional loss of the affected body part or parts and that can be further extrapolated to the body as a whole. The severity of functional and hence economic loss associated with this impairment percentage is further estimated in terms of a *disability rating* expressed as a percentage of the economic worth of the “whole person.” The disability rating is operationally derived from the impairment percentage and is at once intended to reflect direct economic losses, noneconomic losses, and negative impact on QOL in terms of a monetary sum. The whole person value and the magnitude of awards vary according to the disability system in question, and disability payments may be awarded as a lump sum or on an annuity basis.

The IOM recently developed a generalized model to demonstrate the essential features common to all disability systems. Individuals seeking compensation and meeting the criteria for entitlement must demonstrate losses according to five domains of interest (see Fig. 17.3).

The first of these, *medical impairment*, traditionally carries the most weight for several reasons. It is largely anatomically and physiologically based and hence can readily be measured in objective terms. Objectivity enables codification of the disability and fosters standardization, reliability, and reproducibility of measurement according to some uniform scale. Impairment can be measured and expressed in terms of anatomic or functional losses.

The second domain of interest, *functional limitations*, can be expressed and measured in terms of basic ADLs or instrumental activities of daily living (IADLs), or both. ADLs include such basic activities of self-care as feeding, toileting, grooming, bathing, hygiene, and dressing—activities that generally occupy our personal sphere. IADLs require greater cognitive and physical capacity and include...
such activities as meal preparation, driving, and managing finances, medications, and one’s daily routine.

The third domain, work disability, can be understood in terms of loss of earning capacity (an actuarial determination of negative impact on employability and earnings brought about by work restrictions because of the impairment and other considerations such as age, baseline employment and earnings history, availability of accommodation and alternative job opportunities, and other local factors). It can also be understood in terms of actual loss of earnings directly attributable to the impairment.

A fourth domain, nonwork disability, includes losses in terms of inability to visit friends and relatives and to engage in communal activities, hobbies, or other recreational pursuits because of barriers to access or performance attributable to the impairment.

A fifth domain, quality of life, includes losses attributable to diminished life satisfaction and self-esteem and increased burden of care in terms of treatment compliance and caregiver support.

The metrics whereby each of these constructs is defined and measured vary and remain incompletely understood. This is partly due to the persisting confusion in terminology, definitions, and criteria for impairment and disability across the various systems and the continuing emphasis on objective, medically determined impairment as the prime determinant of disablement.

Unfortunately, there is also lack of agreement on the metrics whereby the impairment ratings themselves are determined between and even within the various disability systems of interest. For example, U.S. workers’ compensation (WC) jurisdictions show considerable variability in terms of their acceptance or rejection of standard and uniform impairment rating guides, and those that mandate or recommend use of the same vary in the choice of reference; even in the case of the American Medical Association Guides to the Evaluation of Permanent Impairment (AMA Guides), the actual edition chosen for reference varies from state to state. The same is true for international use of the AMA Guides, where in many countries (e.g., Australia, the Netherlands, South Africa), the various editions are used for individuals in motor vehicle accidents and with other personal injury claims to determine the severity of injury (a threshold) before access to benefits for general damage (nonpecuniary, noneconomic losses) is granted.

The importance of the impairment rating to cash awards also varies within and between the various disability systems, as a closer examination of the U.S. WC system illustrates. Operationally, the WC system awards cash benefits according to three basic approaches: the first of these, the impairment approach, awards benefits in direct relation to the percentage-of-impairment rating; the second, the loss of earning capacity approach, requires that the injured worker have an impairment rating but then bases the actual amount of cash benefits on the estimate of associated loss of earning capacity; the third approach, the actual wage loss approach, requires the worker to have both an impairment and loss of earning capacity and then bases the amount of cash benefits on demonstration of the actual loss of workers’ earnings.

The mechanism by which WC cash benefits are awarded is further complicated by distinguishing between various types of injuries as scheduled versus unscheduled. Scheduled injuries are those typically affecting the upper or lower extremities and listed as percentage of the extremity; unscheduled injuries affect the spine, nervous system, or other organ systems and are awarded as percentage of the “whole person.”

Although the impairment rating is the common factor in determination of disability for cash benefits, it is not the sole factor. In practice, however, many jurisdictions implement procedural shortcuts whereby the impairment rating percentage becomes a direct surrogate for the disability rating according to a predetermined formula that multiplies the impairment percentage times a number of weeks’ wages (up to a cap) times a percentage (generally 2/3 to ¾) of the average weekly wage (up to a cap) to determine a lump sum payout. The adequacy of applying the impairment rating as an operational surrogate measure of disability continues to be a subject of debate.

Implications for pain sufferers can be noted as follows: the metrics for the medical impairment rating clearly favor and emphasize objective over subjective criteria. Accordingly, painful entities such as headache, fibromyalgia, and low back pain often occur in the absence of objective verifiable pathology or may occur in a setting in which objective clinical findings are most consistent with normal anatomic variation and the aging process and may be of little or no clinical significance to the individual’s actual complaints. Impairment ratings in such cases are ineffective, at best, since minimal or no rating percentage is currently allowed for any apparent (and often profound) negative impact that these conditions may be having on ADLs. The disablement and ensuing loss in such cases potentially become more evident if viewed in terms of QOL. Well-respected psychometric instruments are now available to measure QOL; notable
examples include the Quality of Well Being (QWB) scale, the WHOQOL-100, and the Quality of Life Index (QLI). Unfortunately, such metrics are not familiar tools to the typical rating physician and are not routinely taken into account by the rating systems per se; consequently, losses in terms of QOL remain largely unaccounted for by the rating practice summarized above.5

**U.S. DISABILITY SYSTEMS COMPARED (TABLE 17.1)**

**WORKERS’ COMPENSATION**

WC law is determined by jurisdictional statutes, which vary from state to state and may differ in terms of the definition of an employee-employer relationship and the exemptions that may apply. WC is a no-fault system whereby the injured employee forgoes the right to sue the employer for damages in most cases in exchange for coverage when eligibility requirements are met. A causality determination must be made that the injury or illness arose out of and in the course of employment and occurred while the employee was at work and actively participating in work activity (job-related social and recreational activities generally do not qualify). Coverage is established in accordance with jurisdictional statutes, and to qualify for wage loss benefits, the injured employee’s condition must persist beyond a statutory waiting period that typically extends from 0 to 7 days; the injury or illness must also be reported to the employer within 30 days of onset and a claim filed within 1 year for disability and 2 years for death.26-28

WC benefits include survivor benefits (in the case of death), medical and rehabilitation expenses, and wage loss benefits (typically ⅔ the weekly wages up to a cap). An employee risks forfeiture of benefits if the claim is due to intoxication or substance abuse at the time of injury, for refusal to return to work after being medically cleared and to qualify for wage loss benefits, the injured employee’s condition must persist beyond a statutory waiting period that typically extends from 0 to 7 days; the injury or illness must also be reported to the employer within 30 days of onset and a claim filed within 1 year for disability and 2 years for death.26-28

Disability under WC can be determined to be temporary or permanent, partial or total. Many states have enacted a second injury fund whereby employment of individuals with preexisting work-related disabilities is encouraged. Such funds can reduce employer risk (hence cost to ensure) for excessive compensation and medical expenses in such cases.27

Physician rating schedules vary among WC jurisdictions, the majority of which require or recommend a version of the AMA Guides.8,21

**SOCIAL SECURITY**

The Social Security Administration (SSA) is the largest U.S. disability system, with an estimated ⅓ to ⅔ of all persons qualified as disabled being assisted. Coverage is typically extended to persons whose medical disablement renders them unable to “engage in any substantial activity by reason of any medically determinable physical or mental impairment that can be expected to result in death or that has lasted or can be expected to last for a continuous period of not less than 12 months.”27,28

The SSA offers two separate disability programs: the first, Social Security Disability Insurance (SSDI), extends coverage to disabled workers who have worked in a qualified job for 5 of the 10 preceding years and who are younger than 65 years. SSDI is funded through the Federal Insurance Contribution Act (FICA) payroll tax, with deductions covering Old Age and Social Disability Insurance (OASDI). Benefits are afforded to those considered totally incapacitated and their surviving spouses and children and are provided in the form of a monthly stipend.27

The second program, Supplemental Security Income (SSI), provides income for medically indigent persons who suffer from blindness, disability, or old age (>65 years of age). Eligibility is determined according to a means test and also extends to disabled children who demonstrate an inability to function independently and in an age-appropriate fashion. SSI operates as a federal-state partnership that is funded through general revenue (federal and state income tax) and does not require a work history to be eligible.27,28

A separate physician rating scale is provided by the SSA.29

**DEPARTMENT OF VETERANS AFFAIRS**

The Veterans Benefits Administration (VBA) within the Department of Veterans Affairs oversees the Compensation and Pensioning (C&P) Service, and all veterans who have received an honorable or general discharge from active military service are eligible for benefits. Entitlement may be service connected for injuries or disease incurred or aggravated during the time of active duty or non-service connected for conditions determined to be unrelated to active duty. Entitlement is determined by the C&P Service’s Adjudication Division.

Disability compensation for eligible veterans is paid out in monthly pensions not subject to state or federal income tax, is adjusted by Congress to reflect changes in cost of living, and varies according to the number of dependents. In the event of death, monthly benefits are payable to the surviving spouse or children. Additional benefits include hospitalization and medical care, orthotic and prosthetic devices, durable medical equipment, and adaptive modifications to home and vehicle.30

The Veterans Administration Schedule for Rating Disabilities (VASRD)31 is the required physician rating schedule within the VBA.

**FEDERAL EMPLOYEES COMPENSATION ACT**

The Federal Employees Compensation Act (FECA) is the federal workers’ compensation program, a no-fault system in which a federal employee cannot sue the federal government or recover damages under any other statute governing work-related injuries. It is adjudicated by the Office of Workers’ Compensation (OWCP) of the U.S. Department of Labor (USDOL) and provides coverage to more than 3 million civilian employees of the U.S. Government, U.S. Postal Service, and Peace Corps. It also covers nonfederal employees such as state and local law enforcement personnel and employees of the Civil Air Patrol. It provides benefits, including ⅔ to ⅔ wage loss compensation as a monthly stipend, as well as uncapped medical benefits.27

The physician reference guide for FECA is the sixth edition of the AMA Guides.

VARIOUS OTHER DISABILITY PROGRAMS

The Longshore and Harbor Workers Compensation Act (LHWCA) covers shoreside maritime employees for occupational disabilities arising during longshore work, ship building, and other shoreside maritime activity. It is a no-fault federally administered system under the USDOL. Benefits include full medical care, wage loss compensation of up to ½ the weekly wages, death benefits, and lump sum awards. The physician reference guide for the LHWCA is the sixth edition of the AMA Guides.

The Federal Black Lung Program provides coverage of coal miners engaged in surface or underground activity for total disability secondary to pneumoconiosis (black lung) arising from employment in and around coal mines. It is administered through the USDOL. The diagnosis of pneumoconiosis must be made with special chest radiographs according to the International Labor Organization (ILO) classification system. Chest radiographs require official interpretation by B-readers, who are physician specialists certified by the National Institute of Occupational Health and Safety according to the ILO system. Claimants must demonstrate total disability from pulmonary causes as documented by pulmonary function test results according to the USDOL.

The Federal Employers Liability Act (FELA) provides disability benefits for railroad workers under a potentially adversarial system whereby the claimant must prove negligence on the part of the railroad; it has disadvantages similar to those existing under tort law before no-fault systems. Claimants may recover economic damages, as well as receive compensation for “pain and suffering.” Additional benefits may include retirement, sickness, and disability annuity payments.

The Jones Act (Merchant Marine Act) covers sailors for permanent injury suffered while in service of a ship in navigable waters. The system is potentially adversarial in that the claimant must file suit against the ship’s owner; since seamen are regarded as wards of the state, they enjoy liberal treatment by the court system in general and most claims are likely to be settled out of court.

Private disability systems offer long-term disability insurance that is generally available through the workplace. Specific contractual language governs the criteria for eligibility, entitlement, and benefits. The injured party must complete a 90-day waiting period, after which the long-term disability policy takes effect. Such policies may be group policies (more affordable), with coverage of individuals who cannot perform their usual and customary job during a finite period (typically 2 years). Subsequently, disability benefits may continue only if the individual can be determined to be unable to perform any occupation according to the definitions and provisions of the policy. Individual policies, though requiring higher premiums, may provide coverage to individuals who cannot continue to perform their own occupation for a more extended period. Private disability generally pays up to 65% of the individual’s wages (to a cap) and may have a built-in cost-of-living allowance to adjust for inflation.

The process whereby disability determinations are made requires that an initial impairment rating be determined according to standard and specific medical criteria. Since the physician is empowered and charged to render such ratings, the AMA has produced a rating manual to assist physicians in this regard. The AMA Guides is a standardized, objective reference for this purpose that was originally published in 1971 as a compilation of a series of impairment rating articles for different organ systems that were published in the Journal of the American Medical Association from 1958 to 1970. It has periodically been updated and revised to the most current of the AMA Guides published in 2008.

The AMA Guides is recognized nationally and globally as the preferred reference for medical impairment ratings. Various editions are required or recommended by statute in the majority of U.S. WC jurisdictions. The sixth edition of the AMA Guides has recently been adopted by 15 of these jurisdictions and is the reference mandated by the USDOL for the various disability systems outlined earlier; it has also been adopted and used internationally in WC and personal injury claims, including 9 of 10 Canadian provinces and all 3 Canadian territories, the Netherlands, Australia, New Zealand, Hong Kong, and Korea.

The sixth edition of the AMA Guides builds on the precedent of the fifth edition of the AMA Guides in placing increasing emphasis on a diagnosis-based approach, with particular emphasis on musculoskeletal impairment ratings of the spine and extremities. Diagnosis-Based Impairment (DBI) grids are provided for each anatomic region (cervical spine, thoracic spine, lumbar spine, and pelvis for the spine; digits and hand, wrist, elbow, and shoulder for the upper extremity; and foot and ankle, knee, and hip for the lower extremity). Each grid has five potential impairment classes (class 0 to 4), consistent with the ICF classification system, and each covers a broad and precise array of diagnoses ranging from soft tissue conditions (nonspecific, chronic, or recurrent), to muscle-tendon and motion segment injuries (sprains, strains, tendinopathy), to ligament, bone, and joint injuries (fractures, dislocations, arthrodesis, etc.). Impairment rating is a two-step process whereby initial assignment to an impairment class requires the rating examiner to identify the most appropriate diagnosis, and each DBI class has an available range of impairment values with an initial “default” midrange value. The rating is then adjusted within range as a second step by using three separate criteria (functional history, examination findings, and clinical test results) to validate the diagnosis and severity of the condition and by using a simple triangulation method to enable a final numerical adjustment upward for less favorable outcomes or downward for more optimal outcomes according to the specific result in each case.

MEDI COLE G LE CONSTRUCTIONS AND CONSTRAINTS

A pain practitioner in general has unique legal liabilities that include administrative, civil, and criminal liability exposure at both the state and federal level, discussion of
which is beyond the scope of this chapter. Alternatively, a brief overview of the interaction between impairment and the disability assessor and the law is indicated. A pain practitioner participating in such evaluation is encouraged to become familiar with the emerging field of disability medicine, which is described as a subspecialty of clinical medical practice that encompasses the identification, prediction, prevention, assessment, evaluation, and management of impairment and disability in both human individuals and populations.33

**THE INDEPENDENT MEDICAL EXAMINATION**

An independent medical examination (IME) is (usually) a one-time evaluation performed by a physician examiner who is not treating the patient or claimant to answer specific questions posed by the referring party, including determination of MMI, impairment rating, and return-to-work restrictions, if applicable.2 IMEs are examinations performed by a physician who is not involved in the person’s care for the purpose of clarifying medical and job issues. IMEs are performed to provide information to case management and for evidence in hearings and other legal proceedings. IMEs are a component of most WC statutes, although the specifics vary by state and country. They are performed at several stages during the cycle of injury or illness, treatment, rehabilitation, and return to work. The key issues associated with an IME differ from clinical consultations in role and focus. In the WC arena, IMEs may be performed any time there is a dispute, concern, or question regarding the medical treatment or condition of the injured worker. These issues include such topics as the following:

1. **Diagnosis, proximate causation, and work-relatedness of an illness or injury**
2. **Current and proposed medical treatment or diagnostic efforts**
3. **Appropriate work and general activity level during treatment**
4. **Stability of the medical condition and status regarding MMI**
5. **Identification of other nonmedical factors that can have a significant impact on the outcome of the medical condition or treatment**
6. **Impairment rating and related disability issues under certain circumstances**
7. **Ability to return to work (fitness for duty) and reasonable accommodation**

IMEs can help untangle the complex relationship between pathology (a medical condition or diagnosis), impairment (anatomic or functional abnormality or loss), limitations in activity (a reduction in ADLs that can be assessed by functional metrics), and restrictions in participation (a reduction in ability to perform socially defined activities or roles).

The opinions set forth in the IME report are expected to be expressed in terms of medical probability versus medical possibility in all cases where the following definitions apply:

*Medical possibility*: Something could occur as a result of a particular cause (probability of 50% or less).34

*Medical probability*: Something is more likely to occur than not (probability exceeding 50%).34

**PHYSICIAN TESTIMONY AND LIABILITIES**

The IME is a form of expert witness testimony that embraces the important task of assessing claimants’ health in accordance with their legal rights, entitlement, and potential for monetary gain. The independent medical examiner, acting as an agent for the consulting party rather than as a patient advocate, also bears the risk of becoming a target for allegations of wrongdoing leveled by a disgruntled claimant.

From a legal perspective, an independent medical examiner or a disability evaluator is essentially an expert witness. Accordingly and until recently, the expert had enjoyed essentially the same type of immunity as any other witness in the judicial process. This immunity from civil liability ran quite deep and included protection from claims of defamation and negligence. The witness immunity can be traced back to 16th-century English common law.35 The idea behind witness immunity was to ensure that the witness would speak freely when giving testimony.36 Subsequently, the American courts considered the issue of witness immunity to be so important that it was maintained even when there might be negligence.37 Traditionally, the argument for such immunity has been that expert witnesses are an important part of the legal system and that in the interest of justice, expert witnesses need to be protected from liability. Several state courts have affirmed the concept of witness immunity for reasons of public policy because without immunity, there would be loss of objectivity and the fear of infinite vexation would have a chilling effect on the witness and a reluctance to testify.38

The U.S. Supreme Court in the 1980s confirmed the importance of witness immunity in two cases. In *Briscoe v LaHue*39 the court noted that a witness who knows that he might be forced to defend a subsequent lawsuit and perhaps pay damages might be inclined to shade his testimony in favor of the potential plaintiff and to magnify uncertainties and thus deprive the finder of the fact (judge or jury) of candid, objective, and undistorted evidence.

In *Mitchell v Forsyth*40 the U.S. Supreme Court reasoned that witness immunity is important because the judicial process is an arena of open conflict and in virtually every case there is, if not always a winner, at least one loser. The court noted that it is inevitable that many of those who lose will pin the blame on witnesses and would bring suit against them in an effort to relitigate the underlying conflict.

The continuous theme that ran through these cases emphasized that the object of immunity is not to protect those whose conduct is open to criticism but to protect those who would be subject to unjustified and vexatious claims by disgruntled litigants. However, a recent development in the law of liability of expert witnesses in the past 2 decades has caused many cracks in the expert witness armor.

The legal liabilities of an independent medical examiner as an expert witness are mainly grounded in legal theories (referred to in legal parlance as causes of action) of tort law and to some extent in contract law by which the injured party as a plaintiff may bring a lawsuit against a health care provider (Box 17.1). It should be noted that a liability claim against a practitioner can be and is usually brought simultaneously under several legal theories. The plaintiff’s hope is to win under any or all of these claims and receive a monetary award from the defendant practitioner.
The underlying principle of common law (both law of tort and contracts) is to provide a venue for a person who has suffered damage as a result of an action or inaction by others to seek redress for his or her grievance in the courtroom. Tort law has been described as a great equalizer because it gives the individual an ability to bring a potentially mightier wrongdoer (referred to in legal parlance as a tortfeaser) before the bar on a more equal footing for the wrongs that may have been done to the person and secure compensation for the loss. Obviously, the law cannot make tortfeasors undo the injury or harm but makes them pay monetary compensation for both intentional wrongs (e.g., defamation, assault and battery) and unintentional wrongs (e.g., negligence). The law of tort not only shifts the burden of the cost of the injury or damages to the responsible party but also serves to prevent similar harm to other members of society through enforced accountability. The idea is to make the offensive and undesirable behavior costly to the tortfeaser and in principle serves to deter others from engaging in behavior such as the defendant’s in the future.

Traditionally, health care providers’ liability to their patients arises out of medical malpractice claims. The term malpractice refers to any professional misconduct that encompasses an unreasonable lack of skill or unfaithfulness in carrying out professional or fiduciary duties. The law of torts under the theory of negligence is the most common basis for a medical malpractice action against a health care provider. However, under this action the plaintiff must prove that the practitioner had a duty to the patient and breached that duty as a result of which (causation) harm or damage occurred.

Up until recently, medical malpractice actions against IME doctors and expert witnesses failed because of lack of a doctor-patient relationship with the examinee or plaintiff. The continuous theme that ran through the cases across various jurisdictions in the United States was that as long as the IME doctor neither offered nor intended to treat the individual examinee, there was a lack of a doctor-patient relationship that prevented sustaining the medical malpractice cause of action. Many potential cases were either not filed because of a prevailing notion among the legal community based on the previous case law or, when filed, were dismissed on pretrial motions from the defendants. This has, however, changed significantly in the past 2 decades, with increasing case law from various jurisdictions holding independent medical examiners and expert witnesses accountable for the alleged harm suffered by the plaintiff/examinee. This was initially done under the cause of action of simple negligence and outside the law of torts for medical malpractice.

More recently, at least two state Supreme Courts have allowed civil action against IME doctors to proceed under the traditional medical malpractice theory. Legal commentators have observed that this increasing erosion of immunity from civil action for the independent medical examiner as an expert witness is due to proliferation and growth of the litigation/expert witness industry, as well as to courts’ perception of lack of protection of the injured party from unscrupulous witnesses and inadequacy of the traditional safeguards against expert witness malfeasance from potential prosecution for perjury and inadequate cross-examination. The beginning of this trend of judicial hostility toward expert witness immunity can be traced back to the mid-1990s, when state courts in the United States started holding independent medical examiners and expert witnesses without any doctor-patient relationship accountable to their examinee in ordinary negligence. This trend began in Colorado with the Greenberg v Perkins case. Several other jurisdictions have since followed suit. The Virginia Supreme Court in Harris v Kreutzer held as a matter of first impression (making a new precedent) that a doctor could be sued for malpractice for negligent performance of mental and physical examination of a party during an IME.

Similarly, the Court of Appeals in Arizona in the Stanley v McCarver case found that a formal doctor-patient relationship is not the only source of a doctor’s duty toward a patient and that the doctor owed a duty of care to the patient despite the absence of a formal doctor-patient relationship. The Arizona Supreme Court took it a notch further in Ritchie v Krasner and allowed medical malpractice to go forward despite no doctor-patient relationship by essentially stating that the court can envision no public benefit in not holding a doctor accountable to a duty to conform to the legal standard of reasonable care.

As can be seen from the above, under the case law of various jurisdictions in the United States, the immunity of expert witnesses (as well as IME doctors), traditionally enjoyed until recently against a variety of legal causes of action, is now rapidly eroding.
of the Atlantic is even worse. In a recent decision by the U.K. Supreme Court in the Devaney S. Jones v Karney case, expert witnesses were practically stripped of all the immunities that are available to fact witnesses in general. After a lengthy discussion the majority of the Jones court concluded that they see no public policy reason to justify immunity for expert witnesses. Even though this recent decision in the United Kingdom has no authority in U.S. jurisprudence, it is nonetheless regarded by some as a persuasive argument.

In summary, pain practitioners should be aware of not only the legal liabilities in the overall practice of their sub-specialty but also the additional liabilities entailed with exposure to IMEs and expert witness work. It should be emphasized that even though the recent case law in some jurisdictions has significantly removed the traditional immunity of providers with no doctor-patient relationship with their examinees from medical malpractice claims, in American jurisprudence there still remains a great need for expert medical witness service. Practitioners attracted to disability assessment and inclined to serve as independent medical examiners are encouraged to attend several of the high-quality training programs offered in the United States to independent medical examiners and expert witnesses with the goal of empowering them with the knowledge, skills, and abilities necessary to practice as an independent medical examiner or expert witness in the field of disability medicine.

**IMPLICATIONS FOR DISABILITY ASSESSMENT OF INDIVIDUALS WITH CHRONIC PAIN**

An important point of this chapter can best be made by drawing into focus the distinction between impairment ratings and disability ratings as they pertain to the issue of pain. As noted above, the construct of impairment is conceptually and operationally grounded in the medical model of disease discussed earlier; impairment is codified and systematically defined according to a predetermined set of objective and measurable criteria for each organ system. Conditions that affect one or more organ systems and manifest themselves in terms of objective, measurable organ system pathology are infinitely ratable according to these organ systems. The painful experience that often accompanies specific pathology can and should be accounted for in some systematic manner and included in such ratings. However, pain can occur in the absence of observed pathology specific to the organ system, and chronic painful conditions transcend the organ system boundaries of the individual and can perhaps best be described and understood in terms of the biopsychosocial model described above.54

Global pain or other chronic painful conditions not attributable to any specific organ system pathology according to the impairment rating method alluded to earlier can perhaps be more adequately accounted for by adopting and applying QOL measures. Such metrics have the necessary empirical foundation from which to develop standards for losses in terms of nonvocational function, life satisfaction, and the burden of care and medical compliance needed to maintain optimal function in the presence of chronic pain and other disabling conditions.25 Such metrics, when applied properly, can and should enable modification of any disability payment as a percent add-on or stand-alone cash award according to the specifications of each disability system. Perhaps the disabling consequences of chronic painful conditions can be more favorably captured in overall disability determinations at the point of final integration of the impairment rating, functional outcomes, and other relevant disability criteria as evidenced through such QOL assessments.8 Such a shift in emphasis must recognize that a valid disability assessment of pain may require a skill set and applied metrics beyond those typically embodied by the physician disability examiner. Until this ideal can be more closely achieved, the role of pain as a contributor to disability can most properly be accounted for in two separate ways: pain directly affecting impairment can be viewed in terms of the functional outcomes accompanying a specific impairment, as the following Vignette 3 suggests.

**Vignette 3**

Consider the example of a transradial amputee cited earlier in terms of possible functional results. In a “standard” case with expected medical, surgical, and rehabilitative outcomes and availability of resources, the affected individual should achieve acceptable wound healing and uncomplicated scarification; proximal range of motion should be within functional limits; and fitting of a body-powered prosthesis should be uncomplicated and enable the performance of ADLs bimanually at or near the “baseline” level of ability. A “better than expected” outcome could occur if the amputation was undertaken to correct a preexisting malfunction or painful condition and results in an uncomplicated healing scenario with a better than baseline functional outcome. A less than expected outcome could also occur in the presence of complicated wound healing, painful scarification, or a neuroma making fitting of a prosthetic difficult or ineffective or in the presence of permanent loss of proximal range of motion because of pain, nerve injury, or contracture.

It is now possible, by using the DBI approach outlined earlier for impairment rating as put forward in the sixth edition of the AMA Guides, to modify the “expected” impairment rating upward by means of a functionally based “grade modifier” sensitive to pain and other limiters of function in order to award individuals with additional impairment for pain-associated loss of function.

Alternatively, in cases in which a specific diagnosis is lacking and pain appears to be the primary problem, the sixth edition of the AMA Guides currently offers a “stand-alone” assessment of pain that awards up to 3% loss to the whole person when pain is not effectively rated elsewhere.

Clearly, additional work is needed to perfect our current disability infrastructure and further enhance the relevance, validity, and reliability of medical impairment ratings and to provide alternative metrics to expand and modify disability determinations to properly account for functional losses as a result of chronic pain.
A number of educational venues and reference resources are available to enable interested physicians to gain the additional knowledge, expertise, and credentials needed to perform impairment ratings, disability evaluations, and IMEs competently and authoritatively. Such resources include courses, certification examinations, and several reference texts.

**KEY POINTS**

- Maximum medical improvement (MMI) represents a treatment end point (for purposes of case closure) at which a given ratable condition (impairment) has stabilized (is unlikely to change substantially in the next year with or without treatment) and no further improvement in function can be expected.

- The “biopsychosocial model” of disability is currently accepted as the preferred conceptual model of disablement because it simultaneously recognizes three components of disability: the biologic component (the physical and mental aspects of an individual’s health condition), the psychological component (personal and psychological factors that are having an impact on the individual’s functioning), and the social component (contextual and environmental factors that may also have an impact on functioning) in each particular case.

- The International Classification of Functioning, Disabilities and Health (ICF) of the World Health Organization is the currently accepted classification system of disablement for purposes of health policy and legislation. It has replaced earlier systems to provide more interactive (as opposed to linear) representation between individuals with a health condition, the functional consequences of their impairment, and contextual factors of a personal and environmental nature potentially affecting their disablement. The ICF classification system embraces the “biopsychosocial model” of disease by taking into account environmental and personal modifiers of functional outcomes in a given case.

- Within our society a number of different disability systems exist to compensate individuals for losses. They share a common conceptual and operational platform in which the initial estimate of physical or psychological loss (or both) can be translated into an estimate of functional and economic loss and expressed in monetary terms.

- By convention, the severity of physical and psychological loss is defined and measured in terms of a medical impairment rating, which represents a percentage of regional loss of the affected body part or parts and can be extrapolated to the body as a whole. The expected degree of functional and economic loss of the affected individual can be further operationally derived from the impairment percentage as a disability rating—a percentage of the economic worth of the “whole person” awarded in terms of a monetary sum that differs for each particular disability system.

- The International Classification of Functioning, Disabilities, and Health (ICF) of the World Health Organization is the currently accepted classification system of disablement for purposes of health policy and legislation. KEY POINTS—cont’d

of the injured worker. These issues include topics such as the following:

1. Diagnosis, proximate causation, and work-relatedness of an illness or injury
2. Current and proposed medical treatment or diagnostic efforts
3. Appropriate work and general activity level during treatment
4. Stability of the medical condition and status regarding MMI
5. Identification of other nonmedical factors that can have a significant impact
6. Impairment rating and related disability issues
7. Ability to return to work (fitness for duty) and need for reasonable accommodation

- Pain practitioners should be aware of not only the legal liabilities in the overall practice of their subspecialty but also the additional liabilities entailed with exposure to IMEs and expert witness work. Practitioners attracted to disability assessment and inclined to serve as independent medical examiners are encouraged to attend several of the high-quality training programs readily available with the goal to empower themselves with the knowledge, skills, and abilities needed to practice as an independent medical examiner or expert witness in the field of disability medicine.

- Additional work is needed to perfect our current disability infrastructure in order to further enhance the relevance, validity, and reliability of medical impairment ratings and provide alternative metrics to expand and modify disability determinations to properly account for functional losses as a result of chronic pain.

INTRODUCTION

Untreated postoperative pain can result in unwanted psychological and physiologic effects that may increase morbidity and mortality, compromise quality of recovery, and increase the incidence of chronic pain. Although management of postoperative pain has improved tremendously in the last few decades, pain in surgical patients is still undermanaged. In 2000, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) officially recognized patients' rights in pain management and implemented standards for assessment, monitoring, and treatment of pain. In 2004, the American Society of Anesthesiologists established the Pain Task Force and published clinical practice guidelines to promote standardization of procedures and the use of multimodal analgesia. In 2010, the Department of Health and Human Services and the Institute of Medicine agreed to promote the recognition of pain as a significant public health problem and to encourage pain research, pain care, and pain education in the United States. Pain management is becoming an important ethical responsibility of the medical profession and a focus of the health care system, thus encouraging many institutions to support the proper practice of pain control for surgical patients. Opioids remain the primary analgesic agent for treating moderate and severe pain after surgery; however, in many cases opioid-related side effects may compromise a patient's quality of recovery.

PREVENTIVE ANALGESIA

Preventive analgesia is a method of preventing or attenuating the central sensitization that results from a painful insult and the inflammatory reaction that develops after the insult. Previously, the term “preemptive analgesia” described mainly the timing of pain intervention (i.e., before vs. after the insult). Its use was controversial, and proving its clinical relevance in clinical trials was difficult. Recent clinical trials have shown that the effectiveness and duration of pain treatment interventions are clinically relevant in blocking or attenuating the noxious stimuli and decreasing central sensitization to pain. For preventive analgesia to effectively prevent central sensitization and reduce postoperative and chronic pain, intensive multimodal analgesic interventions should be used during the perioperative period. Maximum benefit occurs when pain interventions are extended into the postoperative phase. The focus of this chapter is on available pain treatment intervention techniques and drugs for multimodal analgesia in the setting of surgery and trauma.

MULTIMODAL ANALGESIA

Multimodal analgesia involves the administration of two or more analgesic agents by one or more routes that exert their effects via different analgesic mechanisms and ideally act synergistically at different sites in the nervous system, thereby providing superior analgesia with fewer side effects. The concept of a multimodal strategy, including regional analgesia, was introduced more than a decade ago to allow early ambulation, promote better rehabilitation, accelerate recovery, and reduce the length of hospital stay. In the ambulatory surgery setting, evidence has shown great promise for the use of local anesthetics, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs), among other treatment options, with opioids being reserved as a rescue drug only. Some recent publications have found that NSAIDs and selective cyclooxygenase-2 (COX-2) inhibitors consistently reduce postoperative opioid requirements. Furthermore, the combination of several nonopioid analgesics with opioids delivered by patient-controlled analgesia (PCA) offers advantages over opioids alone. Multimodal pain control strategies for certain procedures could become an integral part of clinical pathways to provide effective postoperative analgesia and rehabilitation.

PAIN MANAGEMENT OPTIONS

Pain management is an art; a clinician must balance the risks and benefits of each modality to customize treatment based on a patient's specific needs. Many institutions have recognized that suboptimal treatment of acute postoperative pain occurs frequently and have begun to support the development of postoperative pain services, many of which are led by anesthesiologists who have clinical experience in regional anesthesia and knowledge of drug pharmacology to provide surgical patients with an optimal pain treatment plan that minimizes side effects. Even though pain treatment modalities may decrease morbidity, more common outcomes generally include improvement in the quality of recovery and quality of life. Patient satisfaction can be used as an indicator of an effective treatment response to these programs. Options available for the management of postoperative pain include, but are not limited to, various combinations of...
systemic and neuraxial opioids, nonopioid analgesics, and regional analgesia (neuraxial and perineural).

### SYSTEMIC ANALGESICS

**OPIOIDS**

Opium and its derivatives are the most commonly used medications for the treatment of acute and chronic pain (Table 18.1). Opioids exert their analgesic effect through μ-opioid receptors. These receptors are located mainly in the central nervous system (CNS), although some are also present in the peripheral nervous system. The therapeutic benefits (and side effects) of morphine, the prototypical opioid analgesic agent, are mediated predominantly through activation of μ-receptor subtypes. Although opioids do not exhibit an analgesic ceiling effect, the analgesic efficacy of opioids can be limited by the development of adverse effects such as nausea, vomiting, pruritus, ileus, and respiratory depression.

One of the many advantages of opioid analgesics for the treatment of acute postoperative pain is that it can be administered via a number of routes (e.g., subcutaneous, oral, intravenous [IV], intramuscular [IM], intranasal, transmucosal, and neuraxial). This feature enhances the versatility of opioids as a therapeutic agent. For the treatment of moderate to severe postoperative pain, opioids are typically administered parenterally (IV, IM), although there may be wide interpatient and intrapatient variability in the relationship between opioid dose, serum concentration, and analgesic response in the treatment of postoperative pain. IV administration of opioids is desirable for treating acute postoperative pain because of the rapid and reliable onset of analgesia. Oral administration of opioids is the most common form used for the treatment of mild to moderate postoperative pain or when inpatients have successfully initiated oral intake.

Opioid receptor physiology is complex and regulated by multiple mechanisms that may play a role in the development of opioid receptor tolerance and desensitization. Tolerance and desensitization may contribute not only to a short-term decrease in analgesic efficacy but also to long-term changes in receptor sensitivity. Desensitization may lead to increased analgesic requirements for a similar pain response.

IV PCA is considered the “gold standard” by which systemic opioids are delivered postoperatively. Unlike traditional “as needed” (PRN) analgesic regimens, IV PCA allows the clinician to compensate for several factors, including the wide interpatient and intrapatient variability in analgesic needs, variability in serum drug levels, and administrative
delays, which might result in inadequate postoperative analgesia. The IV PCA device per se has a safety mechanism integrated into its design, although when the negative feedback loop is violated, excessive sedation or respiratory depression may occur.\(^{23,24}\) Most of the problems related to the use of IV PCA are caused by user or operator error and are not attributable to the device itself.\(^{23}\)

Variables that can be programmed into an IV PCA device include the demand or bolus dose, lockout interval, and background infusion. Optimal settings for IV PCA administration of opioids for the management of postoperative pain are not known; however, there are general principles that may promote effective postoperative analgesia. The setting for the demand or bolus dose should be sufficient to provide analgesia after multiple self-administered doses; it should not be an excessive dose that may result in adverse effects such as respiratory depression.\(^{25}\) For opioid-naïve patients, a commonly used demand dose for morphine is 0.5 to 2.5 mg, for fentanyl it is 10 to 20 µg,\(^{23,25}\) and for hydromorphone it is 0.05 to 0.25 mg (Table 18.2). Commonly used lockout intervals range from 5 to 10 minutes, and varying the interval within this range appears to have no effect on analgesia patterns.\(^{27-29}\) However, a background infusion for opioid-tolerant or pediatric patients may be appropriate.

When compared with traditional PRN analgesic regimens, use of IV PCA may be associated with improved patient outcomes, including superior postoperative analgesia, improved patient satisfaction,\(^{30}\) and possibly decreased risk for pulmonary complications.\(^{30,31}\) At least two meta-analyses have been conducted to compare IV PCA with PRN administration of opioids. Both meta-analyses demonstrated that the analgesia provided by IV PCA is superior to that achieved with PRN administration. An early meta-analysis of 15 randomized trials in which PRN IM dosing was compared with IV PCA failed to demonstrate a reduction in opioid consumption.\(^{30,31}\) IV PCA had no obvious economic benefit, although it may be associated with fewer pulmonary complications.\(^{30}\) In addition, patients tended to prefer IV PCA,\(^{30,31}\) which may result in greater patient satisfaction.\(^{56,57}\) Although IV PCA provides no apparent decrease in cost or length of hospital stay, it does reduce demand on the nursing staff, who are required for delivery of IV or IM PRN analgesics. This reduced administration by the nursing staff may indeed have a cost benefit.\(^{34}\) The incidence of opioid-related side effects, including respiratory depression (0.5%), from IV PCA does not appear to differ significantly from that of other administration routes (e.g., IV, IM, or subcutaneous).\(^{23,30,33,35}\) Many factors could contribute to the occurrence of respiratory depression with IV PCA, including the use of a background infusion, concomitant use of a sedative or hypnotic agent, advanced age, and the presence of pulmonary disease or sleep apnea.\(^{23,33}\)

Transdermal delivery of fentanyl, a continuous passive dose, is not indicated for the treatment of acute pain but could be an option for the treatment of chronic cancer pain; it could also be an alternative to oral opioids when patients cannot tolerate oral intake for an extended time. A recent technological development has added the process of iontophoresis to substantially increase dermal penetration capacity and thereby allow in essence a "PCA fentanyl patch."\(^{56}\) Clinical studies have shown iontophoretic patient-controlled transdermal fentanyl to be superior to placebo and comparable to IV PCA with morphine for the treatment of acute postoperative pain.\(^{37,39}\)

*Bolus doses for adults or children should be titrated and based on clinical evaluation of the patient.

†Continuous infusion is not recommended for opioid-naïve adult patients.
Morphine, in either extended-release or immediate-release form, is still the gold standard for oral opioids. Oxycodone is commonly used alone or in combination with an adjuvant such as acetaminophen. One should be cautious of exceeding the total recommended daily dose of acetaminophen because of hepatic toxicity. Transmucosal fentanyl could be used when acute intense pain is anticipated. With opioid conversion, especially in opioid-tolerant patients, the dose should be decreased by 33% because of incomplete cross-tolerance between drugs.40

Tramadol is a centrally acting, synthetic analgesic agent that is structurally related to codeine and morphine. The use of tramadol for postoperative analgesia may confer several advantages over traditional opioids, including the relative lack of respiratory depression, major organ toxicity, constipation, and dependence.41,42 Common side effects of tramadol include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.42,43

Conversion from one opioid or one route of administration to another should be done with caution to avoid underdosing or overdosing. A conversion table (Table 18.3) may facilitate equianalgesic conversion; however, it provides only an estimate to assist in initiating the opioid dose.

### NONOPIOID ANALGESICS

#### NONSTEROIDAL ANTI-INFLAMMATORY AGENTS AND ACETAMINOPHEN

NSAIDs and acetaminophen are a diverse group of analgesic compounds that exhibit different pharmacokinetic properties and produce analgesia presumably by inhibiting COX enzymes and the subsequent synthesis of prostanoid mediators, which are important mediators of peripheral and CNS hyperalgesia.44 COX has at least two isoforms with different functions. The COX-1 isozyme is constitutively present and mediates platelet aggregation, hemostasis, and gastric mucosal protection. The COX-2 enzyme is upregulated during inflammation and may play a role in nociception. Recently, it has been recognized that the COX-2 enzyme may play an important role in cardioprotection via prostacyclin (PGI₂).45

Nonopioid analgesics are used as part of a multimodal analgesic regimen mainly to decrease systemic opioid consumption and improve postoperative pain.46,47 IV acetaminophen, which has been available in Europe for more than 20 years, was recently approved by the Food and Drug Administration (FDA) in the United States and is quickly gaining popularity for the treatment of acute postoperative pain. The mechanism of pain relief with acetaminophen is still not clear. Acetaminophen rapidly crosses the blood-brain barrier48,49 and inhibits central prostaglandins via the COX pathways.50,52 It also triggers the activation of cannabinoid receptors53,54 and inhibits nitric oxide pathways.55,56 Acetaminophen has weak peripheral anti-inflammatory activity, limited gastrointestinal effects, and little impact on platelet function.57 When compared with oral acetaminophen, IV acetaminophen provides faster onset of pain relief, reduces the duration of meaningful pain, and decreases the time to maximal pain relief.49,58-60 Sinatra and colleagues61 demonstrated a 33% reduction in morphine consumption over a 24-hour period when IV acetaminophen was delivered at 1 g every 6 hours after orthopedic surgery. Acetaminophen has also been shown to reduce the doses of narcotics required after tonsillectomy and endoscopic sinus surgery.62

Acetaminophen is available in rectal, oral, and IV formulations. The peak acetaminophen plasma concentration occurs 3 to 4 hours after a rectal dose, 45 to 60 minutes after an oral dose, and 15 minutes after IV infusion.60,63,64 The rectal form has been associated with lower and more unpredictable bioavailability, thus making it less favored for acute postoperative pain.65,66 The dosage for oral and IV acetaminophen in adults is 1 g every 4 to 6 hours, not to exceed 4 g/day. The dose interval should be at least 6 hours in patients with renal insufficiency.58 Acetaminophen has a known potential for hepatotoxicity with excessive doses, but the risk is extremely low with therapeutic doses.63 It is considered safe, with an adverse event profile similar to that of placebo.67-69 Acetaminophen has only limited potential for drug interactions that is independent of the route of administration.70

In a qualitative systematic review of analgesic efficacy in relieving acute postoperative pain that assessed reductions in pain intensity scores and opioid consumption,71 the combination of acetaminophen and NSAIDs was more effective than acetaminophen alone in 85% of relevant studies and more effective than NSAIDs alone in 64% of relevant studies. Several meta-analyses suggest that the use of NSAIDs, COX-2 inhibitors, or acetaminophen in combination with IV PCA does result in an opioid-sparing effect. However, the use of acetaminophen and COX-2 inhibitors does not appear to decrease the relative risk for opioid-related side effects (e.g., postoperative nausea and vomiting [PONV], sedation, pruritus, urinary retention) or adverse events (respiratory depression), whereas the use of nonspecific NSAIDs appears to decrease the relative risk only for some opioid-related side effects (e.g., PONV, sedation).15,72-75 In terms of pain control, the addition of NSAIDs (multiple dose or infusion only) and COX-2 inhibitors, but not acetaminophen or single-dose NSAIDs, produces significantly lower pain scores postoperatively.15,72-73

*Dosages and range of dosages are approximate and used as an estimate of the calculated dose.
†Immediate- and extended-release forms of oxymorphone are approved by the Food and Drug Administration.
IM, intramuscular; IV, intravenous.
Although NSAIDs are an integral part of postoperative pain management, their use is limited by several adverse effects (e.g., gastrointestinal bleeding, impaired renal function, inhibition of platelet aggregation, and inhibition of bone healing and osteogenesis). These adverse effects occur because of the general inhibition of COX and prostaglandin formation. The inhibition of platelet function and decreased perioperative hemostasis result from NSAID inhibition of COX-1, which is responsible for the synthesis of thromboxane A₂, a mediator of platelet aggregation and vasoconstriction.76,77 Although the available evidence on the effect of NSAIDs on perioperative bleeding is equivocal,77,78 High-risk surgical patients (e.g., those with hypovolemia, abnormal renal function, or abnormal serum electrolytes) may be at risk for NSAID-induced renal dysfunction. Prostaglandins dilate the renal vascular beds, and NSAIDs may inhibit these beneficial diuretic and natriuretic renal effects,79 but euvoletic patients with normal renal function are unlikely to be affected.80 Although it is not clear whether NSAIDs may also have an adverse effect on bone healing,81 they may be associated with a higher incidence of gastrointestinal bleeding78 as a result of NSAID-induced inhibition of cytoprotective gastric mucosal prostaglandins (produced by COX-1 activity).76

Traditional NSAIDs block both COX-1 and COX-2 enzymes. The development of selective COX-2 inhibitors was based on the premise that selective inhibition of COX-2 would provide analgesia without the side effects associated with COX-1 inhibition. Although selective COX-2 inhibitors are associated with a lower incidence of gastrointestinal complications82 and exhibit minimal platelet inhibition even when administered in supratherapeutic doses,83 recent data indicate that COX-2 inhibitors may be associated with a higher incidence of cardiovascular events such as myocardial infarction.84 Because COX-2 inhibitors inhibit PGI₂, these agents may actually promote coronary thrombosis via the unopposed action of thromboxane A₂.85 A meta-analysis of rofecoxib trials indicated that administration of rofecoxib is associated with a 2.3-fold greater risk for cardiovascular events.84 Unlike rofecoxib, celecoxib was not removed from the market, although some data suggest that celecoxib is also associated with a higher incidence of cardiovascular events.85,87

KETAMINE
Ketamine is an N-methyl-d-aspartate (NMDA) receptor antagonist and has generally been used as an intraoperative anesthetic agent. Because of its NMDA antagonistic properties, which may attenuate central sensitization (chronic postsurgical pain) and opioid tolerance, ketamine has been re-examined for its potential use in postoperative analgesia.88 The perioperative administration of low-dose ketamine may be integrated into a multimodal analgesic regimen or used as an adjunct to opioids and local anesthetics to enhance postoperative analgesia and potentially reduce opioid-related side effects.88,89 In one study of patients undergoing total knee replacement surgery under general anesthesia, ketamine or placebo was given during surgery (0.2 mg/kg followed by 2 µg/kg/min) and through the second postoperative day (10 µg/kg/min). Pain scores were lower at rest and with movement in the ketamine group than in the placebo group at all times. Time to achieve 90 degrees of flexion was shorter in the ketamine group, and the incidence of PONV was lower.92 A systematic review revealed that perioperative administration of ketamine (vs. control) resulted in lower pain scores and significantly decreased morphine consumption over a 24-hour period, with no difference in morphine-related adverse effects between the groups.93 However, use of ketamine as an adjunct to IV PCA may not improve postoperative analgesia.94 Low-dose ketamine infusions do not appear to cause hallucinations or cognitive impairment, and in patients undergoing general anesthesia, the incidence of hallucinations appears to be low and may be independent of benzodiazepine premedication.95,96,97 Reports of epidural and intrathecal ketamine have been published,97,98 but neuraxial use of ketamine is discouraged until further safety and neurotoxicity data are available. Although intraoperative IV administration of sub-anesthetic ketamine in conjunction with general anesthesia may attenuate acute postoperative pain and potentially chronic postsurgical pain, the role of low-dose ketamine in postoperative analgesia remains unclear.93,99 In addition, it is unclear at this time whether perioperative use of ketamine will result in better long-term recovery or improved functional outcome. Furthermore, evidence is insufficient to show a clear benefit of S(+) -ketamine over racemic ketamine.99

GABAPENTIN AND PREGABALIN
Gabapentin and pregabalin are analogous in molecular structure to γ-aminobutyric acid. Their use in acute pain models has provided promising preliminary evidence for potential routine use.100 Their role in preempting chronic hyperalgesia is uncertain.101 Five studies have shown benefit in acute pain management when an oral dose of 1200 mg gabapentin was administered preoperatively.102-104 One of these studies also incorporated a limited postoperative dosing course (for 10 days after breast surgery) and reported lower opioid requirements and pain scores with movement.105 After abdominal hysterectomy, use of gabapentin (400 mg four times a day for 1 day preoperatively and 5 days postoperatively) led to lower pain scores 1 month after surgery, but not in the immediate postoperative period.106 Somnolence from single-dose gabapentin pretreatment was described only when epidural analgesia was coadministered,105 thus leading to the possibility that the interaction between gabapentin and local anesthetics may augment the sedative effects.

Based on currently available data, randomized controlled trials, and meta-analyses, there is no clear evidence that the perioperative use of pregabalin reduces postoperative pain scores. The use of pregabalin has a great opioid-sparing effect in the first 24 hours and significantly reduces opioid-related side effects (vomiting).108 Side effects of pregabalin are sedation, dizziness, and visual disturbance.

In summary,

- Opium and its derivatives are the most commonly used medications for the treatment of acute and chronic pain.
- IV PCA is considered the gold standard by which systemic opioids are delivered postoperatively.
- Transdermal delivery of fentanyl is not indicated for the treatment of acute pain unless the patient cannot tolerate oral intake for an extended time.
• Conversion from one opioid or one route of administration to another should be done with caution to avoid underdosing or overdosing.
• The use of NSAIDs, COX-2 inhibitors, or acetaminophen in combination with opioids does result in an opioid-sparing effect.
• The perioperative administration of low-dose ketamine may be integrated into a multimodal analgesic regimen to enhance postoperative analgesia.
• Use of gabapentin and pregabalin for the management of acute pain has shown promising preliminary results.

**NEURAXIAL AND PERIPHERAL ANALGESIA**

Perioperative neuraxial or peripheral techniques in general provide better analgesia than do systemic opioids. Continuous administration techniques have the advantage of decreasing adverse perioperative pathophysiology and improving patient outcomes, including major morbidity.109,110

**CONTINUOUS EPIDURAL ANALGESIA**

Continuous epidural analgesia may provide a longer duration of analgesia than an individual injection and analgesia superior to that with systemic opioids.111 Postoperative use of continuous epidural analgesia may be associated with improved patient morbidity by decreasing pulmonary112-115 (Fig. 18.1), cardiovascular,112,114-116 and gastrointestinal117,118 (Fig. 18.2) complications in high-risk patients and after high-risk procedures. However, many factors can affect the overall outcomes of continuous epidural analgesia. Among them are the congruency of epidural catheter location and the surgical incision, the type of analgesic regimen, and whether the epidural is used as part of a multimodal approach.119,120 Local anesthetics used alone or in combination with opioids will offer better physiologic benefit to the patient than opioid use alone. However, premature discontinuation of epidural analgesia may negate its physiologic benefit. When compared with systemic administration of opioids, local anesthetic-based epidural regimens provide superior analgesia and may decrease opioid-related side effects; epidural infusion of opioids alone may be used to avoid hypotension when sympathetic blockade is a concern.

Postoperative epidural analgesia may be delivered as a fixed continuous infusion or as patient-controlled epidural analgesia (PCEA). Based on the principles of PCA, PCEA allows individualization of postoperative analgesic requirements, reduces drug use, improves patient satisfaction, and provides superior analgesia.121,122

The choice of drug for epidural analgesia is usually a local anesthetic with a long duration of action. It should exhibit preferential clinical sensory blockade and cause only minimal impairment of motor function.123 Another option is a lipophilic opioid (e.g., fentanyl or sufentanil), which allows relatively rapid titration of analgesia, although hydrophilic opioids (e.g., morphine and hydromorphone) may also be used for postoperative analgesia.124

Even though clonidine and epinephrine are potentially useful adjuvants, neither is widely used clinically. Clonidine may enhance postoperative analgesia by activating the descending noradrenergic pathway; however, its clinical usefulness is typically limited by the presence of hypotension, bradycardia, and sedation.125,126 Epinephrine has been shown to improve epidural analgesia and increase sensory block in the postoperative setting.127

**NEURAXIAL OPIOIDS**

Classification of opioids is based on their lipophilic property. Hydrophilic opioids (e.g., morphine and hydromorphone) tend to remain within cerebrospinal fluid (CSF) after neuraxial administration and usually produce a delayed but longer duration of analgesia. They also tend to cause a higher incidence of side effects because of CSF spread, unlike lipophilic opioids (e.g., fentanyl and sufentanil), which tend to provide a faster onset but shorter duration of analgesia as a result of rapid clearance from CSF. Hydrophilic opioids provide analgesia primarily via a spinal mechanism, whereas lipophilic opioids provide analgesia via either a spinal or systemic mechanism.128,129 Single-shot neuraxial administration of a lipophilic opioid may be appropriate for short-duration analgesia, but single-shot neuraxial administration of a hydrophilic opioid will be appropriate for longer-duration analgesia. The latter may
provide effective postoperative analgesia in an appropriately monitored setting (Table 18.4). It is essential that the dose of neuraxial opioid be reduced with use in older patients.

Although some studies indicate that the incidence of pulmonary and cardiovascular comorbidity may be lower with neuraxial morphine than with systemic opioids, the overall benefit is observed only when compared with intermittent IV doses and not when compared with IV infusion of opioids. Neuraxial opioids are associated with side effects that could affect patients' quality of recovery. Side effects include nausea and vomiting in more than 50% of patients and pruritus in up to 60%, as opposed to 15% to 18% for PCEA with local anesthetic or systemic opioids. Other adverse effects include urinary retention in up to 80% of patients and respiratory depression in 0.2% to 1.9%. These side effects are not limited to any specific opioid, and it is not clear whether their incidence is dose dependent. Both early and late respiratory depression can occur with neuraxial opioids. Most reported respiratory depression occurs with morphine because of its hydrophilic nature and cephalic CSF spread. PCEA with combined local anesthetic and neuraxial opioids results in a low incidence of respiratory depression that varies from 0.07% to 0.4%. thus making PCEA relatively safe to use in an unmonitored hospital setting.

EXTENDED-RELEASE EPIDURAL MORPHINE

Extended-release epidural morphine (EREM) incorporates new technology in which microscopic particles consisting of numerous morphine-containing vesicles are each separated by naturally occurring lipid membranes. EREM provides a longer duration of postoperative analgesia than does traditionally available formulations but requires treatment with opioid antagonists in 12.5% of patients. This modality appears to have a dose-dependent relationship for decreased oxygen saturation, with 20- and 25-mg doses being associated with higher rates of desaturation. Clinicians should not freeze, aggressively agitate, or shake the EREM vials. In addition, one should not administer any other agents in the epidural space around the time of EREM administration because an increased peak serum concentration of morphine may result. Side effects of EREM are mainly pruritus and respiratory depression, which requires treatment with opioid antagonists in 12.5% of patients.

Neuraxial analgesic agents, given as a single shot or as a continuous epidural infusion, provide effective postoperative analgesia (see Table 18.5). The choice of a particular technique should be made on an individual basis. The risks and benefits of a particular technique should be weighed for each specific patient.
PERIPHERAL OR PERINEURAL ANALGESIA

The number of ambulatory procedures performed in North America has increased significantly, and the cost-saving benefit of minimizing patients’ hospital stays has gained importance. With the goals of same-day discharge, reduction in hospital length of stay, and improvement in postsurgical outcomes, many anesthesiologists routinely use multimodal analgesia with peripheral techniques. A variety of peripheral regional techniques can be used to enhance postoperative pain control while reducing side effects. Among these techniques are local anesthetic wound infiltration, brachial, lumbar, and sacral plexus blocks; and nonepidural truncal blocks (paravertebral, transabdominal, and rectus sheath blocks). Peripheral analgesic techniques are important for facilitating cost savings in ambulatory surgery centers, especially when phase 1 recovery bypass is achieved and unplanned admissions are reduced. Peripheral regional analgesia delivered as a single injection or as a continuous infusion through a perineural catheter (PNC) provides analgesia superior to that with systemic opioids or epidural analgesia and is associated with minimal side effects, better rehabilitation, and shorter hospital stay. Use of a PNC in the lower extremity provides analgesia equal to that of an epidural with minimal side effects (hypotension, urinary retention, and inability to ambulate). Regardless of location, the analgesia provided through a PNC is superior to that of single-shot blocks, epidural analgesia, intra-articular analgesia, and IV PCA.

The number of complex orthopedic procedures such as joint replacement has increased tremendously in the last 2 decades and is expected to continue to increase as the population advances in age. Joint replacement, which is well known to improve a patient’s quality of life, typically causes severe pain in the immediate postoperative period and thus interferes with physical rehabilitation. Multimodal analgesia and the use of a PNC as the main techniques for control of pain have been shown to provide better analgesia, earlier passive joint movement, and earlier discharge home with adequate joint movement and earlier discharge home with adequate joint movement. A large series of hospital patients and outpatients treated with a PNC reported minimal clinician interventions and clinical adverse effects during treatment. With adequate instructions and phone access to health care providers, patients were able to manage their pain at home and remove the PNC without a hospital visit. More studies are needed before home use of a PNC becomes a widely applicable standard of care.

Techniques for peripheral single-injection or PNC analgesia vary among practitioners and include a paresthesia technique, peripheral nerve stimulation, and ultrasound-guided regional anesthesia (UGRA). Although evidence regarding the safety of UGRA is currently limited in comparison to what is known about nerve stimulation, it is becoming the technique of choice for most single-injection and continuous-infusion techniques.

Studies have shown that when compared with nerve stimulation, use of UGRA for upper or lower extremity blocks and placement of catheters offers a faster onset of sensory blockade and a greater block success rate. UGRA has also been shown to achieve faster block performance, require fewer needle passes, and induce less block-related discomfort, thus making this technique better received by patients. Local anesthetics are the main analgesics used for peripheral blocks and in continuous-infusion catheters. Drugs with an intermediate duration of action, such as lidocaine and mepivacaine, are commonly used for blocks, whereas long-acting drugs such as ropivacaine, bupivacaine, and levobupivacaine are used mainly for continuous infusion. Some data suggest that bupivacaine and levobupivacaine are more potent than ropivacaine; therefore, the ropivacaine concentration is often increased to compensate. However, ropivacaine, bupivacaine, and levobupivacaine have provided similar analgesic profiles in human trials.

Several medications are infrequently added to the local anesthetic to improve perineural analgesia. Although there

ASRA, American Society of Regional Anesthesia; IV PCA, intravenous patient-controlled analgesia.
are reports of opioids being added,\textsuperscript{184-186} insufficient evidence is available to draw any conclusion regarding the efficacy of this practice.\textsuperscript{187,188} Clonidine has been reported to prolong the duration of perioperative analgesia,\textsuperscript{159,184,185,189} but randomized controlled studies have failed to demonstrate any clinical benefit.\textsuperscript{190-192} Epinephrine is commonly used in blocks to detect inadvertent intravascular injection, but it is rarely used in a continuous infusion because it causes prolonged vasoconstriction.\textsuperscript{193-196} Other adjuvants have been reported, but none are currently approved for perioperative use in humans because of systemic side effects.\textsuperscript{197,198}

In summary,

- Continuous neuraxial techniques provide superior analgesia and better patient outcomes, including those related to major morbidity.
- Many factors affect the overall outcomes of continuous epidural analgesia, including the congruency of epidural catheter location and placement of the surgical incision and the type of analgesic regimen.
- Neuraxial opioids provide postoperative pain control when administered alone or in combination with local anesthetics.
- Peripheral or perineural regional techniques provide pain control superior to that with systemic opioids or epidural analgesia and are associated with minimal side effects.
- Perineural continuous analgesia is beneficial in complex orthopedic procedures and is used as part of multimodal analgesia in the perioperative setting.

**BRACHIAL PLEXUS BLOCKS**

Nerve conduction in the brachial plexus (Fig. 18.3) can be blocked at many levels to provide anesthesia and postoperative analgesia during and after surgical procedures on the upper extremity (Table 18.5). Use of UGRA may increase the overall success rate when compared with nerve stimulation or other methods.\textsuperscript{199} UGRA techniques for the brachial plexus may allow patients to receive the best anesthetic and analgesic effect with less local anesthetic volume and minimal side effects. An analysis of neurologic complications in 1000 UGRA procedures for elective orthopedic surgery showed that the rate of postoperative neurologic symptoms was very similar to that previously reported for traditional techniques.\textsuperscript{200} The incidence of nerve injury from a peripheral nerve block (PNB) has been estimated to be 0.4 per 1000 PNBs based on large prospective audits.\textsuperscript{201} Use of PNCs or perineural continuous infusion of local anesthetic is being advocated when prolonged analgesia of the arm is needed. PNCs could be used in the hospital setting or in an ambulatory setting as a home PNC. Insertion of a PNC may be facilitated by using paresthesia, nerve stimulation, or ultrasound guidance.\textsuperscript{202}

**Interscalene Block**

The gold standard technique for shoulder and upper arm procedures is the interscalene block (ISB). The interscalene groove is commonly approached through an anterolateral technique. A posterior approach to the brachial plexus remains underused despite its effectiveness in securing a continuous interscalene block (CISB) catheter.\textsuperscript{203,204} The interscalene approach typically provides a complete block for the superior and middle trunk, but the inferior trunk is often blocked incompletely, thus making this approach unsuitable for forearm and hand procedures. For elbow procedures, the ISB is frequently supplemented by other nerve blocks such as the intercostobrachial, medial cutaneous and medial antebrachial cutaneous, and ulnar.

A single-injection ISB provides analgesia superior to that of systemic opioids. A reduction in verbal pain scale scores of greater than 50\%\textsuperscript{205-207} and a reduction in total opioid requirement\textsuperscript{205-208} have been reported. CISB for shoulder surgery provides better analgesia than placebo or systemic opioids do and is associated with less opioid consumption and fewer opioid-related side effects.\textsuperscript{184,209-213} CISB with perineural infusion of local anesthetic has been shown to benefit patient rehabilitation\textsuperscript{214} and can be continued at home with a portable infusion pump.\textsuperscript{215} In a randomized controlled study, Ilfeld and colleagues\textsuperscript{166} showed that ambulatory CISB with perineural infusion of 0.2\% ropivacaine decreased the time until readiness for discharge after total shoulder arthroplasty by allowing good shoulder range of motion and providing adequate pain control without parenteral opioids. When compared with ISB for moderate to severe outpatient shoulder procedures, 2-day CISB provided better pain control, reduced opioid requirements, improved sleep quality, and increased patient satisfaction.\textsuperscript{216} In the last decade, the UGRA technique for ISB has become more popular than the nerve stimulator technique. It provides a better block profile, has a faster onset and longer duration, requires fewer needles, and is associated with better patient satisfaction. Moreover, it has not sacrificed patient safety or increased the incidence of neurologic complications.\textsuperscript{217,219}

Concomitant phrenic nerve block occurs after brachial plexus block at the interscalene level, especially at the C6 level, because of its close proximity (2 to 4 mm) to the plexus.\textsuperscript{220} Blocking the brachial plexus at this level should be considered with great caution if a patient has respiratory insufficiency or chronic obstructive pulmonary disease. Some investigators have shown no difference in hemidiaphragmatic paresis after a reduction in local anesthetic volume of up to 10 mL at the ISB when ultrasound was used.\textsuperscript{221} Others are trying to identify the minimum effective local anesthetic volume necessary to provide postoperative analgesia with minimal side effects.\textsuperscript{219,222} Although the local anesthetic volume needed for ultrasound-guided ISB may be reduced, the optimal volume for analgesia still remains to be determined. For shoulder procedures, the addition of tramadol or dexamethasone as an adjuvant to local anesthetic prolongs the duration of analgesia.\textsuperscript{223,224}

Recently, different ultrasound approaches have been tried in an attempt to block the brachial plexus at the interscalene groove. No difference in block onset time or block quality was observed when intraplexus injection of local anesthetics or periplexus blocks were used.\textsuperscript{225} A low approach to the brachial plexus resulted in more distal spread of sensory and motor coverage than when the traditional approach was used.\textsuperscript{220}

**Supraclavicular Block**

The supraclavicular block is considered the spinal of the arm. This block is associated with the greatest blockade of the brachial plexus at the trunk and division level where all the trunks are compact and can be achieved with a single injection of local anesthetic. At lower volumes of
local anesthetic, the supraclavicular block misses the dorsal scapular nerve, which arises from the root of C5, and also misses the superficial cervical plexus. Unless the local anesthesia tracks proximally toward the interscalene region, this block may be inadequate for shoulder surgery, but it provides adequate block for upper arm surgery. As with the ISB, supplemental blocks are required for elbow procedures (i.e., intercostobrachial). Of all the brachial plexus blocks, the supraclavicular block has the highest risk for pneumothorax, especially when done with the traditional “plumb bob” technique. Some recent studies have shown that the calculated volume of local anesthetic required for an ultrasound-guided supraclavicular block does not seem to differ from the conventionally recommended volume required for supraclavicular blocks performed with non-ultrasound-based nerve localization techniques. The minimum effective volume of 1.5% lidocaine with 5 µg/mL epinephrine was 32 mL. Multiple studies have confirmed that when UGRA is used, a single injection offers the same clinical profile and analgesic benefit as two injections.

Infraclavicular Block

Like the supraclavicular block, the infraclavicular block also approaches the brachial plexus where it is compact.
(Fig. 18.4), at the level of the cords. This block can be used for procedures involving the elbow, forearm, and hand. It is especially useful in patients unable to abduct their shoulder to allow access to the axilla. A single injection or a continuous-infusion catheter placed with this technique provides effective analgesia. This approach also results in the most secure catheter insertion site of all brachial plexus blocks. This block has two main approaches—the traditional perivascular infraclavicular approach and the coracoid approach. They provide similar results, but the coracoid approach is associated with less risk for pneumothorax. For outpatient wrist and hand surgery, Hadzic and colleagues compared the use of a chloroprocaine infraclavicular nerve block with general anesthesia induced with volatile agents. They found that general anesthesia with volatile agents led to increased postanesthesia care unit admissions (vs. phase 1 recovery bypass), higher reports of postoperative pain, longer time to ambulation, and longer time to same-day discharge. Chelly and coworkers stated that PNB catheters are probably indicated for implantation procedures after trauma, as well as for open reduction and internal fixation of the hand or digits, although a prospective randomized trial to definitively verify this intuitive concept may be difficult to conduct. Ilfeld and colleagues showed that use of a continuous infracavicular brachial plexus catheter resulted in less postoperative dynamic pain and opioid consumption and fewer sleep disturbances than did placebo catheter infusion. The surgical procedures performed included open reduction and internal fixation (elbow, radius, or ulna), bony and capsular wrist procedures (carpectomy, capsulodesis, fusion, or shrinkage), metacarpal arthroplasty, suspensionplasty, and ulnar nerve transposition.

An infracavicular brachial plexus block for regional anesthesia of the lower part of the arm has efficacy comparable to that of other brachial plexus blocks. This block has a lower likelihood of tourniquet pain during surgery and provides more reliable blockade of the musculocutaneous and axillary nerves than does a single-injection axillary block. Many investigators have confirmed that when using UGRA for an infracavicular block, a single injection

of local anesthetic posterior to the axillary artery is as effective as multiple injections.\(^{237,239}\) A randomized comparison of infraclavicular and supraclavicular PNCs for postoperative analgesia showed that local anesthetic infusion via an infraclavicular PNC provides analgesia superior to that via a supraclavicular PNC.\(^{240}\)

**Axillary Block**

This block produces the most effective block for all surgical procedures on and distal to the elbow, but it requires supplementation for the tourniquet (intercostobrachial, medial brachial cutaneous, and medial antebrachial cutaneous) if it is to be used as a surgical block. Axillary blocks have been shown to reduce postoperative pain scores by more than 50%, decrease the total in-hospital opioid requirement, and lengthen the time until the first analgesic dose.\(^{241,242}\) The axillary sheath at this level is often discontinuous, and the block should target the individual terminal branches. A nerve stimulator can be used to identify all the individual components and to obtain a consistently effective block.\(^{243-245}\) A small study demonstrated that each terminal branch can be targeted under ultrasound guidance with as little as 1 mL of 2% lidocaine with 1:200,000 epinephrine per nerve to provide a fast onset and surgical anesthesia.\(^{246}\) The traditional transarterial and single-injection techniques can often miss the musculocutaneous nerve (C5-6); therefore, that nerve should be specifically sought and blocked. It can be visualized in the coracobrachialis muscle and traced proximally to the axillary artery under ultrasound guidance.

**Intravenous (Bier) Block**

The mechanism of IV regional anesthesia (IV RA) is generally accepted to involve diffusion from veins to small nerves and nerve endings after exsanguination. IV regional blocks for the upper extremity, which use a proximal arm tourniquet or double tourniquet, have been well described. IV regional blocks for the lower extremity have been reviewed as well.\(^{247}\) Traditional IV regional techniques that use a single- or double-tourniquet technique for the lower extremity may carry a high failure rate,\(^{248}\) in which case supplementation by the surgeon or conversion to general anesthesia is required. Of potential interest, however, is an intercuff technique for IV RA that has been developed for use in knee surgery in an effort to produce better localization and reduce overall dosing requirements.\(^{249,250}\)

Opioids (other than meperidine, 30 mg or more) are generally considered not to be beneficial when given via the IV regional technique;\(^{251}\) systemic side effects of meperidine are manifested at the 30-mg threshold. Tramadol, 100 mg, administered as IV RA with lidocaine is associated with a self-limited rash below the tourniquet and does not necessarily confer an analgesic benefit.\(^{252}\) In addition, tramadol has not been shown to improve block or postoperative analgesic quality when coadministered with ropivacaine.\(^{253}\) Less controversial additives to IV RA appear to have the potential to provide intraoperative tourniquet tolerance, postoperative analgesia, or both. Ketorolac can achieve both end points when the tourniquet is applied to both the upper and lower parts of the arm. Its use for this purpose is generally accepted, with no basis at this time for exceeding a 20-mg dose in adults.\(^{254}\) Clonidine at a dose of 1 µg/kg is accepted to improve tourniquet tolerance and reduce postoperative analgesic requirements with minimal side effects. Dexmedetomidine (0.5 mg/kg) has also shown benefit.\(^{254}\) Ketamine at a dose of 100 µg/kg has also been shown to improve tourniquet tolerance and reduce postoperative analgesic requirements.
in a manner that appears to be more potent than 1 μg/kg clonidine.\textsuperscript{255} When compared with plain lidocaine, dexamethasone (8 mg) was recently shown to reduce postoperative analgesic requirements during the first 24 hours after surgery.\textsuperscript{256} Given the multiple mechanisms that contribute to postoperative pain, the logical future study would involve a step-function assessment of serial additives and combinations of ketorolac, clonidine or dexmedetomidine, ketamine, and dexamethasone. The coadministered local anesthetic (0.5% ketorolac, clonidine or dexmedetomidine, ketamine, and dexamethasone) is unlikely to influence results with respect to duration of postoperative analgesia beyond the recovery room period.\textsuperscript{257}

Complications with IV RA are very uncommon. Seizures have been reported after deflation of the tourniquet with a tourniquet time as long as 60 minutes and with lidocaine at its lowest effective dose (1.5 mg/kg). Several cases of compartment syndrome have also been reported.\textsuperscript{258}

In summary,

- Interscalene analgesia is the gold standard technique for shoulder and upper arm procedures. Phrenic nerve paresis is a common side effect.
- Supravclavicular analgesia is considered the spinal of the brachial plexus. It provides an adequate block for upper arm surgery; supplemental blocks are required for elbow procedures. It is associated with a risk for pneumothorax.
- Infraclavicular analgesia can be used for procedures involving the elbow, forearm, or hand. It provides the most secure catheter insertion site.
- Axillary analgesia produces the most effective block for all surgical procedures on the elbow, forearm, and hand. Supplemental blocks are required, especially musculocutaneous.
- IV (Bier) regional analgesia is well described in the upper extremity but used less frequently in the lower extremity.

### LOWER EXTREMITY BLOCKS

For patients undergoing surgical procedures on the lower extremity, nerve conduction in the lumbar and sacral plexuses can be blocked at many levels for anesthesia and postoperative analgesia (Table 18.6). The nerve supply to the lower extremity is derived from two nerve plexuses arising from the ventral rami of the spinal nerve roots of the lower extremity, nerve conduction in the lumbar and sacral plexuses can be blocked at many levels for anesthesia and postoperative analgesia (Table 18.6). The nerve supply to the lower extremity is derived from two nerve plexuses arising from the ventral rami of the spinal nerve roots of the lower extremity.

LA, local anesthetic; LPB, lumbar plexus block; NS, nerve stimulator; US, ultrasound.
Spinal cord (Fig. 18.5)—the lumbar plexus (L1-4) and the sacral plexus (L4-5, S1-3). The lumbar plexus gives rise to the femoral nerve (L2-4), the obturator nerve (L2-4), the lateral femoral cutaneous nerve (L2-3), and three other branches that supply the inguinal and genital areas (iliohypogastric, ilioinguinal, and genitofemoral nerves). The sacral plexus gives rise to the sciatic nerve (L4-5, S1-3) and provides branches that supply the musculature around the hip and pelvis.

**Lumbar Plexus Block**

Because the main nerves supplying the hip joint are the femoral and obturator nerves, this block (either single shot or continuous infusion) provides adequate postoperative analgesia for procedures involving the hip joint, including total joint replacement and repair of hip fractures. In a randomized clinical trial of patients undergoing hip hemiarthroplasty under general anesthesia, Turker and colleagues compared the use of continuous infusion from a lumbar plexus catheter with the use of an epidural catheter. They found that patients who received a lumbar plexus catheter had less motor block, ambulated sooner, and experienced significantly fewer overall complications. More than a decade ago investigators reported that for patients undergoing total hip arthroplasty, those who received lumbar plexus single-injection blocks had less pain and less blood loss during and after surgery than did those who did not receive the block. Others reported that in elderly patients with hip fractures, those who received lumbar plexus and parasacral blocks (vs. general anesthesia) exhibited significantly less hypotension during surgery, had fewer intensive care unit admissions (0/30 vs. 11/30), and had a shorter length of hospital stay (7 vs. 14 days). A lumbar plexus block also provides excellent postoperative analgesia for most invasive knee procedures such as anterior cruciate ligament (ACL) reconstruction, multiligament reconstruction, or total knee arthroplasty (TKA). Matheny and colleagues found that the opioid requirement after arthroscopic ACL reconstruction was 89% lower in the group that received a continuous lumbar plexus block than in those who had IV PCA. However, a femoral nerve block in the groin is much simpler and easier to perform than a lumbar plexus block and provides equally efficacious analgesia for invasive knee procedures in which obturator nerve coverage is not relevant. In a randomized triple-masked trial, Ilfeld and colleagues compared the use of an overnight lumbar plexus catheter with use of the catheter for four nights in patients who had undergone hip arthroplasty. They found that use of the catheter for four nights decreased the time that patients needed to reach discharge criteria by 38% but did not significantly increase ambulation distance.

**Femoral Nerve Block**

Like the lumbar plexus block, a femoral nerve block provides excellent postoperative analgesia for invasive procedures around the knee (excluding the posterior aspect of the knee). Unlike the lumbar plexus block, a femoral nerve block preserves hip adduction and psoas-mediated hip flexion. A femoral block must often be supplemented with a single-shot or continuous sciatic nerve block for procedures such as TKA or ACL reconstruction with a hamstring autograft.

Many randomized controlled studies that have compared UGRA, peripheral nerve stimulation, and loss-of-resistance techniques for the femoral nerve suggest that the ultrasound technique could offer faster onset of sensory loss and longer analgesia with less local anesthetic volume.

In the late 1990s, two studies from Europe examined rehabilitation outcomes after total knee replacement when a continuous femoral block (CFB) was used. When compared with IV PCA, CFB led not only to better pain relief but also to significantly better knee flexion, faster achievement of ambulation goals, and overall faster convalescence. Patients who received CFB infusions experienced fewer side effects than did epidural patients in both studies, and patients in the CFB groups were discharged home from inpatient rehabilitation units 20% sooner than were patients in the IV PCA groups.

In the United States, a similar anesthetic treatment method was applied to patients undergoing total knee replacement. All patients underwent general anesthesia and were randomized to receive IV PCA, epidural infusion, or single-injection femoral-sciatic blocks followed by a continuous femoral infusion. Continuous femoral infusion patients (vs. IV PCA patients) had a 72% reduction in postoperative bleeding ($P = 0.05$), achieved better performance on continuous passive motion, had a 90% decrease in serious complications (including less blood loss), ambulated sooner (2.5 vs. 3.5 days), and had a 20% decrease in the length of hospitalization (4 vs. 5.5 days). In 2010, a meta-analysis of 23 randomized controlled trials showed that a femoral nerve single block or continuous infusion provides better analgesic outcomes after TKA than does IV PCA. A continuous femoral nerve block after TKA was associated with lower opioid consumption and better functional recovery at 6 weeks than periarticular infiltration was.

A continuous femoral nerve block is an acceptable analgesic alternative to a continuous posterior lumbar plexus
block for hip arthroplasty when a stimulating PNC is used. However, patients who receive continuous femoral catheters might experience more motor block, thus making ambulation suboptimal.272

**Fascia iliaca Block**

The fascia iliaca compartment block was mainly described for the pediatric population in 1989273 and was widely reported to provide good analgesia for hip and knee procedures in adolescents and adults.274 In 2008, Dolan and colleagues275 compared the use of UGRA for this block with the traditional fascial loss of resistant (LOR) technique for postoperative analgesia in hip and knee arthroplasty. They found that when compared with the LOR technique, use of UGRA significantly increased the block success rate, especially at the medial aspect of the thigh (95% versus 60%), and increased the percentage of patients in whom the femoral, obturator, and lateral cutaneous nerves were all completely blocked (82% vs. 47%)

**Sciatic Nerve Block**

Proximal sciatic nerve blocks are most often used as an adjunct to femoral or lumbar plexus blocks for painful procedures around the hip, as discussed earlier.154 but they can also provide excellent analgesia for all major foot and ankle procedures (especially when a thigh tourniquet is planned).

In patients undergoing TKA, continuous sciatic nerve blocks provide greater analgesia, decrease morphine request, and improve early rehabilitation when compared with the use of single-injection sciatic nerve block or lumbar plexus blocks.276 Studies that have examined subgluteal continuous sciatic nerve blockade for orthopedic ankle and foot surgery have reported significant reductions in visual analog pain scores.277,278 Similarly, continuous sciatic nerve blockade has shown significant analgesic benefit in patients undergoing below-knee amputation.279 Use of a proximal sciatic nerve block for distal foot and ankle procedures is often limited by concerns of hamstring muscle weakness.280

Studies that have compared UGRA of the sciatic nerve with peripheral nerve stimulation techniques281,282 have shown that UGRA has a higher sensory block success rate and requires less local anesthetic and less time to perform. Insufficient data are available to compare the block failure rate and the actual duration of sensory blockade between the two techniques.174

**Popliteal Fossa Sciatic Nerve Block**

The nerve can be blocked from the posterior or lateral approach, although the lateral approach may be superior when there are concerns regarding patient positioning.283-285 A popliteal fossa block provides effective postoperative analgesia for all foot and ankle procedures (assuming that the saphenous nerve is concomitantly blocked). It also preserves hamstring function, thus facilitating ambulation.286

Effectiveness of the popliteal sciatic block for outpatient foot and ankle procedures was demonstrated by McLeod and colleagues.287 They compared the lateral popliteal fossa block with an ankle block288 and with subcutaneous infiltration of local anesthetics.284 The popliteal fossa block provided longer postoperative analgesia.285 When the UGRA technique is used, blocking the tibial and common peroneal nerves in the popliteal fossa separately at the bifurcation provides a faster onset than does a prefurcation sciatic block.288

Continuous popliteal sciatic nerve catheters were first introduced by Singelyn and colleagues, who described a challenging Seldinger (catheter-over-guidewire) technique for catheter placement and achieved a 92% success rate.289 Since then, authors have repeatedly found that continuous-infusion nerve blocks lead to excellent analgesic outcomes when compared with single-injection blocks or placebo catheters.290-292 Ultrasound guidance may reduce the time required for placement of popliteal-sciatic PNCs and result in fewer placement failures than when stimulating catheters are used, but analgesia may be mildly better with successfully placed stimulating catheters.175 Patient satisfaction with block placement was also higher with ultrasound guidance than with the nerve stimulation technique.176 Adding continuous femoral catheter infusion of ropivacaine to continuous popliteal catheter infusion improved postoperative analgesia during movement after major ankle surgery. This effect was still present 6 months after surgery.293

In summary,

- The nerve supply to the lower extremity comes from the lumbar plexus and the sacral plexus.
- Lumbar plexus analgesia provides excellent postoperative analgesia for most invasive hip and knee procedures. It is considered a high-risk block.
- Femoral nerve analgesia provides excellent postoperative analgesia for invasive knee procedures; it is relatively non-invasive and safe.
- A fascia iliaca block is performed via an anterior approach to the lumbar plexus.
- The sciatic nerve can be blocked at various sites along its course (parasacral, subgluteal, and popliteal) to provide analgesia below the knee joint.

**TRUNCAL BLOCKS**

**Paravertebral, Interpleural, and Intercostal**

Among truncal blocks (interpleural/intrapleural, paravertebral/extrapleural, and intercostal analgesia), the most effective technique appears to be the paravertebral block.294 A paravertebral block provides analgesia presumably via direct somatic nerve, sympathetic nerve, or epidural blockade.294 A paravertebral block can be administered as a single injection or continuous infusion through a catheter. The analgesia provided by paravertebral catheters is superior to that with placebo and may be equal to that of thoracic epidural analgesia.295 A systematic review of six trials (152 subjects received extrapleural/paravertebral analgesia; 149 received epidural analgesia) indicated that extrapleural/paravertebral catheters provide analgesia that is equivalent to that of thoracic epidural analgesia at 8 to 12 hours postoperatively.

Evidence for the analgesic efficacy of interpleural analgesia is not as compelling as that for paravertebral catheters. When compared with epidural or paravertebral analgesia, interpleural analgesia provides inferior pain control. Moreover, it does not preserve lung function after thoracotomy or reduce the incidence of postoperative pulmonary complications.296 A systematic review of eight trials (141 subjects received interpleural analgesia; 134 received saline placebo) indicated that interpleural catheters do not provide analgesia that is significantly superior even to placebo.
Intercostal blocks may be another option for postoperative analgesia for thoracic pain. These blocks may be administered by the surgeon at the end of the open thoracic procedure, but they provide only short-term postoperative analgesia that is limited to the duration of action of the local anesthetic injected. Intercostal blocks may be repeated postoperatively, but at the risk of increasing the incidence of pneumothorax (1.4% per nerve blocked with an overall incidence of 8.7% per patient).\textsuperscript{297} Intercostal blocks have not been shown to reduce the incidence of pulmonary complications postoperatively when compared with systemic opioids.\textsuperscript{297}

**Transversus Abdominis Plane Block**

Our current understanding of the transversus abdominis plane (TAP) block and its role in postsurgical pain control is limited by the small number of randomized controlled trials. Improved analgesia was noted in patients undergoing laparotomy for colorectal surgery, laparoscopic cholecystectomy, and open and laparoscopic appendectomy.\textsuperscript{298-302} Analgesic outcomes were better when 15 mL or more of local anesthetic was used per side versus smaller volumes.\textsuperscript{298,301,303-305} Blocks can be achieved by using anatomic landmarks or by ultrasound-guided techniques. Preincisonal timing for injection has yet to be tested in randomized trials.\textsuperscript{298,299,302,303,306-309} Reported complications include intraperitoneal injection or hemorrhage, transient femoral nerve palsy, and local anesthetic toxicity.\textsuperscript{310-312}

In summary,

- A paravertebral (extrapleural) block may be beneficial for thoracic, breast, and upper abdominal surgery and for the treatment of rib fracture pain.
- When compared with epidural or paravertebral analgesia, interpleural analgesia provides inferior pain control and does not preserve lung function after thoracotomy.
- A TAP block has been shown to reduce pain and analgesic requirements after abdominal surgery.
- Our current understanding of the TAP block and its role in postsurgical pain control is still limited.

**CONTINUOUS WOUND INFUSION OF LOCAL ANESTHETICS**

The mechanisms of action of local anesthetic wound infusions include blockade of nociceptive transmission from the wound surface, inhibition of the local inflammatory response to surgical injury,\textsuperscript{313,314} and spinal cord suppression from systemic absorption of local anesthetics.\textsuperscript{315} Recently, special wound infusion catheters have become available that can be placed intraoperatively into the wound under direct supervision of the surgeon to infuse local anesthetics, and use of such a technique is an acceptable option as part of multimodal postoperative analgesia.\textsuperscript{316,317}

A systematic review of randomized trials that examined the use of continuous wound catheters in multiple surgical procedures consistently demonstrated analgesic efficacy in terms of reduced pain scores and opioid use for all surgical subgroups examined.\textsuperscript{150} A total of 39 randomized controlled trials (1761 patients) were included in the final analysis. Overall, when compared with placebo, local anesthetic infusions resulted in a significant decrease of approximately 33% in pain scores of patients both at rest and with activity. Subgroup analysis confirmed the decreased pain scores in patients undergoing all types of surgical procedures except for abdominal surgery. When compared with subjects given placebo, those who were randomized to receive subcutaneous infusions of local anesthetics demonstrated reduced need for opioid rescue and decreased daily opioid consumption, which may have contributed to a reduction in the incidence of nausea in the continuous wound catheter group (21% vs. 39%, odds ratio = 0.42, 95% confidence interval = 0.27 to 0.67). When compared with epidural morphine, continuous wound infusion with ropivacaine for 48 hours after cesarean delivery was associated with better analgesia, lower incidence of side effects, and shorter hospital stay.\textsuperscript{318} PCEA with opioids and local anesthetics was superior to patient-controlled local anesthetic wound infusion for laparotomy. The incidence of side effects was similar in both groups.\textsuperscript{319}

**INTRA-ARTICULAR ANALGESIA**

Intra-articular analgesics have been used for more than 2 decades. Despite the many studies published on intra-articular analgesia, the effect of single-agent intra-articular injections on postoperative pain management remains unclear. Combination therapies have been shown to produce maximum benefit with fewer side effects.\textsuperscript{320,321}

**Intra-articular Morphine**

In the intra-articular region, morphine may act on peripheral receptors,\textsuperscript{322} and through systemic absorption.\textsuperscript{323} Morphine, the most commonly used opioid,\textsuperscript{324,326} is used intra-articularly at doses of 1 to 5 mg.\textsuperscript{323,327} Reductions in pain intensity occur mainly during the first 6 hours after surgery.\textsuperscript{323} The results from a meta-analysis indicated that intra-articular morphine provides a definite but mild analgesic effect.\textsuperscript{323} This effect is dose dependent, and the possibility of systemic absorption cannot be excluded. Some investigators have reported that postoperative intra-articular morphine is effective only in patients with moderate or severe pain,\textsuperscript{327,328} but others support the idea that inflammation is a prerequisite for the peripheral analgesic effectiveness of opioids.\textsuperscript{329}

Local anesthetics are considered effective short-term postoperative analgesics, whereas opioids produce more sustained intra-articular analgesia. A study by Marchal and colleagues\textsuperscript{329} revealed that patients who had undergone “low inflammatory surgery” received greater short-term (4 to 8 hours) benefit from intra-articular bupivacaine, whereas those who had undergone “high inflammatory surgery” received greater long-term (24 hours) benefit from intra-articular morphine (5 mg).\textsuperscript{329}

Intra-articular meperidine is favored by some practitioners because of its dual opioid and local anesthetic effect. In the literature, the dose of intra-articular meperidine varies from 50 to 200 mg.\textsuperscript{330} Doses greater than 100 mg (which produce a higher circulating concentration of normeperidine) are associated with a higher incidence of side effects (nausea, vomiting, and somnolence).

**Intra-articular NSAIDs**

Both ketorolac and tenoxicam have shown efficacy when delivered via the intra-articular route. Two studies have demonstrated improved analgesia and ambulation in patients when ketorolac was combined with either morphine\textsuperscript{331} or bupivacaine.\textsuperscript{332} It was shown that the addition of ketorolac...
to continuous intra-articular infusion of ropivacaine and morphine led to lower pain scores and less analgesic consumed after ACL reconstruction than when ketorolac was omitted.\textsuperscript{333} Tenoxicam, 20 mg, has been used successfully both as a sole intra-articular analgesic and as an adjunct in combination therapy.\textsuperscript{334,335}

\textbf{Intra-articular Neostigmine and Clonidine}

Intra-articular administration of neostigmine (0.5 mg) was shown by Yang and coworkers\textsuperscript{336} to provide more pain relief than morphine (2 mg) in patients undergoing knee arthroscopy. Intra-articular neostigmine (0.5 mg) has not been reported to increase PONV.\textsuperscript{337} Neostigmine (0.5 mg) and clonidine (1 µg/kg) as sole analgesics have been demonstrated to be superior to tenoxicam (20 mg), and all three individual agents were superior to either morphine (2 mg) or bupivacaine (100 mg) given alone.\textsuperscript{338} Clonidine (1 µg/kg) coadministered with bupivacaine provided greater analgesic benefit than did either agent used alone. The combination of clonidine (150 µg) and neostigmine (0.5 mg) was no more effective than either agent given alone, but all intra-articular treatment groups had lower pain scores than the intra-articular placebo group.\textsuperscript{339} Clonidine (150 µg) was found to be equivalent to morphine (2 mg) and superior to placebo, but the combination of clonidine and morphine provided no additional benefit.\textsuperscript{340} The analgesic benefits of intra-articular clonidine have been shown to be unrelated to vascular uptake.\textsuperscript{341}

Evidence suggests that regional anesthesia might be superior to intra-articular injection of local anesthetics. In a prospective randomized blinded study, Singelyn and colleagues\textsuperscript{342} compared the analgesic effects of brachial plexus block, suprascapular nerve block, intra-articular injection of local anesthetics, and a control group for arthroscopic acromioplasty. Patients were observed for 24 hours. No significant difference was observed between the group that received intra-articular local anesthetic injection and the control group. Pain scores were lower in the groups that received suprascapular nerve block and brachial plexus block, but pain relief was better in the latter group. Patient satisfaction scores were higher and opioid use lower in the group that received the brachial plexus block.

In another study it was shown that for ACL repair, epidural or continuous femoral nerve block provided adequate pain relief but that intra-articular infusion of ropivacaine was insufficient to provide pain control.\textsuperscript{343} Another prospective randomized controlled study showed that adding an inter-scalene brachial plexus block to intra-articular and subacromial injection of local anesthetics improved analgesia.\textsuperscript{344}

In summary,

- Combination drug therapies for intra-articular analgesia have been shown to produce maximum benefit with fewer side effects.
- Intra-articular morphine provides benefit mainly for highly inflammatory joint surgery.
- Intra-articular meperidine could be favored because of its dual local anesthetic effect.
- Both ketorolac and tenoxicam have shown efficacy when delivered via the intra-articular route.
- Continuous perineural analgesia provides better analgesia than does intraarticular injection of local anesthetics, but it requires strong technical skills.

\section*{ACUTE PAIN MANAGEMENT IN SPECIAL POPULATIONS}

\section*{OPIOID-TOLERANT PATIENTS}

Acute pain management is sometimes extremely challenging in opioid-tolerant patients. Tolerant patients could be those who use opioids legitimately for the treatment of chronic pain, those who obtain and use opioid medications illicitly, and those who abuse heroin. An opioid-tolerant patient will be encountered in the acute pain setting after routine operative care or trauma. Drug use among trauma victims is high. Studies have shown that as many as 50\% of all trauma victims test positive for drugs other than alcohol.\textsuperscript{345,346} Data also suggest that patients with substance use disorders are more likely to have chronic pain conditions, thus further complicating acute pain management.\textsuperscript{347,348} Concerns that health care providers might contribute to a patient’s opioid addiction and tolerance often lead to the undertreatment of acute pain. However, data suggest that the risk for iatrogenic addiction from the use of opioids for pain management is minimal.\textsuperscript{349,350} Regardless of why a patient is opioid tolerant, it is important from both a patients’ rights perspective and an ethical perspective to treat pain adequately in the acute phase. Undertreated pain can lead to drug-seeking behavior known as pseudoaddiction.\textsuperscript{351}

A comprehensive analgesic plan should start in the preoperative period and preferably be discussed with the patient and surgical and nursing teams. The pain treatment regimen should be continued until the morning of surgery. Then multimodal analgesia, including regional analgesia, should be considered.\textsuperscript{352} Tolerant patients will sometimes require higher doses of long-acting opioids to achieve adequate analgesia. Patients who abuse opiates typically deny the magnitude of their opioid use and usually report high pain scores.\textsuperscript{353} Therefore, it is advisable to base the treatment plan on a functional, objective pain scale that includes ambulation and maintenance of effective deep breathing. It is generally recommended that if a patient was using a long-acting opioid such as methadone or transdermal fentanyl before the trauma or surgery, it be continued after the event or be resumed as soon as possible. In patients who are unable to take oral medications, parenteral dosing with a transdermal patch, scheduled nurse-administered IV or IM injections, or baseline continuous IV infusion is preferred. When converting from oral to parenteral administration, the dose is usually decreased because parenteral administration bypasses gastrointestinal absorption variables and first-pass hepatic effects.\textsuperscript{354,355} Caution is needed when using continuous high-dose opioid therapy that causes excessive CNS and respiratory depression. Frequent assessment of the patient is recommended, especially during the early phase of therapy before a stable dose has been reached.

Multimodal analgesia can be used to decrease the total amount of opioid medication that is administered. The use of nonopioid analgesics, including acetaminophen and NSAIDs, can help to decrease the pain from inflammation and reduce the subsequent use of opioids. Ketorolac is particularly useful because it has been shown to decrease morphine use and morphine-related side effects.\textsuperscript{356} Use of ketorolac must be weighed against an increased risk for bleeding and potential impairment of bone fracture.
phine and nalbuphine should be avoided in opioid-tolerant patients because of its long duration of action, extremely powerful analgesic effects, and very low cost.364,365

It is also used in the management of severe chronic pain in opioid-dependent patients. Methadone is a synthetic opioid and an NMDA receptor antagonist. It is commonly used in maintenance therapy as an anti-addictive agent for patients with opioid dependency. It is also used in the management of severe chronic pain because of its long duration of action, extremely powerful effects, and very low cost.364,365

The use of opioid agonists/antagonists such as buprenorphine and nalbuphine should be avoided in opioid-tolerant patients because they may potentiate acute opioid withdrawal reactions.366,367

In summary,

- Acute pain management is sometimes extremely challenging in opioid-tolerant patients.
- Undertreated pain can lead to drug-seeking behavior and loss of trust between patients and caregivers.
- A comprehensive multimodal analgesic plan that includes regional analgesia should be started early and may decrease opioid requirements.
- NMDA receptor antagonists such as ketamine potentiate the analgesic effects of opioids.

### THE ELDERLY POPULATION

According to the U.S. Census Bureau, more than 12% of Americans are 65 years or older. This number is projected to increase to more than 20% by the year 2020 (Fig. 18.6).165 Recent reports show that 50% of all surgically treated cancers are diagnosed in patients older than 70 years and that one third of colorectal cancers are diagnosed in patients older than 80.368,369 Most patients in this age group will have at least one chronic condition, more than 90% will be taking multiple medications,370 a situation known as polypharmacy. Most of these patients will be taking pain medication on a regular basis. One quarter to one half of elderly individuals who live in the community and 50% to 80% of those who live in nursing homes suffer from chronic pain.371,373 Pain in this population is often underreported, underestimated, and undermanaged (Table 18.7).374 Despite global aging, discussions of pain management in the elderly are scarce in the literature.

As a consequence of age-related decreases in physiologic reserves and increased rates of comorbidity, elderly patients have a higher incidence of postoperative complications than do younger patients, especially if their pain is uncontrolled. Assessment of pain after surgery is frequently difficult because of cognitive dysfunction, difficulties in communication, and the common presence of depression. Depression can mask or exaggerate a patient’s perception of pain.375-377 Assessment of pain with a functional pain scale in frail elderly individuals is very reliable, especially when visual analog scales and other scales fail.378 Unfortunately, the general lack of knowledge among health care providers regarding pain management in geriatric patients and the fear of analgesic side effects379,380 have led to undermanagement of pain in this age group. The consequences of such undermanagement include suboptimal ambulation, higher rates of postoperative complications, longer length of hospital stay, and increased cost.374,381

Some clinical studies have indicated that pain perception may decrease with increasing age, in part because of decreased Aβ- and C-fiber function and delays in central sensitization.378,382 These studies have been interpreted by some to mean that elderly patients experience less pain than others. The response to pain in the elderly depends on the intensity and duration of the painful stimulation. Elderly patients tend to show increased tolerance of low-intensity and short noxious stimuli but may have an increased response to high-intensity and persistent stimuli, such as from surgery or trauma.383,384 The decrease in descending modulation after intense noxious stimuli may contribute to the decrease in pain tolerance and increased incidence of chronic pain.382,384

Nonopioid analgesics such as acetaminophen and NSAIDs are the first-line agents because neither impairs cognitive function. Given the adverse gastrointestinal and renal effects of NSAIDs and the recent association between COX-2 inhibitors and cardiovascular events,385 acetaminophen is probably the agent of choice for the treatment of mild to moderate pain in older patients without hepatic impairment. Opioids are effective for the treatment of moderate to severe pain and should not be withheld from patients for whom nonopioid medications have proved to be ineffective. However, opioid side effect profiles are particularly troubling in this population.

There are age-related changes in the pharmacokinetic effects of drugs. Older patients have increased sensitivity to and bioavailability of opioids because of a decrease in the number and affinity of tissue receptors and diminished first-pass activity. Therefore, opioids should be titrated slowly while patients are monitored for side effects. The use of IV titration of opioids or PCA in the elderly is a safe and common practice and will compensate for the wide interpatient variability.386,387 No difference in the incidence of pulmonary complications has been observed in the elderly with the use of PCA and systemic injections.388 Of note, some semisynthetic opioid agonists such as oxymorphone
are particularly safe to use because they are not metabolized through the cytochrome P-450 system. Hence, they have less risk for drug interaction. Measures to decrease the use of opioids should be applied whenever practical. Examples include adding adjuvant nonopioid medications to the treatment regimen and using regional nerve block techniques with local anesthetic drugs for postoperative pain control.

Delirium and impaired cognitive function could present a challenging complication in the elderly. Delirium is manifested as impaired consciousness and decreased ability to focus. It fluctuates during the course of the day and could persist for more than a few days in frail elderly persons. Postoperative delirium develops in 10% of elderly patients after noncardiac elective surgery and in 45% after major cardiac surgery. Although delirium is multifactorial, it is caused by an imbalance in CNS neurotransmitters. Risk factors include advanced age, preexisting cognitive dysfunction, and increased intensity of untreated pain. Meperidine in particular is consistently associated with delirium. Although the benefits of using regional anesthesia on postoperative cognitive function are not clear, use of an epidural with local anesthetics has been shown to provide analgesia superior to that of systemic opioids with fewer side effects. Peripheral analgesia and especially continuous analgesia have been shown to decrease postoperative delirium, although more double-blinded studies are needed.

Delirium and cognitive dysfunction should be treated by maintaining adequate tissue oxygenation and hemodynamic stability, using multimodal analgesia (including regional analgesia if possible), shortening the length of hospital stay, and improving rehabilitation and recovery.

Because of loss of reserve capacity, the elderly are more prone to the development of postoperative ileus. Postoperative pain and the use of opioids may induce or worsen ileus, thereby leading to increased hospital stay and cost. A systematic review of 23 studies (2871 patients) that examined the use of μ-opioid receptor antagonists for opioid-induced bowel dysfunction revealed that methylaltrexone bromide and alvimopan were both superior to placebo in reversing opioid-induced bowel dysfunction. Moreover, alvimopan appears to be safe and efficacious in the treatment of postoperative ileus. Nonpharmacologic interventions such as physical therapy, massage, alternating heat and cold compresses, transcutaneous electrical nerve stimulation, and

acupuncture may also benefit patients with ileus by stimulating the release of endogenous opioids.\textsuperscript{394-396} Additionally, the use of cognitive-behavioral approaches may improve patients’ coping strategies and thus further reduce the need for opioid medications.\textsuperscript{397}

In summary,

- Global aging will increase the annual number of surgical procedures performed in the elderly.
- The available data on pain management in the elderly are limited.
- The use of multimodal analgesia, including regional analgesia, may minimize sedation and cognitive dysfunction.
- Future research should focus on the impact of using continuous regional analgesia (nerualal and perineural) on quality of recovery after surgery and trauma in the elderly.
- Pain management in the elderly should be taught to all health care providers who interact with these patients.

**OBESITY AND OBSTRUCTIVE SLEEP APNEA**

In the United States, 20% to 25% of the population are either obese or morbidly obese. Obesity is defined as a body mass index (BMI) greater than 30 kg/m\textsuperscript{2} and morbid obesity as a BMI greater than 35 kg/m\textsuperscript{2}. Obstructive sleep apnea (OSA) is defined as more than five episodes of apnea (cessation of airflow for 10 seconds or longer) per hour. Up to 90% of patients with OSA are obese, and a large percentage of obese patients have OSA.\textsuperscript{398} The frequent association between the two conditions makes postoperative care of patients with OSA challenging.\textsuperscript{399} When considering pain management options for such patients, one should avoid using sedating medications, and systemic opioids should not be used as a first choice.

Regional analgesic techniques consisting of local anesthetics may be preferable to any opioid use.\textsuperscript{400} The literature contains no reports of whether low doses of circulating local anesthetics (delivered via incisional, perineural, or neuraxial techniques) inhibit respiratory drive in these patients. However, IV lidocaine has been shown to depress the ventilatory response to hypoxia in healthy subjects.\textsuperscript{401}

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea published an article in Anesthesiology in 2006 recommending that NSAIDs and multimodal analgesia be the first choice for patients with OSA.\textsuperscript{402} Furthermore, they recommended that regional techniques with local anesthetics be considered rather than systemic opioids. If parenteral narcotics are chosen, the patient should be monitored for respiratory depression.\textsuperscript{402}

The task force also recommended that opioids be excluded from epidural infusions and that basal infusion of opioids be avoided. Nonopioid analgesics such as tramadol should be considered rather than opioids. The use of NSAIDs and acetaminophen should be optimized with a scheduled dose. Patients with OSA may require careful monitoring and vigilance, especially during the first 24 hours after surgery.

PNBs may be critical components in providing postoperative pain relief to patients who are overweight. This concept was reviewed by Nielsen and colleagues,\textsuperscript{403} who prospectively collected observational data on almost 7000 patients receiving 9000 nerve blocks. Their findings indicated that block failure was 1.62 times more likely in obese than in nonobese patients ($P = 0.04$) and that the unadjusted rate of acute complications was higher in obese patients ($P = 0.001$). However, when compared with patients with a normal BMI, postoperative pain at rest, unanticipated hospital admissions, and overall satisfaction were similar in overweight and obese patients.\textsuperscript{404} Therefore, nerve blocks in overweight and obese patients will probably be more technically complicated and have a higher risk for failure, but PNBs (in the hands of experienced practitioners) are the logical first choice of analgesic technique, pending further study.

In summary,

- The frequent association between obesity and OSA in certain patients makes their postoperative pain management very challenging.
- Encourage the use of multimodal pain regimens, including regional analgesic techniques consisting of local anesthetics.
- Discourage the use of sedating medications and long-acting systemic opioids.

**TRAUMA AND CRITICALLY ILL PATIENTS**

Extensive tissue injury from trauma causes an immediate, potent, and magnified inflammatory response. Activation of nociceptors not only transmits afferent messages to the dorsal horn of the spinal cord but also initiates the process of neurogenic inflammation. Neurogenic inflammation causes release of neurotransmitters, notably substance P and calcitonin gene–related peptide, which leads to severe vasodilation, as well as plasma leakage of proteins and fluid from postcapillary venules.\textsuperscript{404} The magnified inflammatory process frequently results in major morbidity and mortality in trauma patients. Hemorrhagic trauma could lead to generalized ischemia, and reperfusion can contribute to multiple-organ dysfunction, acute lung injury, and acute brain injury.\textsuperscript{405,406} Numerous reports point to the inadequacy of pain management in trauma patients, particularly during the evaluation and resuscitation phases of care (Table 18.8).\textsuperscript{407-412}

Undertreatment of acute pain in trauma patients may have many causes, including lack of proper pain assessment, especially if the patient cannot report the pain; late or improper administration of analgesics; concerns about hemodynamics; fear that analgesia may interfere with the accurate diagnosis of injuries; the misconception that sleep automatically indicates the absence of pain; unfounded concerns that opioid use in the management of acute pain leads to addiction; and beliefs that trauma patients do not remember painful events.\textsuperscript{409,413,414}

Evidence indicates that untreated pain in trauma and critically ill patients has a negative impact on the physiologic stress response to injury and can contribute to the incidence of complications such as pulmonary dysfunction, thromboembolic phenomena, myocardial infarction, decreased immune function, and immobility.\textsuperscript{415-417} Furthermore, evidence suggests that acute pain may lead to secondary hyperalgesia, allodynia, and chronic pain by inducing changes in the way that pain signals are transmitted and processed within the CNS.\textsuperscript{418-420} Finally, there are reports of depression and post-traumatic stress disorder (PTSD) resulting directly from uncontrolled pain.\textsuperscript{421,422} Treating pain properly and early in patients with trauma and critical illness will suppress
the production of inflammatory mediators, decrease the catabolic response of pain, improve the lymphocytic immune system, and decrease the incidence of PTSD.423-427

EVALUATION OF ANALGESIC NEEDS IN TRAUMA PATIENTS

The prehospital and emergency department evaluation and resuscitation phase of trauma care is a period of severe physiologic stress for the victim. The primary therapeutic goals during this time are to maintain a patent airway, ensure adequate oxygenation and ventilation, support the circulation, and assess global neurologic function.428,429 Assessment and management of life-threatening injuries take priority above all else, but treatment of pain is not necessarily contraindicated.

Once the patient has been determined to have a stable or hyperdynamic circulation, careful use of short-acting IV opioids such as fentanyl is indicated. Often a patient will become more cooperative once adequate analgesia is achieved, which facilitates further evaluation and detection of previously unrecognized injuries. Such cooperation is particularly important during the evaluation of cervical spine injuries, wherein distracting injuries can contribute to late or missed diagnoses.430,431 In rare cases, the stress response to pain and associated elevations in catecholamine levels may contribute to the patient’s hemodynamic stability, and alleviation of pain may result in hemodynamic decompensation. In such cases, even though analgesic administration may be the proximal cause of the decompensation, the actual cause is generally related to blood loss and hypovolemia, which is responsive to rapid but careful fluid resuscitation.

In a study evaluating the use of fentanyl during air medical transport for trauma, only 4 (2.2%) of 177 patients exhibited reductions in systolic blood pressure to below 90 mm Hg after fentanyl administration, with the lowest in this study being 81 mm Hg. In all cases, systolic blood pressure returned to 90 mm Hg or higher within 3 to 10 minutes.432 This finding indicates that fentanyl is a safe and effective analgesic in the prehospital setting and that analgesia should not be withheld because of concerns regarding hemodynamic instability in patients who are otherwise stable.

In patients who are conscious but hemodynamically unstable, ketamine or tramadol have been shown to be useful alternatives.433,434 Nitrous oxide may be available in some clinical settings for the management of pain related to specific procedures, such as establishment of IV access, diagnostic peritoneal lavage, or manipulation of extremity fractures. Nitrous oxide should not be used in patients with pneumothorax.435,436 If respiratory depression is of concern, dexmedetomidine, a centrally acting α₂-adrenergic agonist that lacks respiratory effects, has been shown to provide effective analgesia and sedation; it produces minimal hemodynamic decompensation, induction of amnesia is still commonly indicated.

amnesia and minimize the psychological impact associated with uncontrolled pain (see Table 18.8). 439

During the initial hospitalization time, additional invasive and noninvasive diagnostic studies are performed to identify and further characterize the patient’s injuries. Operative management of second-priority injuries such as eye and facial trauma, musculoskeletal and spine injuries, and vascular or visceral trauma may be undertaken at this time. 428, 429 Titration of short-acting opioids is recommended.

Although systemic opioids will probably continue to be the primary pain therapy for trauma and critically ill patients, a multimodal approach that includes regional analgesia should also be considered. Intermediate-acting agents such as morphine and hydromorphone are useful for achieving a stable level of analgesia for background pain. IV PCA is a very useful mode of delivery and could be converted to an oral preparation after the patient begins to tolerate oral intake of food. A plan must also be in place to provide additional analgesia for times when a patient may need to undergo procedures or dressing changes that trigger intense exacerbation of pain. In special cases, other adjuncts such as propofol, along with fentanyl, ketamine, or midazolam, may be used to provide adequate analgesia and sedation. Sometimes general anesthesia may be needed. 440

Spinal or epidural analgesia can be very useful for treating postoperative pain in trauma patients and after procedures such as laparotomy, thoracotomy, or reduction of lower extremity fractures. 441 Continuous epidural analgesia was found to be superior to IV PCA after intra-abdominal surgery. 442 The potential hemodynamic impact of the sympathetic blockade associated with these techniques must be carefully considered. IV crystalloid administration during placement of a spinal anesthetic has been shown to decrease hemodynamic changes. 443

Depending on the mechanism of injury, one should confirm definitive spine clearance before proceeding with a neuraxial technique. Another consideration, depending on the nature and extent of the patient’s injuries, is that patient positioning may factor into the feasibility of these techniques. Finally, one should be alert for the presence of coagulopathy in patients with polytrauma, which would be a contraindication to neuraxial techniques.

Selected peripheral regional analgesic techniques may be useful for the management of pain related to specific sites of injury. For example, paravertebral blocks may be indicated for pain related to rib fractures. 444 Isolated PNBs may also be useful in the management of extremity injuries. These may include femoral and sciatic nerve blocks for knee injuries, popliteal sciatic nerve and saphenous nerve blocks for lower leg injuries, and brachial plexus blocks for upper extremity injuries. 445-448 The use of continuous-infusion PNCs should be considered in patients with more extensive trauma for which the duration of severe pain is expected to be longer than 1 to 2 days.

Peripheral regional techniques not only improve pain and patient satisfaction and decrease side effects related to systemic opioids but also facilitate participation in physical therapy and examination of painful injured extremities. 148, 149 The ongoing benefit of perineural and neuraxial catheters must be weighed against the small but real potential for infection if catheters are left in place for long periods. 450

**ANALGESIA FOR TRAUMA IN ALCOHOL-INTOXICATED PATIENTS**

Alcohol consumption has a strong association with trauma, 451, 452 both accident related and violence related. According to the Insurance Institute for Highway Safety, alcohol is a contributing factor in 50% of all trauma deaths. Patients who are not accustomed to regularly using alcohol are subject to higher risk for an injury immediately after alcohol consumption than are patients who drink more heavily. 453 Furthermore, alcohol abuse is associated with an increased risk for readmission for new trauma. 454

During the acute phase of injury, administration of sedative or opioid medications places an intoxicated patient at risk for increased CNS and respiratory depression because of the additive effects with alcohol. However, once the acute effects of alcohol intoxication have worn off, a chronic alcoholic patient will demonstrate tolerance to sedative medications, as well as cross-tolerance to opioids. As a result, much higher doses of opioids may be necessary to achieve adequate analgesia. This situation may be particularly problematic if the patient’s alcohol abuse history is undocumented and normally adequate doses of opioids are proving to be ineffective. In patients with alcoholic cirrhosis and advanced liver disease, altered metabolism and excretion of drugs will change the dosing of hepatically metabolized medications, including opioid analgesics. In patients with end-stage liver disease, coagulopathy may contraindicate the use of neuraxial and some PNB techniques for pain control. Patients with a history of chronic alcohol abuse also have a twofold increased risk for complications, particularly pneumonia, infection, prolonged hospitalization, and respiratory failure. 455 Pain control in patients with abdominal and thoracic trauma becomes particularly important to promote deep breathing and appropriate pulmonary toilet. Given the increased risk for pneumonia and the known respiratory depressant effects of opioids, one may consider neuraxial or regional techniques in alcoholic patients who undergo exploratory laparotomy or thoracotomy, as long as coagulopathy has been ruled out. Paravertebral nerve blocks can also be considered for the same reasons in chronic alcoholic patients with rib fractures.

**ANALGESIA IN PATIENTS WITH HEAD TRAUMA**

Acute pain management of head trauma patients presents several unique considerations. First, it is difficult to assess the level of pain in patients with altered mental status. Another concern is that the sedating effects of opioids could interfere with adequate neurologic assessment. As a result, trauma patients with head injuries are less likely to receive opioids than are patients with comparable injuries who have not sustained head trauma. 414 Whether the pain results directly from the head trauma or, more likely, is a result of other injuries, it is important to tailor the analgesic regimen to facilitate ongoing neurologic assessment. To minimize the sedating effects of opioids, analgesic treatments should include the use of nonsedating analgesic agents and opioid-reducing strategies whenever possible. IV aceterminophen (recently approved by the FDA in the United States) is a good choice for mild to moderate pain. NSAIDs such as ibuprofen and ketorolac are best avoided in any patient at risk for intracranial bleeding because of the platelet-inhibiting effects of this drug class. For moderate
to severe pain, shorter-acting opioids such as fentanyl or remifentanil (as an infusion) can be used for the management of background and breakthrough pain in the acute period. IV PCA is a good choice in sufficiently alert patients. A continuous background infusion can be added via IV PCA to provide baseline analgesic requirements. Morphine and hydromorphone have longer half-lives than fentanyl does and can be used in many cases, but the sedating effects may persist longer than the analgesic effects and thus possibly impede neurologic evaluation. In the critical care setting, continuous brief infusions of fentanyl, alfentanil, sufentanil, or ultrashort-acting remifentanil can be used. As a result of their shorter half-lives, these infusions can be temporarily stopped to enable rapid neurologic assessment. Because both morphine and fentanyl have prolonged context-sensitive half-lives with extended infusions, recovery is prolonged after their termination. Longer-acting or sustained-release preparations should be started only after intracranial injury has been definitively excluded or the patient’s neurologic status has stabilized.

Paravertebral blocks or catheters may be a better alternative to epidural analgesia in this setting because of the small but real risk of dural puncture associated with an epidural. Dural puncture could result in expansion of an intracranial hematoma or uncal herniation. Continuous nerve block techniques should be considered for the management of coexisting extremity injuries to further reduce opioid requirements.

**ANALGESIA IN PATIENTS WITH BLUNT THORACIC TRAUMA**

Injuries typically categorized under this heading (Table 18.9) include rib fractures, flail chest, pulmonary and cardiac contusions, disruption of thoracic vessels, hemothorax, pneumothorax, and soft tissue trauma. Motor vehicle accidents and falls account for most of these injuries. Thoracic injuries contribute significantly to trauma-induced morbidity and mortality and lead to 25% of trauma-related deaths. Rib fractures are the most common injury and are seen in 10% of all trauma patients. Thoracic injuries can impair respiratory function directly through physiologic and mechanical changes, such as those seen with pneumothorax, flail chest, and pulmonary contusions. Thoracic injuries can also have indirect effects via increased pain with respiration, commonly seen with multiple rib fractures. These factors lead to splinting during respiration, which increases atelectasis, decreases functional residual capacity, impairs coughing ability, and predisposes patients to pneumonia. Furthermore, these effects can lead to changes in pulmonary ventilation-perfusion matching (V/Q mismatch) and result in hypoxia.

CNS, central nervous system; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs; PCA, patient-controlled analgesia.
Because of these latter pain-related sources of morbidity, adequate pain control is of obvious importance, particularly in patients who are breathing spontaneously.

Multiple options exist for the management of pain in patients with blunt thoracic trauma. Traditionally, systemic opioids administered via IV PCA have been the primary means of controlling pain in these patients. The primary disadvantage is that opioids cause CNS and respiratory depression and impair the cough reflex. These factors lead to hypoxemia and further impairment in ventilation.

Continuous epidural infusion (CEI) of a local anesthetic combined with a low-dose opioid has been shown to confer better pain relief than IV PCA and result in increased tidal volume and inspiratory force. CEI can be combined with a patient-administered bolus via PCEA to give patients a similar degree of control over their pain management as seen with IV PCA. Hypotension is the most common side effect noted with epidural infusions and is related to local anesthetic-mediated effects on the sympathetic nervous system. Good analgesic results have also been reported with continuous epidural opioid infusions. As with IV opioids, epidural opioids often produce nausea, pruritus, and constipation. In some cases, excessive sedation and respiratory depression occur. If these side effects are seen with epidural infusions of local anesthetic and opioid in combination, one can opt for an epidural infusion of a local anesthetic only. Opioid IV PCA can be added for more precise control of the opioid dose.

Paravertebral blocks provide an alternative to epidural analgesia in patients with unilateral thoracic trauma, which occurs commonly in side-impact motor vehicle accidents and in falls. With paravertebral blocks, local anesthetic injected into the paravertebral space produces an ipsilateral block at multiple dermatomes. For continuous provision of analgesia, a catheter can also be inserted percutaneously or by the surgeon under direct vision during thoracotomy. Paravertebral analgesia has been shown to provide effective pain relief in patients with multiple rib fractures and to improve respiratory parameters and oxygenation. Paravertebral techniques are considered easier to perform than epidural techniques. Catheters could be an option.

Paravertebral blocks have a low incidence of complications, including failure, inadvertent vascular puncture, hypotension, hematoma, epidural or intrathecal spread, pleural puncture, and pneumothorax. Paravertebral blocks are an excellent choice in patients who already have chest tubes inserted on the side of the planned block. Because the sympathetic effects of paravertebral blocks are typically unilateral, patients who receive these blocks experience hypotension much less frequently than those who receive continuous epidural analgesia, provided that the patient is adequately fluid-resuscitated.

Intercostal nerve blocks are another effective option for the management of pain associated with chest trauma and rib fractures. These blocks have been shown to improve oxygenation and respiratory mechanics and offer pain relief that is comparable to that of epidural analgesia. The technique is limited by the relatively large doses of local anesthetic required; the relatively high intravascular uptake from the intercostal space increases the risk for local anesthetic toxicity. The most common complication associated with this technique is pneumothorax (occurring at an incidence of 1.4% per individual nerve block and in 5.6% of patients with multiple blocks for multiple rib fractures).

Because the duration of analgesia is only 6 to 12 hours, multiple daily injections are often necessary. Even though percutaneously placed intercostal nerve block catheters can deliver effective continuous analgesia, the technical difficulty associated with their placement results in a high rate of misplaced catheters.

Local anesthetics can be delivered via a catheter into the interpleural space; the local anesthetics then diffuse through the parietal pleura to block the intercostal nerves. Interpleural blocks may or may not be as effective as epidural blocks in patients who have rib fractures or have undergone thoracotomy. Because insertion may be technically difficult, catheters may be misplaced into either the pleura or the chest wall. Pneumothorax is the most common complication of interpleural catheters. Despite these limitations, this technique may be useful for patients in whom other techniques are contraindicated.

In summary,

- The extensive tissue injury in trauma and critically ill patients causes a potent and magnified inflammatory response.
- Untreated pain in trauma and critically ill patients can lead to increased morbidity and mortality.
- The choice of analgesic drug in trauma patients depends on the patient’s hemodynamic status and the need to assess CNS function.
- Ketamine, tramadol, and nitrous oxide have been shown to be useful alternatives in patients who are conscious but hemodynamically unstable.
- Selected peripheral regional analgesic techniques may be useful for the management of pain related to specific sites of injury.
- Peripheral regional analgesic techniques can play an important role in analgesia for trauma patients because they can substantially reduce the use of opioids.
- Both perineural and neuraxial continuous techniques are beneficial in blunt chest trauma.

**ANALGESIA IN PATIENTS WITH BURN INJURY**

Burn injuries cause severe pain that is associated with the injury itself and with the multiple interventions that follow. Thus, patients have background pain that is exacerbated during wound care, dressing changes, and débridement. The level of pain can be difficult to predict. Full-thickness burns involve the destruction of nerve fibers and consequently do not result in pain. Patients with extensive full-thickness burns will experience pain only from tissues at the margins of the burned areas. Patients with partial-thickness burns will have damaged but functioning nerve fibers that are exposed at the surface of the skin. These nerve fibers can transmit severe pain, particularly in response to surface contact. Furthermore, activation of nociceptive and inflammatory mediators can alter the response to additional stimulation and result in hyperalgesia and temporal summation. Pain can persist well beyond the healing period and cause impaired function and psychological problems. Therefore, it is imperative to manage burn pain aggressively.

**OPIOIDS IN PATIENTS WITH BURN INJURY**

Opioids continue to be the primary therapy for the management of background and procedural pain (Table 18.10). Despite the enhanced potency of opioids after acute burn injury, opioid requirements can be quite high. Burns cause substantial changes in metabolism and protein binding, but the pharmacokinetics of IV opioids remains unaltered. Therapy is initiated with small IV boluses, which are titrated to effect. To this end, IV PCA has been shown to be safe and effective. Absorption of IM and transdermal opioids is variable because of decreased tissue perfusion and uptake, which makes these routes unsuitable in this patient population. However, gastrointestinal absorption and emptying appear to be unchanged. Once an adequate baseline opioid requirement is established for the management of background pain, opioids can be given via continuous IV infusion or by equianalgesic enteral formulations of long-acting or sustained-release opioids.

Dressing changes and wound débridement cause brief but intense periods of pain. During such episodes, opioids are the principal therapy, with preference given to fentanyl or short-acting opioids such as alfentanil and remifentanil. These opioids can be administered by a clinical provider or via IV PCA. Opioids whose effects last longer than the duration of the procedure can produce excessive sedation and respiratory depression once the intervention is completed.

**NONOPIOID ANALGESICS IN PATIENTS WITH BURN INJURY**

NSAIDs can be useful as adjuncts to opioids by decreasing inflammation and opioid requirements. Ibuprofen may improve tissue perfusion after burn injury and may decrease the hypermetabolic response. However, one should be wary of NSAIDs’ gastrointestinal side effects, including gastric ulcers, particularly in a patient population already predisposed to stress gastritis. In addition, NSAIDs have been implicated as a contributing cause in renal impairment after burn injury. Acetaminophen may be a better alternative for mild pain in burn patients with normal hepatic function.

Local anesthetics have been used in a variety of ways for burn patients. Topical application has been shown to be effective for the treatment of postburn pain and pruritus. However, local anesthetics pose an increased risk for rapid systemic uptake and toxicity when applied to non-intact skin and can potentially cause seizures or dysrhythmias. Lidocaine, when given by IV infusion, has significant opioid-reducing effects and acts to decrease inflammation at the burn site. Local anesthetics, administered either topically or by local infiltration, have also been used successfully to decrease the pain associated with skin grafting.

Ketamine, a dissociative anesthetic, has the advantage of providing analgesia while maintaining stable hemodynamic function and causing minimal respiratory depression. Studies also suggest that ketamine may suppress burn-induced secondary hyperalgesia. Ketamine can be administered via IV or IM injection, as well as by the oral, rectal, or nasal route. The primary clinical use of ketamine has been to provide sedation and analgesia during wound dressing changes and débridement, particularly in children. Ketamine infusion has also been used successfully for long-term sedation and analgesia in a burn patient, with remarkable opioid-sparing effects. Its dissociative effects can be unpleasant for patients, however, and can lead to emergence delirium.
Delirium may be attenuated by preemptive or rescue doses of midazolam or propofol.490,492

Clonidine, an \(\alpha_2\)-adrenoceptor agonist, exerts sedative and analgesic effects through its action on the CNS. Clonidine exhibits synergistic effects with opioids and has been used as an adjunct in the management of postoperative pain.493 Several case studies have reported its successful use in burn patients.494,495 Clonidine does not cause respiratory depression, and its opioid-sparing effect can be used to decrease opioid-related side effects. One should avoid using clonidine in hemodynamically unstable or hypovolemic patients because of the risk for hypotension.

PERIPHERAL REGIONAL ANALGESIC TECHNIQUES IN PATIENTS WITH BURN INJURY

Patients with burn injuries are generally poor candidates for regional analgesic techniques. In most cases the duration of pain after burn injury is far longer than it is practical to maintain an indwelling PNC. Also, the skin overlying the proposed peripheral block site must be intact to reduce the risk for infection in patients already at high risk for infection and sepsis. In addition, many burns are not limited to the distribution of one or two peripheral nerves that are easily blocked. Hence, the usefulness of these techniques is limited to cases of mild isolated extremity burns. However, nerve blocks have been used successfully in the management of pain at graft donor sites.496

PSYCHOLOGICAL SUPPORT AFTER BURN INJURY

Burn trauma can be devastating to a patient both physically and psychologically. Patients can become depressed or have high levels of fear and anxiety, particularly if the degree of injury or disability is severe or if hospitalization is lengthy. The anxiety often revolves around the repeated painful wound treatments that patients must undergo. Evidence has shown a relationship between patients’ levels of depression and anxiety and their reported levels of pain.497 In a study by Van Loey and associates,498 PTSD developed in as many as 25% of patients after burn injury. Predictors included anxiety, female gender, and severity of injury. Effective anxiolysis with benzodiazepines such as midazolam, diazepam, and lorazepam has been shown to reduce pain in patients with burn injuries.499,500 Low doses of antidepressants, including selective serotonin reuptake inhibitors and tricyclic antidepressants, have also been shown to potentiate the analgesic effects of opioids.501,502 Other therapeutic interventions, including hypnotis, acupuncture, auricular electrical stimulation, massage therapy, biofeedback, mental imagery, and relaxation training, have been used to reduce pain scores in burn patients with mixed results.413,503,504

In summary,
- Pain after burn injury can persist well beyond the healing period and result in impaired function and psychological problems.
- IV opioids are still the primary therapy for the management of acute pain and procedural pain in burn injury.
- Absorption of IM and transdermal opioids is variable because of decreased tissue perfusion and uptake.
- Short-acting opioids such as alfentanil and remifentanil are essential for wound débridement.
- Ketamine has the advantage of providing analgesia while maintaining stable hemodynamic function with minimal respiratory depression.
- Regional anesthetic techniques are of limited use in patients with extensive burns but could be used in cases of mild isolated extremity burns.

SUMMARY OF THE CHAPTER

- Adequate postoperative pain control continues to be a public health problem.
- Multimodal analgesia is becoming the standard practice in acute pain management.
- Systemic opioids are still the traditional foundation for the treatment of acute pain in many practices.
- Nonopioid analgesics play a primary role in pain management and result in an opioid-sparing effect.
- Neuropathic and peripheral analgesic techniques have established an important role in acute pain management; however, their use is limited by variability in the skills and experience of practitioners.
- Neuropathic needs warrant special consideration in patients who have suffered trauma or burn injury and for patients who are elderly, obese, or opioid tolerant.
- Pain management is becoming an important ethical responsibility of the medical profession and the focus of the health care system.

ACKNOWLEDGMENT

Portions of this chapter were transcribed or modified from the chapter “Postoperative Pain and Other Acute Pain Syndromes” authored by Dr. Brian A. Williams and colleagues in Raj’s Practical Management of Pain (fourth edition).

Chronic pain as an outcome of surgery is an area of investigation that has received increased attention over the last 15 years. Twenty years ago there were a few identified postsurgical pain syndromes, such as post-mastectomy pain syndrome and post-thoracotomy pain syndrome. The problem of persistent postsurgical pain (PPSP) as a more generalized syndrome has received attention more recently. Cross-sectional quality-of-life surveys reveal that 40% of the population who underwent surgery in the last 3 years reported persistent pain at the surgical site. The risk for PPSP is now commonly discussed with patients before surgery. In addition to the ethical obligation to discuss this risk prospectively, there may be ways to minimize the risk for certain subpopulations of patients. In this chapter we address the extent of the problem of chronic pain following surgery in general and then, by using four specific surgeries as examples, attempt to better understand the effect of patient factors, surgical factors, and analgesic interventions on the risk for PPSP. Among the questions that we will address are the following:

- Can patients at increased risk for the development of PPSP pain be identified prospectively?
- Are there interventions that can be initiated in the preoperative, intraoperative, or immediate postoperative period to minimize the risk for chronic pain?
- What is the relative importance of patient factors, surgical factors, and analgesic factors in the development of chronic pain following surgery?

To discuss these questions in an effective manner, it is necessary to agree on the definitions of the terms used in the discussion. Table 19.1 is a list of definitions of important terms used in this chapter.

Pain is a common phenomenon after surgery. Some degree of postsurgical pain is expected after most surgical procedures. However, the extent of acute postoperative pain is highly variable among individuals undergoing similar surgery. As a generalization, more extensive surgical procedures are associated with greater acute pain. In many studies the extent of acute postoperative pain has been a predictor of PPSP. Consequently, a number of studies have been conducted to address questions that may relate to both acute postoperative pain and PPSP. Does the use of minimally invasive approaches have advantages beyond the acute postoperative period? Does our ability to alter the acute pain experience influence the probability of PPSP? If acute postoperative pain control alters PPSP, how does that happen?

What patient factors are predictive of PPSP? We will explore these questions by using the examples of breast surgery, hip surgery, inguinal hernia repair, and thoracotomy.

In a recent review, Katz and colleagues emphasized that the timing of the preemptive intervention needs to correlate with the period of intense nociceptive stimulation and not just be a single intervention of short duration. They suggested that the term “preventive analgesia” would be more useful, and we agree, although it has been pointed out that evidence to support the concept of preventive analgesia is weak. The concept of preemptive analgesia originated with a paper by Clifford Woolf in 1983. The findings of this study, when combined with what is known as wind-up or increasing pain intensity when a given painful stimulus is delivered repeatedly above a critical frequency, gave rise to the hope that interventions that decrease nociceptive input or block central sensitization would have lasting analgesic benefit. How pain progresses from acute nociceptive pain, to subacute pain, to chronic pain has been reviewed by Devor and Seltzer, who incorporated animal model data and human data. Briefly, persistent acute nociceptive stimulation elicits both pain and activation of sensitization in the spinal cord. In the subacute pain period there is probably some nociceptive stimulation that can maintain the sensitization and pain. In some models and some individuals there does not appear to be any resolution of this sensitization. It is not clear whether some nociceptive input is needed to maintain the sensitization or whether changes in the spinal cord following nerve injury are sufficient to maintain sensitization and thus pain.

Numerous factors related to the surgery appear to be of importance. First among these is the surgical procedure. Previous reviews have documented that the prevalence of chronic pain varies with the type of surgery, with some surgical procedures such as lower extremity amputation and posterolateral thoracotomy having a high prevalence of chronic pain (greater than 50%). Table 19.2 summarizes the prevalence of chronic pain following many common surgical procedures. As shown in this table, chronic pain is infrequent following some surgical procedures, such as cataract extraction, but prevalent following other surgical
procedures, such as thoracotomy. Additionally, the prevalence of pain may decrease following certain surgeries (hip arthroplasty, lumbar laminectomy for a herniated disk) but increase following other surgeries (thoracotomy, breast surgery). This does not mean that PPSP cannot result from a surgery such as hip arthroplasty, but rather that the majority of patients experience a reduction in pain following the procedure, and a smaller number may have increased pain.

Within a given type of operation, a number of surgical approaches may be possible. For thoracotomy, an anterior approach appears to be associated with less acute and chronic pain than the classic posterolateral approach. Additionally, there may be less acute and chronic pain with visually aided thoracoscopic surgery than with the same operation performed as an open procedure. Likewise, laparoscopic inguinal hernia repair is associated with less acute pain and less chronic pain than open inguinal hernia repair is. Thus there are data to support the hypothesis that minimally invasive surgical procedures are associated with less chronic pain than the same operations performed as open procedures.

Another factor may be what has been referred to as “volume-dependent outcome.” Database studies demonstrate that for a number of major high-risk surgeries, outcome is worse when the procedure is performed in a low-volume institution and that a large part of the risk can be attributed to low-volume surgeons. We previously noted that in the case of hernia repair, the lowest prevalence of chronic pain is reported by high-volume hernia centers. The incidence of complications, including chronic pain, following laparoscopic hernia repair has been noted to be greater early in the experience of surgeons. This may be analogous to the observation that hernia surgery performed by trainees has a higher incidence of recurrence and chronic pain than the same surgery performed by experienced surgeons.

Adjuvant treatments associated with a number of surgical procedures for cancer may also play a role in the development of PPSP. In particular, radiation therapy for women undergoing breast and axillary surgery is associated with an increased probability of chronic pain.

CABG, coronary artery bypass grafting; VATS, video-assisted thoracic surgery.
therapies in the perioperative period affect the risk for chronic postsurgical pain after other cancer surgeries has not yet been determined.

It should be understood that patients vary in their sensitivity to pain and in other factors that may predict the evolution of acute pain to chronic pain. This has been an area of research for many years, with Lasagna and Beecher finding that one third of patients following surgery did not experience significant pain relief with commonly used dosages of morphine. Likewise, in subsequent studies, Lasagna and associates continued to find significant patient variability in response to both surgery and opioids and that patients’ reports of pain sensitivity predicted neither the extent of pain nor the response to opioids. A number of more recent studies have investigated the genetic basis of pain variability (see Young and colleagues for a review).

There are also psychological factors, other than pain sensitivity, that appear to predispose certain individuals to experiencing pain. Psychological vulnerability has been found to be a predictor of long-term pain and symptoms following surgery and that patients’ reports of pain sensitivity predicted neither the extent of pain nor the response to opioids. A number of recent studies have investigated the genetic basis of pain variability (see Young and colleagues for a review).

The intensity of pain in the postoperative period has been a reproducible predictor of chronic pain following a number of surgeries, including those of lower extremity amputation, thoracotomy, mastectomy, cholecystectomy, and inguinal hernia surgery. Usually, pain intensity is measured directly with some instrument, but analgesic consumption is also frequently measured as a surrogate algometer. When looking at studies of interventions aimed at decreasing the intensity of acute pain and reducing the prevalence or intensity of chronic pain, there are a number of factors that we believe should be considered.

- What intervention or interventions were implemented?
- When were they initiated relative to the initial nociceptive stimulus?
- How long were the interventions continued?
- Were the interventions effective in decreasing acute pain or acute opioid consumption?
- Were the doses of medication used in a clinically reasonable range?
- Was there a systematic evaluation of pain and symptoms both acutely and chronically?
- What chronic pain was assessed?
- Were the randomization and blinding adequate to eliminate investigator bias?

We will be reviewing studies for some selected surgical procedures in the following sections and will try to identify how some of these factors may have influenced the observed outcome. In particular, specific drugs such as gabapentin or pregabalin have been advocated to decrease the prevalence of PPSP, but the results have been highly variable.

## BREAST SURGERY

The majority of studies of chronic pain following breast surgery involve women with cancer. There are also some reports of reasonable quality following augmentation mammoplasty or reduction mammoplasty. Studies of both cancer surgery and augmentation mammoplasty document a significant prevalence of chronic pain following breast surgery (see Table 19.2). Women undergoing cancer surgery also have problems with persistent arm pain following axillary dissection. Radiation therapy and chemotherapy following breast surgery will further increase the prevalence of persistent pain. Careful handling of the intercostal brachial nerves in the axilla appears to decrease the risk for persistent pain.

A number of studies now demonstrate that axillary sentinel node biopsy is associated with less persistent pain than primary axillary dissection. Radiation therapy and chemotherapy following breast surgery will further increase the prevalence of persistent pain. Careful handling of the intercostal brachial nerves in the axilla appears to decrease the risk for persistent pain. In women with negative pathology on a sentinel node biopsy, arm pain and other arm symptoms are significantly less likely to develop. In women who underwent secondary axillary node dissection, chronic pain was as likely or more likely to develop than in those who underwent primary axillary node dissection.

Breast-conserving surgery has been associated with a higher prevalence of chronic pain than simple mastectomy, but only in studies where persistent pain was assessed as a tertiary, not a primary or secondary, outcome, and this association has not been found consistently. There are no randomized studies on this issue.

Paravertebral block has been advocated as an analgesic technique for breast surgery and the immediate postoperative

RCT, randomized controlled trial.
period. In 2006 two randomized controlled studies looked at the influence of perioperative paravertebral blockade on persistent pain following breast surgery. Both found a significantly lower prevalence of chronic pain in women who had the block. One was a follow-up study of 60 women who had participated in an acute perioperative pain study. In this study, the prevalence of pain at both 6 and 12 months was significantly lower in the women who had received a block (17% vs. 40% at 6 months and 7% vs. 33% at 12 months). The second study was smaller (29 subjects) and involved placement of a paravertebral catheter preoperatively in patients in the treatment arm. A dose of 10 mL of 0.25% bupivacaine was administered before surgery and every 12 hours for 48 hours. A telephone follow-up inquired about pain 3 months following surgery (“Do you have chronic pain as a result of your breast surgery?”). The paravertebral block group had a significantly lower prevalence of pain at 3 months (0% vs. 80%). There has now been a third study published supporting the use of paravertebral block to decrease the prevalence of PPSP at 4 to 5 months. If the data from these three studies are combined, the calculated odds ratio of preventing PPSP with a paravertebral block is highly significant (see Table 19.3).

A number of randomized controlled studies have investigated perioperative interventions to decrease the prevalence of persistent pain after breast surgery. Romundstad and associates compared a single dose of methylprednisolone (125 mg) with a single dose of parecoxib (40 mg) and placebo in women undergoing augmentation mammoplasty. At 12 months the prevalence of pain at rest in the three groups was 16%, 7%, and 16%, respectively. Evoked pain was found in 16%, 14%, and 29%, respectively. The calculated odds ratio and 95% confidence intervals were 0.49 (0.30 to 0.74) for methylprednisolone versus placebo and 0.40 (0.25 to 0.64) for parecoxib. Fassoulaki and colleagues published two randomized controlled studies of perioperative gabapentin. In the first, women received gabapentin, 400 mg three times a day starting the evening before surgery, plus placebo. In the second study, women undergoing breast cancer surgery received a combination of gabapentin, 400 mg four times a day for 10 days starting the evening before surgery, plus EMLA cream (20 g) for 3 days starting the day of surgery, plus intraoperative irrigation of the brachial plexus with 10 mL of 0.75% ropivacaine. The control group underwent placebo administration in each of the interventions. This study found a significantly decreased prevalence of pain at both the 3- and 6-month follow-up in the intervention group (30% vs. 57% at 6 months). The calculated odds ratio for pain at 6 months was 0.32 (0.18 to 0.62). A recent systematic review comparing open hernia repair with laparoscopic repair with mesh, identification and sectioning of major nerves versus preservation of these nerves, the use of lightweight mesh versus regular mesh, and comparison of open mesh repairs with open nonmesh repairs. Table 19.4 is a summary of the effects of different surgical interventions on the probability of persistent pain. These data are presented as odds ratios and 95% confidence intervals. A recent systematic review comparing open hernia repair with laparoscopic

Meta, meta-analysis.
repair found a lower risk for PPSP with a laparoscopic approach for primary, unilateral hernia repair. Repair of recurrent hernias appears to be different, with no benefit found when comparing laparoscopic and open hernia repair. A Cochrane Database review did not find a difference in the prevalence of chronic pain when comparing a Shouldice repair with an open mesh repair or when comparing a Shouldice repair with an open nonmesh repair. A systematic review of nerve preservation versus sectioning found three randomized controlled trials and four cohort trials. Intentional sectioning of the ilioinguinal and iliohypogastric nerves did not alter the probability of persistent pain following hernia repair at 6 months (21% prevalence of pain for nerve sectioning and 23% prevalence for nerve preservation). Lightweight mesh appears to be associated with a lower prevalence of chronic pain than heavyweight mesh does. Use of tissue adhesives rather than sutures to secure the mesh in open hernia repairs is associated with fewer moderate to severe complications at 6 to 12 months. In another study comparing a cyanoacrylate as an adhesive for the mesh with sutures, pain prevalence at 15 months was zero in the adhesive group and 18% in the suture group.

Few analgesic interventions have been reported to be of benefit regarding PPSP. A consensus statement was issued regarding prevention and management of PPSP, but neither anesthetic nor postoperative management was addressed. One study of a single dose of gabapentin given 1 hour before surgery reported lower mean pain intensity at 1, 3, and 6 months' follow-up. There are some data on which patients are at increased risk for the development of PPSP following hernia repair. Aasvang and colleagues performed detailed somatosensory examinations on patients scheduled for elective, unilateral hernia repair both before and 6 months following surgery. The studies were performed at two hernia centers; one center performed only open mesh repairs, whereas the other center used a laparoscopic transabdominal preperitoneal (TAP) approach and used fibrin glue rather than tacks. They found a significant interaction between pain sensitivity and nerve damage, and nerve damage was strongly associated with the open repair. Patients with a high pain threshold were unlikely to have pain at 6 months regardless of the surgical approach, whereas patients with a low pain threshold who also had documented nerve damage were at high risk of having pain at 6 months. Bittner and coworkers noted that patients undergoing a TAP hernia repair were more likely to report pain at 6 months if they reported pain before the procedure. Together, these studies raise the possibility that patients with increased pain sensitivity or those who already have pain are at higher risk for PPSP.

Surgical treatment of chronic pain following hernia repair has been reviewed recently. Neurectomy of the ilioinguinal, iliohypogastric, genitofemoral, or lateral femoral cutaneous nerve was described in 14 papers, with most reporting good outcomes. However, the reviewers questioned the quality of these studies in terms of methodology, preoperative and intraoperative diagnostic criteria, and follow-up. They also found insufficient data on the effect of removal of mesh or staples to make a recommendation on this. Medical management of persistent post-herniorrhaphy pain is limited to a few case reports.

**HIP REPLACEMENT**

Total hip arthroplasty (THA) is the most successful treatment of arthritis-induced pain in the hip, but unfortunately, the success rate of treating pain is not 100%, and some patients have worse pain following THA. There are a wealth of data regarding outcomes following THA, including pain, quality of life, and patient satisfaction. Reports include numerous national registries, as well as prospective randomized studies, that looked at various interventions and surgical approaches. A report from the Swedish Hip Arthroplasty Register (nearly 35,000 procedures) documented that mean pain scores on a visual analog scale (VAS) decreased from 62 out of 100 preoperatively to 14 out of 100 at 12-month follow-up and that 88.6% of the patients reported that they were satisfied with the procedure. Predictors of a worse outcome included a preoperative report of pain in multiple joints, older age, and male gender. One finding that has become obvious recently is that the presence of pain at other sites is a major predictor of persistent pain following THA. Wyld and associates found an increasingly large odds ratio for persistent pain with an increasing number of other reported pain problems. This was echoed by Liu and associates and supported by data from the Swedish registry. Additionally, mental health has an effect, with depression being associated with a higher probability of persistent pain or worse score on the mental health component of the 36-item Short Form Health Survey (SF-36).

Depression has been associated with worse outcomes and is a predictor of PPSP. Data from the Swedish registry document less of an improvement in mobility and more pain in individuals who had greater anxiety or depression before surgery. Wyld and associates found a statistically significant association between depression and PPSP. There have been a number of attempts to incorporate minimally invasive surgery into THA. A systematic review found that minimally invasive surgery resulted in less acute postoperative pain and more rapid discharge, but there was no decrease in the prevalence of PPSP.

Since more severe acute pain has been associated with PPSP, there is hope that improved acute pain control will decrease PPSP. Use of local anesthetics has been tried by a number of investigators, but with equivocal benefit. Aguirre and colleagues used continuous wound infusion of ropivacaine for 48 hours and found no difference in rest pain at 3 months, but subjects in the ropivacaine group reported less discomfort to touch and pressure in the area of the wound. One small study compared a single iliofascial injection of 1-bupivacaine, clonidine, and epinephrine with a single epidural injection of 1-bupivacaine with sufentanil. A statistically significant difference in pain prevalence was observed at 3 months, but no difference at 1, 6, or 12 months. There are no reports of continuous epidural infusions, femoral nerve blocks or infusions, or sciatic blocks decreasing long-term pain following THA.

A single study demonstrated improved pain at 6 months in patients who received a ketamine infusion intraoperatively and then for 24 hours. They noted a morphine-sparing effect in the acute postoperative period and facilitation of rehabilitation for the first month. At 6 months, 8% of the ketamine subjects and 21% of the control group had pain at rest. Acute pain control was not different. Whether the
improved outcome at 6 months can be directly attributed to the ketamine infusion or attributed to the improved participation in rehabilitation will need to be determined. One study of incorporating gabapentin (600 mg before surgery and 600 mg after surgery) into a multimodal analgesic regimen showed no benefit on acute or chronic pain.81

THORACOTOMY

The prevalence of pain before thoracotomy is generally low (12%), but persistent pain following thoracotomy is a significant problem, with estimates of pain prevalence at 1 year of 50%.2 The presence of existing pain is thought to be a risk factor for PPSP.82 A recent review of the subject83 identified more areas needing answers than having clearly resolved issues.

The use of thoracic epidural analgesia has been advocated,84 but recent studies have found that a paravertebral block works just as well for acute pain control and has fewer side effects.85,86 Whether paravertebral blocks are of benefit for long-term pain has not been addressed. Thoracic epidural analgesia may be of benefit. Obata and associates87 and Senturk and colleagues88 both found a lower prevalence of PPSP 6 months following thoracotomy in patients who received a continuous infusion of epidural local anesthetic starting before skin incision and continuing throughout the surgery and postoperatively than in patients in whom the infusion was started postoperatively. All the patients in these two studies underwent posterolateral thoracotomy. In contrast, Ochroch and coworkers89 did not find a significant benefit, but only a minority of their patients (32%) underwent posterolateral thoracotomy. The studies also differed in that Ochroch’s group was looking at mean differences in VAS-measured pain, whereas Obata’s and Senturk’s groups looked at pain prevalence. There were also differences in the amount of local anesthetic in the epidural infusions, with Ochroch’s subjects receiving the least local anesthetic.

How the intercostal nerves are handled can make a difference. In a prospective randomized study of 120 patients undergoing posterolateral thoracotomy, pericostal (control group) sutures were compared with intracostal sutures and an intercostal muscle flap.89 By 6 months postoperatively there were no differences in pain and analgesic use between the groups, but at 3 months the intercostal muscle flap group was using fewer analgesics, and at the 4-week follow-up the intercostal muscle flap group had less pain and was using fewer analgesics.

A single study of low-dose (600 mg) gabapentin preoperatively found no benefit on either acute pain or pain at 3 months.90 A study in which a low dose of ketamine was added to an epidural infusion also lacked benefit.91 High-dose remifentanil is associated with increased alldynia and increased pain for up to 6 months.92

SUMMARY AND CONCLUSIONS

Based on the data presented in this chapter, we come to a number of conclusions. First, chronic pain following surgery is far from rare. Second, the surgical technique can make a significant difference in the prevalence of PPSP in hernia and breast surgery. Third, the addition of gabapentin appears to be of benefit in the perioperative period for breast surgery, but an optimal dose or duration is not known. Fourth, local anesthetics may be useful in epidural infusions for thoracic surgery or paravertebral blocks for breast surgery, but dosing has not been established. Fifth, individual patient factors are important. Such factors include pain sensitivity (as measured by thermal pain sensitivity), personality factors such as neuroticism and somatization, and the presence of depression or anxiety (or both). The extent to which any of the interventions alter spinal cord sensitization is not clear.

KEY POINTS

- Chronic pain following surgery is not rare and should be discussed as a risk before surgery.
- Minimally invasive surgery performed by experienced surgeons appears to decrease the risk for chronic pain. This is best documented for laparoscopic hernia repair and for sentinel node biopsy.
- For breast surgery, a paravertebral block has been shown to decrease the prevalence of chronic pain.
- For patients undergoing posterolateral thoracotomy, intraoperative plus postoperative epidural analgesia with local anesthetics decreases the prevalence of chronic pain.
- Adjuvant analgesics have not been adequately studied, but gabapentin, ketamine, and venlafaxine have been associated with a lower prevalence of chronic pain.
- Patients vary in their sensitivity to pain and probably in psychological factors that will alter the individual’s risk for the development of chronic pain.

SUGGESTED READINGS

REFERENCES

Recognition and treatment of acute pain in children have vastly improved the care of pediatric patients. Data emphasizing the efficacy of adequate pain control and decreases in adverse neurohormonal changes have led to better treatment of infants and children. Recent advances in pharmacologic therapy and regional anesthetic techniques have helped expand the scope of pediatric acute pain management. In addition, the establishment of pediatric acute pain services has played an important role in ensuring timely and consistent care of children.

**DEVELOPMENTAL NEUROBIOLOGY OF PAIN**

The study of pain in neonates has been a major focus in the field of neuroscience. Nociceptive pathways are well developed even at birth. A study of brain perfusion in response to pain has demonstrated significant changes in perfusion with noxious stimuli versus non-noxious stimuli. Newborn rats appear to have significant proliferation of A and C fibers at the site exposed to pain; a pattern of hyperalgesia appears to develop in these animals. Human neonates exposed to repeated heel sticks may have cutaneous hyperalgesia, which can be reversed with topical local analgesia. Studies in the area of pain in infants and children continue to be published, thus signifying interest in both pediatric pain management and its neurobiology.

**ASSESSMENT OF PEDIATRIC ACUTE PAIN**

Essential to acute pain management in children is assessment of pain. Unlike adults, pediatric patients may be too young, developmentally immature, or unwilling to provide adequate interpretation of their pain. Measures of acute pain in such patients often rely on observer reports, whereas assessment in older children involves self-report measures (see Table 20.1). Observational pain assessment tools use information about pain-related behavior, such as body movements, facial expression, and vocalizations; physiologic changes such as heart rate and oxygen saturation; and the child’s behavioral state. These measures have been designed to assess procedural pain (e.g., Premature Infant Pain Profile [PIPP]), Neonatal Facial Coding System [NFCS], or postoperative pain (e.g., Children’s Hospital of Eastern Ontario Pain Scale [CHEOPS], Toddler-Preschooler Postoperative Pain Scale [TPPPS]).

The FLACC scale (faces, legs, activity, cry, consolability) is another pain assessment tool that can be used for all ages, including mentally challenged children (see Table 20.2). These scales have been shown to have construct validity and internal and inter-rater reliability despite intrinsic limits in their specificity for pain, such as physiologic parameters, which can vary because of other conditions not associated with pain.

Developmentally appropriate children 5 years and older can typically provide self-reports on one of several validated visual analog (e.g., coloured analogue scale [CAS]), or faces scales (e.g., Faces Pain Scale—Revised [FPS-R], Oucher) (Fig. 20.1). McGrath and Hillier developed a separate Facial Affective Scale (FAS) designed to measure pain affect, as distinct from pain intensity. Interestingly, the faces scales anchored with a smiling face produce higher pain ratings than do those anchored with a neutral face. The well-described discordance between an observer’s ratings of a child’s pain and the child’s self-report allows the clinician to consider the child’s self-report as the “gold standard” whenever it can reliably be obtained.

The majority of pediatric pain assessment measures that have been developed focus on acute, procedure-related pain. Alterations in the behavioral and sensory aspects of pain that can habituate when pain becomes chronic may not be captured by these measurement scales. However, a systematic evaluation of chronic pain in children is beyond the scope of this chapter (see Chapter 33).

**NONMEDICAL MANAGEMENT OF PEDIATRIC ACUTE PAIN**

Management of pain through nonmedical techniques (e.g., environmental and behavioral strategies) has proved effective in modulating pain, both independently and in conjunction with pharmacologic interventions in children. Cognitive-behavioral therapy (e.g., relaxation, problem solving, cognitive coping skills) and distraction techniques such as deep breathing, cartoon videos, party blowers, and hypnosis have strong empirical support for their efficacy in easing procedure-related pain in children. Distraction methods are hypothesized to work by engaging children and redirecting their attention away from the pain, thereby reducing perceived pain intensity and inhibiting the neural activity that underlies pain perception. Complementary and alternative medicine techniques such as acupuncture have also been described as potential treatments of acute pain in children.
### PAIN TREATMENT MODALITIES

Acute pain in infants and children can be treated with various analgesics. The use of multimodal analgesia is beneficial for the management of pediatric pain. A pain treatment plan is best developed before the patient’s surgery, and an important goal is to provide a consistent approach to treating pain with minimal adverse effects.

### MILD ANALGESICS

**SUCROSE**

Administration of glucose and sucrose orally can provide mild analgesia since opioid peptides in the ventral striatum and cingulate gyrus may play a role in regulating positive responses to energy-rich food sources. A Cochran database review suggested that sucrose may be effective in reducing procedural pain in neonates. Doses in the range

of 0.01 to 0.1 g can be used to reduce procedural pain in infants younger than 6 months.78

**ACETAMINOPHEN**

Acetaminophen is commonly used in children to reduce or eliminate pain. It can be administered via the oral, rectal, and intravenous routes. The rectal and intravenous routes are preferable during the perioperative period. Rectal suppositories require higher dosing and may have variable absorption but can be an effective analgesic for postoperative pain in children. Specifically, an initial rectal dose of 30-40 mg/kg is recommended, followed by subsequent doses of 15-20 mg/kg at 4- to 6-hour intervals. This produces therapeutic plasma levels that may be adequate for managing pain.79,80 Intravenous acetaminophen has recently been made available in the United States; it has more predictable bioavailability and achieves maximum concentration more rapidly than rectal dosing does.81

Dosing in premature and term neonates can be affected by renal and hepatic immaturity. Hepatotoxicity is a potential risk with acetaminophen use and is dose dependent. Though a rare complication, the incidence of hepatic toxicity with higher doses of acetaminophen should be presented cautiously to parents so that injudicious use of the medication is avoided.82

**NONSTERoidal ANti-INFLAMMATORY DRUGS**

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in children in the perioperative and postoperative periods and can be administered via the oral, intravenous, or intramuscular routes. NSAIDs have been used effectively in children undergoing surgery to reduce postoperative pain and decrease requirements for supplemental pain medications.83,85 Neonatal clearance of NSAIDs improves with age. Ibuprofen is metabolized by the 2C9 and 2C8 subgroups of cytochrome P-450 (CYP).86 Ketorolac is commonly used in children and can be administered via the intravenous or intramuscular routes. The clinical significance of the effects of NSAIDs on bleeding remains controversial, which has led to its avoidance by some for procedures such as tonsillectomy. Known side effects, including bleeding, renal toxicity, and gastritis, are more likely to occur with prolonged administration and in the presence of coexisting disease. Despite conflicting views about the use of intravenous ketorolac following orthopedic surgery in animal experiments, a short duration of therapy does not seem to affect bone healing.87 NSAIDs are excellent adjuncts to opioids for pain relief. In certain surgeries that could lead to postoperative bleeding, it may be wise to avoid using ketorolac88 (see Table 20.3). A randomized controlled trial of acetaminophen, ibuprofen, and codeine for relief of acute pain in children with musculoskeletal trauma demonstrated that ibuprofen provided the best analgesia among the three study medications.89

**TRAMADOL**

Tramadol is increasingly being used for the control of pain in children.90,91 The absence of respiratory depression, along with a decrease in postoperative nausea and vomiting, makes it an attractive alternative to conventional opioids.92 It is metabolized to O-desmethyltramadol by CYP2D6.93 The recommended dose of tramadol is 1 mg/kg orally every 6 hours. Children with significant obstructive sleep apnea may particularly benefit from the use of tramadol as an alternative to intravenous opioids with respect to respiratory compromise.94

**OPIOID ANALGESICS**

Opioids can be used effectively in infants and children, particularly in the postoperative setting and for managing chronic painful conditions, including sickle cell disease, cystic fibrosis,95 and painful cancer states. Dosing may be achieved via the oral, parenteral, intranasal,96,97 and epidural routes. Opioids have lower clearance in neonates and infants but reach normal mature values in the first 6 months of life.98 Opioid-induced respiratory depression may be more pronounced in neonates and infants, whose respiratory reflex responses to airway obstruction and hypoxemia are immature at birth but mature during the first year of life.99 Opioids are commonly used in combination with acetaminophen or NSAIDs (or both) to achieve multimodal analgesia. Commonly used oral opioids are listed in Table 20.4 and parenteral opioids in Table 20.5.

Intravenous opioids are chosen when patients are unable to take oral medications or require markedly increased pain control. Adverse effects of opioids, including respiratory depression, nausea and vomiting, pruritus, and itching, can be managed effectively, thereby resulting in a favorable postoperative outcome (Table 20.6).100

**PATIENT-CONTROLLED ANALGESIA**

Patient-controlled analgesia (PCA) can be used to provide analgesia to children and adolescents in a controlled autonomous fashion. Several controlled trials support the safety and efficacy of PCA in children older than 6 years.101 In the

(see Table 20.3). A randomized controlled trial of acetaminophen, ibuprofen, and codeine for relief of acute pain in children with musculoskeletal trauma demonstrated that ibuprofen provided the best analgesia among the three study medications.89
in the pediatric realm, PCA use is commonly extended to include the educated provider of the child, most often the patient’s nurse or parent. The use of nurse-controlled or parent-controlled analgesia has been controversial because of safety issues. However, cautious use of PCA, whether it is nurse or parent controlled, can provide excellent pain relief in the postoperative period, even in developmentally delayed children or infants. Morphine, fentanyl, and hydromorphone are commonly used opioids for PCA. A basal infusion may be added to PCA settings to increase analgesia in patients undergoing major surgery. Children likely to experience significant postoperative pain may require additional continuous infusions of adjuvant medications for further pain control. Appendix A is a sample order set for managing PCA in children undergoing spinal fusion, for which we administer continuous epidural analgesia in addition to PCA.

REGIONAL ANESTHESIA

Enthusiasm for the use of regional anesthesia to manage acute pain in children has been increasing. Despite some controversy regarding the performance of regional anesthesia in children under general anesthesia, there is consensus among pediatric anesthesiologists about the importance and use of safely providing a regional anesthetic technique under general anesthesia.

CAUDAL ANALGESIA

One of the most commonly used pediatric regional anesthetic techniques for postoperative analgesia is a caudal block, which is used in children undergoing surgery from the lumbosacral to midthoracic dermatome levels with anticipated moderate postoperative pain. Its popularity originates in part from the readily palpable landmarks and relative ease of placement in infants and children versus adults. A needle with a blunt stylet is passed through the sacrococcygeal ligament into the caudal space. A distinct “pop” is usually felt when the caudal space is entered. Nerve stimulation and ultrasonography have also been described as tools to assist in caudal placement. Local anesthetics include bupivacaine (0.125% to 0.25%) and ropivacaine (0.1% to 0.375%) with 1:200,000 epinephrine at a dose of 1 mL/kg (maximum dosage, 30 mL).

SPINAL ANESTHESIA

Spinal anesthetic techniques have been used, especially in former preterm infants who are undergoing hernia repair as a method to avoid apnea and bradycardia. The procedure can be performed in an awake infant, thereby avoiding exposure to general anesthesia. This technique, though effective, has limitations because of the lack of adequate training to perform this block on a routine basis.

CONTINUOUS NEURAXIAL CATHETERS

Continuous epidural analgesia is a commonly used technique in infants and children. Epidural catheters may be placed in the thoracic, lumbar, or caudal regions. It is also possible to insert a caudal catheter and thread it cephalad to the desired dermatomal level. Bupivacaine and ropivacaine are frequently used local anesthetic solutions. Common additives to these solutions include opioids and α2-agonists, including fentanyl, morphine, hydromorphone, and clonidine. It is
imperative that standardized dosing parameters for a single injection, as well as for continuous infusion, be used in neonates, infants, and children to avoid local anesthetic–related systemic toxicity.109 Suggested pediatric dosing regimens are listed in Table 20.7. Patient-controlled epidural analgesia can be used successfully with continuous infusions of local anesthetic and patient-determined boluses, which are delivered to augment analgesia.110

PERIPHERAL NERVE BLOCKADE

Peripheral and truncal nerve blocks have played an increasing role in pediatric postoperative pain management.111,112 In addition, these techniques have been described as an effective means of achieving analgesia in the setting of pediatric trauma.113 These techniques are typically performed under general anesthesia and increasingly with the use of ultrasound guidance. Head and neck, transversus abdominis plane (TAP), rectus sheath, ilioinguinal/iliohypogastric, and upper and lower extremity blocks are performed frequently to provide analgesia in suitable candidates (Box 20.1).114-125 Common dosing guidelines for these blocks have been included as a reference point for practitioners (Table 20.8). Multicenter databases such as the Pediatric Regional Anesthesia Network have been created to accumulate valuable information about the frequency of use and complication rates with both neuraxial and peripheral blocks in the pediatric population.126

CONTINUOUS PERIPHERAL NERVE BLOCKADE

Continuous peripheral nerve blocks (CPNBs) with ultrasonographic guidance are now more widely used in pediatrics as a way to provide pain relief for an extended duration.127 CPNBs can not only control pain but may also enable physical therapy in children with chronic regional pain syndromes.128 They can be placed in various locations to ensure analgesia in site-specific areas.

Brachial plexus catheters are useful for surgical procedures on the elbow, forearm, and hand. Perineural catheter placement in the axillary region can provide pain control, but concerns over catheter sterility and migration exist.129 Catheters placed in the supraclavicular location are effective and may reduce these concerns.

The TAP block provides somatic analgesia to the anterolateral abdominal wall. Three muscle layers lie lateral to the rectus abdominis: the external oblique, internal oblique, and transversus abdominis. The thoracolumbar nerve roots

</table>
(T8-L1) course between the internal oblique and transversus abdominis muscle (TAP plane). A single-injection TAP block with the assistance of ultrasonography can provide relief of pain following abdominal incisions. Placement of a catheter into the TAP plane provides continuous analgesia and decreases supplemental postoperative systemic opioid requirements.\textsuperscript{130} The use of continuous TAP catheters in pediatric patients is an alternative to conventional neuraxial catheters.\textsuperscript{131} TAP catheters can also provide analgesia in patients with severe spinal deformities that preclude neuraxial anesthesia.\textsuperscript{132}

CPNBs are useful in providing lower extremity analgesia for an extended period. Femoral catheters have been used safely and effectively in the pediatric population.\textsuperscript{133} Continuous femoral nerve blocks are commonly used to treat pain from surgery on the distal end of the femur and anterior aspect of the knee and have also been used in the treatment of complex regional pain syndrome and cancer-related pain. The proximity of the femoral nerve to major vessels (the femoral vein and artery) makes vessel puncture and hematoma formation potential complications. Risks associated with indwelling catheter placement include infection, nerve damage, and falls as a result of block-induced quadriceps motor weakness.

Continuous sciatic nerve blockade can be used successfully to provide analgesia to the lower extremity in infants and children. It has been shown to have fewer adverse effects than epidural anesthesia in children undergoing major foot and ankle surgery.\textsuperscript{134} The sciatic nerve is formed by the L4 to S3 nerve roots and provides innervation to the posterior aspect of the thigh and the distal end of the leg (beyond the knee) with the exception of the calf. The sciatic nerve exits the pelvis through the greater sciatic foramen and then courses deep to the gluteus maximus muscle and distally to the posterior popliteal fossa. There it bifurcates to form the tibial and common peroneal nerves. Sciatic nerve catheters can be placed at the subgluteal or popliteal fossa in children (Fig. 20.2).

Continuous peripheral nerve blocks are evolving as a novel extended analgesic modality in children. The use of ultrasonography can facilitate and confirm placement of the catheter, which may reduce pain and diminish or eliminate the need for opioid medications and their undesirable side effects.

**CONCLUSION**

Acute pain management in children has made significant strides. The addition of medications with better safety profiles and the emerging role of regional anesthesia have clearly improved the care of neonates, infants, and children.\textsuperscript{135} Pediatric patients have unique needs, and it is critical that we continue to advance this field through ongoing research and innovation.

**KEY POINTS**

- Various measures of pain intensity are available for the pediatric population, and selection of the correct scale must be based on the patient’s age, development delay, and willingness to provide feedback.
- Nonopioid analgesics, in the forms of acetaminophen and nonsteroidal anti-inflammatory drugs, can provide relief of mild to moderate pain and are administered via the oral, intravenous, intramuscular, and rectal routes.
- Patient-controlled opioid analgesics can be used effectively to control pain and improve patient satisfaction.
- Neuraxial anesthesia can provide reliable effective pain relief after general anesthesia is induced in infants and young children.
- Continuous peripheral nerve blockade provides site-specific analgesia and is being used more commonly in pediatrics.

Sample Patient-Controlled Analgesia Order Set
Low back pain (LBP) is the most common cause of pain and disability in modern society, and costs related to disorders that cause LBP amount to billions of dollars each year. Pathologic conditions responsible for LBP are protean, and their precise diagnosis remains elusive. Pain can originate not only from the various components of the spinal column, such as the intervertebral disks (IVDs), vertebral bodies, facet joints, spinal nerve roots (NRs), and surrounding muscles and ligaments, but also from adjacent structures such as abdominal and pelvic viscera. The list of conditions that can produce LBP is exhaustive and includes causes as diverse as degenerative conditions, spinal metastasis, vertebral body fractures, abdominal aortic aneurysm, and chronic pancreatitis. Furthermore, the various disorders causing LBP are often present concomitantly, and their symptoms and signs are frequently analogous. The problem is further compounded by the fact that the tests currently used for diagnosis of these disorders are nonspecific and may show abnormalities in asymptomatic individuals. It is therefore crucial that a thorough clinical evaluation be accompanied by appropriate diagnostic testing to elucidate the cause of the LBP. In this chapter we will discuss the causes of chronic LBP that are pertinent to the practice of pain medicine. The clinical conditions discussed here include lumbar radicular syndrome (LRS), herniated lumbar disk (HD), lumbar spinal stenosis (LSS), internal disk disruption (IDD), and lumbar facet syndrome (LFS). Other significant causes of chronic LBP such as myofascial pain syndrome, spondylosis, spondylolisthesis, spinal instability, and sacroiliac joint dysfunction are discussed elsewhere in this book. Notable but less common causes of LBP such as spinal fractures, malignancies, osteomyelitis, and inflammatory and metabolic conditions such as ankylosing spondylitis and Paget’s disease are usually excluded before a patient is evaluated by a pain medicine physician and are beyond the scope of this chapter.

**LUMBAR RADICULAR SYNDROME**

**DEFINITION AND TERMINOLOGY**

Pain, paresthesias, and numbness in a typical dermatomal distribution, with or without the accompanying signs of weakness, diminished reflexes, and a positive straight-leg raise (SLR) test, are typically due to pathology or dysfunction of the sensory spinal nerve roots (SSNRs) or dorsal root ganglia (DRGs). Although radicular signs and symptoms are often present in conjunction with axial LBP, LRS is distinctive in its etiology and treatment. The term lumbar radiculopathy is frequently used to describe this clinical entity; however, it inappropriately implies the obligatory occurrence of objective signs of NR damage—loss of sensation, muscle weakness, and diminished reflexes. Lumbar radiculitis is another term commonly used, although it incorrectly proposes that an inflammatory process is primarily responsible for the radicular signs and symptoms. Another term used, lumbar radicular pain, mistakenly assumes pain as being the predominant symptom. Hence, the descriptive term lumbar radicular syndrome may be the most accurate in that it correctly suggests a constellation of clinical signs and symptoms of variable etiology secondary to pathology or dysfunction of the SSNRs or DRGs. Although the term sciatica is often used synonymously for LRS, this term is more suited to describe pain in the distribution of the sciatic nerve.

**PREVALENCE**

Epidemiologic studies of low back and lower extremity pain are often inexact in that the conditions producing these symptoms are frequently nonhomogeneous and poorly defined. Although the prevalence and lifetime incidence of LBP are reported variably, its overall occurrence ranges from 13.8% to 31%, and the related health care costs amount to billions of dollars each year. The incidence of radicular symptoms in patients with LBP has been reported to range from 12% to 40%.

**ETIOLOGY AND DIFFERENTIAL DIAGNOSIS**

Pathologic involvement of SSNRs and DRGs generates ectopic impulses at these locations that are perceived as pain, numbness, and tingling in areas innervated by the affected axons (i.e., a dermatomal distribution) (Fig. 21.1). Pathologic processes that can affect SSNRs and DRGs are diverse, with lesions of the IVDs and degenerative spinal disorders being most prevalent. Neoplastic, infectious, traumatic, metabolic, and vascular lesions involving SSNRs, DRGs, the spine itself, and lumbosacral plexuses can also produce radicular signs and symptoms. Pathologic lesions and entrapment neuropathies involving the sciatic nerve (e.g., piriformis muscle and ischial tunnel syndromes) can generate pain and paresthesias in its distribution and often affect multiple dermatomes. Pain originating in the IVDs and in the sacroiliac and facet joints and pain of myofascial origin can also be referred to the lower extremities. This somatic referred pain is due to interneuronal convergence within the spinal cord. It is nondermatomal, has a deep aching quality, rarely radiates below the knees, and lacks the objective signs of NR involvement. In this chapter we review the two most common causes of radicular pain in the lower extremities, HDs and LSS.
CHAPTER 21 — LOW BACK PAIN

CLINICAL FEATURES

Although pain is the predominant symptom, other symptoms of radicular involvement include paresthesias, numbness, and weakness in the territory of the involved NR. Radicular pain typically travels along a narrow band and has a sharp, shooting, and lancinating quality. Objective signs of gait disturbances, loss of sensation, reduced muscle strength, and diminished reflexes involve the appropriate dermatome. HDs and the degenerative conditions commonly involve the lower lumbar NRs, whereas other, often more sinister causes of LRS involve higher NRs with greater frequency. The following are characteristic features of various lumbar and sacral NR involvement:

- **S1**: Pain, paresthesia, and numbness of the posterior part of the thigh, calf, and plantar surface of the foot; there may be associated difficulty in toe walking, weakness of plantar flexion, and loss of the plantar reflex.
- **L5**: Similar symptoms involving the buttock, anterolateral aspect of the leg, dorsal surface of the foot, and great toe, with possible difficulty heel walking (steppage gait) and weakness of ankle and toe extension.
- **L4**: Radicular symptoms involving the anterior part of the thigh, knee, and upper to medial portion of the leg with weakness of knee extension and a diminished patellar tendon reflex.
- **L3 and L2 NRs**: Tend to produce symptoms and sensory alterations involving the groin and inner thigh areas.
- **Lower sacral NRs**: Involvement produces decreased sensation in the buttock and perineal areas (i.e., saddle anesthesia) and autonomic dysfunction, as indicated by bowel and bladder dysfunction, typically urinary retention and constipation followed by incontinence, and sexual dysfunction manifested as loss of erection in men and vaginal anesthesia in women.

CLINICAL TESTS OF NERVE ROOT IRRITATION

Several tests can be used to confirm the presence of NR irritation (Box 21.1). Passive SLR with ankle dorsiflexion of the extended lower extremity causes traction on the lower lumbar NRs by pulling them caudally between 1.4 and 4 mm. The radicular nature of the pain is suggested by worsening pain in the radicular distribution caused by such a maneuver. A positive SLR or Lasègue test is therefore suggestive of radicular pathology of the lower lumbar NRs (L4, L5, and S1). Radicular pain in the affected leg when the contralateral asymptomatic leg is similarly raised constitutes a positive crossed straight-leg raise (X-SLR) test. Although a positive SLR test is highly sensitive, X-SLR is more specific for lumbar NR irritation. An increase in back pain during an SLR is typically attributed to lumbar spinal movement and indicates the mechanical nature of the LBP. One exception noted is that centrally, HDs can generate LBP with an SLR because of strain on the anterior theca. The tripod test is a maneuver to confirm a positive SLR test when the patient is sitting—extending the knee and dorsiflexion of the foot with the patient seated. The femoral stretch test places the L2 and L3 NRs under tension and indicates irritation of these NRs; this is tested by bending the knee and extending the hip with the patient in the prone position.

“RED FLAGS” IN THE MEDICAL HISTORY OF A PATIENT WITH LOW BACK AND RADICULAR PAIN

As previously stressed, the list of conditions causing LBP, with or without radicular symptoms, is intimidating. Fortunately, in the vast majority of patients the pain is due to
benign, self-limited musculoskeletal conditions, such as muscular sprain or ligamentous strain, and the symptoms typically resolve in 4 to 6 weeks. Indiscriminate diagnostic workup in these patients can be expensive and may produce findings that are unrelated and could be misleading. Hence, the Agency for Health Care Policy and Research (AHCPR) developed guidelines to help identify signs and symptoms—red flags—that indicate the presence of conditions that pose significant threat to life or neurologic function and would require further diagnostic testing (Table 21.1). These conditions include malignancies, infections, fractures, and cauda equina syndrome (CES). The following is the list of “red flags” proposed in the AHCPR Publication 95-0643, published in 1994.

- **Age younger than 20 or older than 50 years**: Patients younger than 20 years have a higher incidence of congenital and developmental anomalies, and those older than 50 years are prone to neoplasms, pathologic fractures, serious infections, and life-threatening extraspinal processes as a cause of their low back and radicular symptoms.

- **Duration of symptoms**: The AHCPR guidelines consider symptoms of less than 3 months’ duration as acute and subacute LBP. Chronic pain, or pain greater than 3 months’ duration, indicates symptoms of a less serious etiology.

- **History of trauma**: A history of trauma in older patients and those with serious medical conditions may result in bony injury and require further workup.

- **Constitutional symptoms**: A history of fever, chills, malaise, night sweats, and unexplained weight loss should make one suspect a serious underlying disorder such as malignancy or infection.

- **Systemic illness**: A history of cancer, recent bacterial infections such as serious respiratory or urinary tract infections, intravenous drug abuse, immunosuppression (e.g., infection with human immunodeficiency virus), organ transplantation, and chronic corticosteroid use increase the likelihood of pathologic fractures, epidural and vertebral body abscesses, and metastasis.

- **Unrelenting pain**: Pain of benign etiology is typically relieved with rest and in supine position, especially at night. Unrelenting pain from serious pathologic conditions is often worse at night and is unresponsive to rest and analgesics.

- **Cauda equina syndrome**: CES is caused by acute compression of the spinal NRs comprising the cauda equina in the lumbar or sacral spine. In approximately 10% of patients with symptoms similar to CES, however, the cause is spinal cord compression at higher levels—the thoracic and even the cervical spinal cord. Although CES is rare, with a prevalence of approximately 4 in 10,000 patients with LBP, it is a neurosurgical emergency that requires emergency spinal decompressive surgery. Massive midline disk herniation or smaller disk herniation in a previous stenotic spine is the most frequent cause of CES. Rare causes of CES include spinal metastases, hematoma, epidural abscess, traumatic compression, acute transverse myelitis, and abdominal aortic dissection. Almost 70% of patients with CES relate a history of chronic LBP, whereas the rest of the patients have CES as their primary complaint. These patients are typically seen within 24 hours of the onset of their symptoms (Box 21.2), usually with bilateral radicular pain, although pain in one leg is often worse than pain in the other, and less frequently with back pain. The pain is often accompanied by weakness in both feet, gait disturbances secondary to pain and weakness, and abdominal discomfort as a result of urinary retention, which may be followed by overflow urinary incontinence. Objective signs include motor and sensory deficits, diminished reflexes, and a positive SLR test, often in both lower extremities. Of particular importance is diminished sensation in the buttocks and perineum (saddle anesthesia), diminished sphincter tone, and evidence of urinary bladder retention. Imaging of the entire spine, with magnetic resonance imaging (MRI) being the “gold standard,” is indicated because of the possibility of spinal cord compression at higher levels. Once the diagnosis is made, treatment involves high-dose intravenous steroids and urgent decompressive surgery to reduce permanent neurologic disability.

**DIAGNOSTIC STUDIES**

Because of the favorable natural history and often spontaneous resolution of symptoms, in the absence of red flags, diagnostic studies are not typically recommended for low back and radicular pain of less than 4 to 6 weeks’ duration. In addition, the common presence of abnormal diagnostic findings in asymptomatic individuals makes
interpretation of the test results challenging. Diagnostic
tests should be used to corroborate the clinical findings and
to determine the site of surgical or minimally invasive spinal interventions. Ordering tests selectively and correlating
their results with the clinical findings should prevent inap-
propriate diagnoses and poor outcomes.16

IMAGING STUDIES

- **Magnetic resonance imaging (MRI):** MRI is considered the gold stan-
standard in determining the etiology of low back and radicu-
lar pain (Figs. 21.2 and 21.3). It offers the best resolution
of the spinal canal, spinal cord, neural foramina, NRs, and
disk spaces and allows evaluation of the entire spine. In
patients with a history of previous spine surgery, contrast-
enhanced MRI is recommended to differentiate between
scar tissue and recurrent disk herniation. Limitations of
MRI include a lengthy examination time, claustrophobia,
and its effects on metallic objects. It is contraindicated in
patients with pacemakers, mechanical heart valves, aneu-
rysm clips, and intraocular foreign bodies.
- **Computed tomography (CT):** CT scanning is superior to
MRI in evaluating bony details of the spine, particularly
the facet joints and lateral recesses. When combined with
myelography (CT-myelography), the results are compara-
table to those of MRI in diagnosing spinal canal lesions. It
can therefore be used as a substitute when MRI is contra-
indicated.24 CT without myelography cannot distinguish
between HDs and other intradural lesions such as tumors,
and its routine use is therefore discouraged.24
- **Plain radiography:** The anteroposterior, lateral, and oblique
spinal plain x-ray views are the simplest and most readily
available tests that reveal bony abnormalities; however,
only diminutive spinal soft tissue details are envisioned
(Fig. 21.4). Among the skeletal abnormalities, spinal
fractures and deformities are easily appreciated; how-
ever, lumbar lordosis, transitional vertebrae, disk space
narrowing, and spondylolisthesis are common in asym-
ptomatic individuals,23 and routine spine roentgenograms
are therefore not recommended.25 Flexion and extension
films are used to reveal segmental instability as a source
of pain, but there is little correlation between abnormal
motion and pathologic instability.26

- **Myelography:** Myelography without CT is useful in detect-
ing lesions in the spinal canal when other studies
yield conflicting information, are not available, or are
contraindicated.

ELECTRODIAGNOSTIC STUDIES

Electrodiagnostic studies, including electromyography (EMG), nerve conduction velocity (NCV), and somatosens-
sory evoked potentials (SSEPs), are useful in establishing
the radicular nature of symptoms when the clinical features
of LRS are inconclusive and indistinguishable from the

---

**Box 21.2 Clinical Signs and Symptoms of Cauda Equina Syndrome**

**Features in the Clinical History**
- Radicular pain in both lower extremities; pain in one leg may
  be greater
- Isolated low back pain is rare
- Complaint of weakness in one or both legs and feet
- Gait disturbances because of pain and weakness
- Abdominal discomfort as a result of urinary retention

**Features in the Clinical Examination**
- Motor and sensory deficits in the lower extremities
- Diminished lower extremity reflexes
- Positive straight-leg raise and crossed straight-leg raise tests
- Saddle anesthesia
- Diminished sphincter tone
- Evidence of urinary bladder retention

discal magnetic resonance images of the lumbar spine.
symptoms of peripheral neuropathy. In contrast to the imaging studies, combined EMG and NCV results have high diagnostic specificity, however, they give no information on the etiology of LRS and correlate poorly with the anatomic level of the radicular lesions. Routine use of EMG/NCV is therefore not recommended. Use of SSEPs is typically limited to identifying intraoperative nerve injury because the test cannot pinpoint the exact location of nerve dysfunction.

OTHER DIAGNOSTIC TESTS

Various other diagnostic and laboratory tests, such as bone scan, complete blood count, urinalysis, erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, antinuclear antibodies, and HLA-B27 antigen, are useful when spinal tumors, infections, and rheumatologic disorders are suspected.

HERNIATED LUMBAR DISK

HISTORY AND EPIDEMIOLOGY

Although radicular symptoms have been known since ancient times, they were first attributed to “posterior displacement of the disc” by Goldthwaite in 1911. The incidence of symptomatic HD is estimated to be 1% to 2% in the general population, for which approximately 200,000 lumbar diskectomies are performed each year.

TERMINOLOGY

Disk herniation may be defined as displacement of disk material beyond the confines of the IVD space. Even though the nucleus pulposus (NP) is the predominant component of the herniated material, other disk constituents (e.g., cartilage, bone, and annular tissue) frequently constitute the herniated elements. Although various terms such as herniated nucleus pulposus, ruptured disk, and prolapsed disk have been used to describe this entity, the term herniated disk seems to be most appropriate because it conveys the image of displacement of any disk component regardless of the cause. HD is variably classified, typically according to the morphology of the herniated material. A protruded disk is present if the neck of the herniated material (i.e., the distance between the edges of the base) is wider than the widest disk diameter in any given plane. Disk extrusion is the opposite of disk protrusion; the neck is narrower than the widest disk diameter in any given plane. Disk sequestration is a type of disk extrusion wherein no continuity exists between the herniated material and the parent disk. HD is also sometimes classified according to the integrity of the overlying annulus fibrosus (AF). In contrast to noncontained herniation, the term contained herniation is used when the displaced disk portion is covered by an intact annulus. However, with currently available diagnostic modalities such as CT, MRI, and diskography, the details of the integrity of the annulus are often not identified, and these distinctions are therefore arbitrary. The terms disk desiccation, disk fibrosis, disk narrowing, disk bulging, disk fissuring, and disk sclerosis are often used; these terms, however, suggest degenerative disk processes and do not reflect disk herniation.
PATHOPHYSIOLOGY

Since Mixter and Barr first reported alleviation of lumbar radicular pain after removal of the HD material in 1934, HD is thought to be the most common cause of radicular pain. Although MRI findings of degenerated, bulging, and protruded disks are common, disk extrusion is uncommon in asymptomatic individuals. Mechanical compression of the spinal NR by the herniated disk material (see Fig. 21.5) has commonly been acknowledged as the primary factor inducing radicular symptoms. Data from animal studies indicate that compression of the NR impairs its nutrition and can lead to NR ischemia and injury. Deformation of the NR by HD fragments is also seen on diagnostic imaging in patients with radicular symptoms. There is, however, no direct evidence of increased mechanical pressure created by the HD. Moreover, clinical studies have demonstrated that only NRs that are exposed to HD material for a prolonged period produce pain on mechanical deformation and that similar NR deformation, not exposed to HD material, produces no pain. These observations suggest that mechanisms other than mechanical pressure may be at work in the causation of radicular pain. The presence of inflammatory mediators in the HD material, retrieved from patients at diskectomy, has been demonstrated. Additionally, in animal models, application of NP to the NR, and not epidural fat, produced the physiologic and anatomic evidence of radiculopathy. Furthermore, the presence of clinical and electromyographic evidence of radiculopathy has been demonstrated in patients with normal findings on spinal imaging. These observations suggest that factors other than mechanical compression and inflammatory mediators and inflammation may play a major role.

NATURAL HISTORY

The natural history of HD is favorable in that the majority of patients (60%) experience significant resolution of their symptoms within the first few months of their onset. In a smaller percentage of patients (20% to 30%), however, the symptoms fail to improve over time. Clinical improvement is usually accompanied by resolution of the HD on spinal imaging. Large extruded disks have a higher tendency to decrease in size than do smaller disk protrusions and disk bulges. Spontaneous regression is thought to be caused by the phagocytic process, predominated by macrophages, which is most prominent in the outermost layers of the HD material.

CLINICAL CORRELATIONS

Most lumbar disk herniations occur at the lower lumbar levels, with an L4/5 HD being the most common (59%), followed by L5/S1 (30%) and L3/4 (9%) disk herniation. Herniation at these levels produces the typical radicular signs and symptoms in the affected dermatomes described earlier. Central HDs may, however, produce primarily LBP, which is exacerbated by SLR.

NONOPERATIVE TREATMENT OF HERNIATED DISKS

Because of the favorable natural history of LRS caused by HDs, in the absence of progressive neurologic deficit and red flags in the clinical history, expectant and symptomatic treatment is recommended. A wide array of nonoperative treatments are available, and each has claimed success.

- **Medications**: Although opioids, muscle relaxants, and neuroleptics are routinely used for the symptomatic treatment of HDs, there are scant data in the literature to support their use. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to have some efficacy in the management of acute radicular symptoms. Systemic corticosteroids are prescribed, both orally and parenterally, for the treatment of acute disk herniation; however, evidence to support this practice is also lacking.
- **Bed rest**: Strict bed rest used to be the hallmark of treatment of acute HDs. However, because of the potentially harmful effects of prolonged bed rest, continuation of activities within the limits permitted by the pain has been reported to result in more rapid recovery and is currently being recommended.
- **Bracing**: Bracing is another method of immobilizing a painful spine, but there is limited evidence in support of the use of lumbar braces versus no treatment.

![Figure 21.7](image1.png) **Figure 21.7** T2-weighted sagittal magnetic resonance images of a 31-year-old man with severe axial and lower extremity pain showing two distinct disk pathologies. At the L5-S1 level there is left-sided disk extrusion, and the L4-5 disk shows desiccation and a high-intensity zone; the remaining disks appear normal.
• **Traction:** Once a mainstay of treatment, traction in either a continuous or intermittent form remains an unproven treatment of HD. Vertebral axial decompression is a newer modality based on traction principles; it also remains untested in the treatment of HD.

• **Acupuncture:** There are a few observational studies that claim acupuncture to be effective in the treatment of chronic LBP; however, its support in the literature for the treatment of acute LBP is lacking.

• **Physical therapy:** Physical therapy techniques for acute low back and radicular pain include active and passive exercises. Although active exercises are claimed to be more effective, the overall role of physical therapy in the treatment of acute HD remains questionable.

• **Psychological treatments:** Behavioral therapy, biofeedback, and other psychological treatments have been shown to have some efficacy in patients with chronic LBP; however, their role in the treatment of HD remains unknown.

• **Miscellaneous treatments:** Chiropractic manipulations, massage therapy, magnets, transcutaneous electrical nerve stimulation, and ultrasound application are often used in the treatment of low back and radicular pain, but their use remains unproven.

**INTRASPINAL INJECTIONS**

Epidural steroid injections (ESIs) have been used to treat HDs for more than 50 years. Traditionally, a posterior interlaminar (IL-ESI) approach is used. Fluoroscopically guided transforaminal injections (TF-ESIs) have the theoretical advantage of delivering the injectate directly into the anterior epidural space. Fluoroscopic guidance significantly improves the precision with which the injectate is deposited in the epidural space. The literature is replete with case series and uncontrolled studies, both in support of and against the efficacy of ESI. A review of the literature on randomized controlled trials (RCTs) of IL-ESI for sciatica showed four such trials; ESIs were found to be more beneficial than control treatments, especially in the short term. Although no long-term RCTs exist for TF-ESI, it was found to have results superior to those of IL-ESI in one study. ESIs are discussed in detail elsewhere in this book.

**PREDICTORS OF OUTCOME WITH NONINVASIVE TREATMENT**

There are several predictors of a favorable outcome of conservative treatment (Box 21.3), including a negative X-SLR test, absence of leg pain with spine extension, absence of stenosis on spine imaging, favorable response to ESIs, return of any neurologic deficits within 12 weeks, a motivated physically fit patient with more than 12 years of education, no workers’ compensation claims, and a normal psychological profile.

**PERCUTANEOUS DISK DECOMPRESSION**

Percutaneous disk decompression (PDD) was developed following the success of intradiscal injection of chymopapain for radicular pain from an HD. The positive results of intradiscal chymopapain injections suggested that dissolution of non herniated intranuclear discal contents may resolve HD symptoms without directly targeting the HD material (Fig. 21.8). Although the HD material causing radicular irritation is directly removed in addition to the non herniated NP during surgical diskectomy, removal of the non herniated nuclear tissue during PDD is postulated to reduce intradiscal pressure, which allows inward collapse of the herniated fragment. This has been suggested to be true especially in the presence of an intact AF—a presumed contained disk herniation—with the HD fragment acknowledged as

**Box 21.3 Predictors of Favorable Outcomes of Conservative Noninvasive Treatment of Herniated Disks**

- Negative crossed straight-leg raise test
- Absence of leg pain on extension of the spine
- Return of neurologic function within 12 weeks of onset
- Absence of stenosis on spine imaging
- Favorable response to epidural steroid injections
- Patient with 12 years of education
- Motivated and physically fit patient
- Normal psychological profile
- Absence of workers’ compensation claim

![Figure 21.8 Schematic depiction of surgical diskectomy and percutaneous disk decompression.](image)
typically being smaller than 4 mm.\textsuperscript{58} Chymopapain injections are now rarely performed in the United States because of complications associated with unintentional injection into the subarachnoid space and the rare occurrence of severe allergic reactions. Based on the principles of joint endoscopy, PDD was initially performed with large-bore endoscopes (7 mm or greater in internal diameter) to remove the intradiscal material. These early endoscopes were cumbersome to operate, with the added risk of trauma to the disk annulus, and were quickly abandoned. The technique of automated percutaneous lumbar diskectomy (APLD) was then introduced, wherein a smaller introducer cannula (2.5 mm) was used and the nuclear material was removed with a suction and cutting technique. Later, a variety of lasers were used to vaporize the nuclear material; these laser disk decompression devices used cannulas smaller than 3 mm in internal diameter and often included a fiberoptic channel for observation. The technique of disk nucleoplasty used a 1.5-mm (17-gauge) introducer needle and bipolar radiofrequency (RF) energy to create small channels in the disk to remove the nuclear material. Proponents of this technique claimed that the procedure provided localized disk ablation with minimal damage to the surrounding tissue. A percutaneous diskectomy technique with the proprietary name of DeKompressor uses 1.5- and 1.0-mm (19-gauge) outer cannulas and a probe that rotates to remove the disk material. A modified intradiscal electrothermal therapy (IDET) catheter (Acutherm) is also available and aims to induce localized thermal lesioning and shrinkage at the base of the HD material.

Despite its use spanning several decades, there is little evidence in the literature to support the use of various PDD techniques. In one study, MRI of patients before and after APLD showed no measurable difference in the size of HDs at 6 weeks.\textsuperscript{30} Although animal\textsuperscript{60} and cadaver studies\textsuperscript{61} have shown a reduction in disk pressure after PDD, there is no evidence of either high intradiscal pressure in patients with HDs or its reduction after disk decompression procedures. The amount of nuclear material removed is also variable in the various PDD techniques, with a range of 4 to 5 g for APLD to 1 g for nucleoplasty and the DeKompressor device; it varies greatly for various laser decompression devices and is unknown for the Acutherm device. No studies have correlated either disk pressure or eventual outcomes with the amount of nuclear material removed, and the optimum amount of disk material that should be removed is unknown. Removing large amounts of disk material has been correlated with disk collapse and accelerated disk degeneration.\textsuperscript{62} It is therefore prudent to remove the least amount of disk material possible to achieve the most beneficial results. Removing nuclear contents from within the disk protrusion itself via a more lateral percutaneous approach has also been recommended.\textsuperscript{58} Use of smaller-gauge introducer cannulas would limit the annular damage and therefore should be preferred. Diskography followed by a post-diskography CT scan has been used to assess the size and location of the HD and the integrity of the disk annulus; its use before PDD has been linked to improved clinical results.\textsuperscript{63} Two randomized trials of APLD showed success rates of 29\%\textsuperscript{64} and 33\%.\textsuperscript{65} There are no randomized trials supporting the use of laser disk decompression, nucleoplasty, DeKompressor, and Acutherm, and their use is based mostly on anecdotal reports.

**OPERATIVE TREATMENT OF HERNIATED DISKS**

Detailed discussion of the various surgical procedures performed for HDs is beyond the scope of this chapter. Classic diskectomy, popularized since the first report on HDs by Mixter and Barr,\textsuperscript{32} is the most popular procedure performed for HDs. The essentials of this technique include laminectomy and release of the ligamentum flavum to access the epidural space and remove the HD fragment and annulotomy to remove the nonherniated disk material (see Fig. 21.8). Several variations of this technique exist and differ in the extent to which laminectomy, ligamentum flavum release, and annulotomy are performed during the procedure. The more recent microdiskectomy procedure is less invasive and aims to minimize surgical trauma in order to limit the potential for NR injury and epidural scarring. Although surgery is commonly performed for HDs,\textsuperscript{29} there is little high-quality evidence in its support. A prospective, randomized trial comparing surgical with nonsurgical treatment of HDs demonstrated that during the first year, the surgically treated patients had significantly better results (92\%) than did the nonsurgically treated patients (61\%).\textsuperscript{96} However, the results of the surgery deteriorated over time and the difference between the groups became statistically insignificant at 4 years and insignificant at 10 years. This study was criticized for lack of careful randomization, lack of blinding, large number of crossovers to the surgically treated group, insensitive outcome measures, and small sample size.\textsuperscript{67} There is one other frequently cited study of operative treatment of HDs, and although this was a major prospective study, it was nonrandomized and observational.\textsuperscript{68} The results of this study were similar to those of the previous quoted study at 1 and 5 years; at 10 years, the results of surgical treatment were slightly better (56\% vs. 40\%, \(P = 0.006\)), but the incidence of work and disability status remained the same.\textsuperscript{68} A more recently published study showed the efficacy of both surgical and nonoperative treatment of lumbar disk herniation. The Spine Patient Outcomes Research Trial (SPORT)\textsuperscript{69} showed between-group differences in improvements to be consistently in favor of surgery for all the observation periods, but these differences were small and not statistically significant for their primary outcomes. Patients in both groups were satisfied with their care, with the main benefit of surgery appearing to be more rapid resolution of the disabling pain.

It appeared that the decision to undergo surgery depended on how urgently a patient wished to achieve pain relief in the next 2 to 4 months.\textsuperscript{70} The need for surgery in patients with CES appears to be absolute,\textsuperscript{19} and it is generally agreed that surgical treatment is necessary in patients with progressive motor deficits. However, other indications for surgery are relative and include intractable pain and poor response to conservative therapy.\textsuperscript{71} The lack of consensus and the variability with which these indications are adhered to are supported by a nearly 20-fold difference in surgery rates in otherwise demographically similar populations within the United States.\textsuperscript{72} The results of microdiskectomy have been reported to be superior to those of traditional diskectomy.\textsuperscript{73} Although patients with sciatica of more than 12 months’ duration have been shown to have less favorable results after surgery,\textsuperscript{74} the full effects of a potential delay in operative treatment while nonsurgical treatment is attempted remain unknown.
LUMBAR SPINAL STENOSIS

TERMINOLOGY AND ETIOLOGY

Though recognized for some time, modern descriptions of the clinical syndrome and pathologic lesions of LSS first appeared in 1954. LSS is defined as a clinical syndrome consisting of neurogenic claudication or radicular pain secondary to narrowing of the spinal or NR canal and compression of its neural elements. Traditionally classified into congenital and acquired types, it is the degenerative variety of the acquired type that is most prevalent. Developmental LSS is either idiopathic in nature or due to rare developmental bone dysplasias such as achondroplasia. Aside from the degenerative type, less common causes of acquired spinal stenosis include metabolic disorders such as Paget’s disease, trauma, surgery, spinal tumors, and spinal deformity. Anatomically, LSS can be classified as central spinal canal stenosis, or central stenosis, and as lateral recess and neural foraminal stenosis, or lateral stenosis.

PATHOPHYSIOLOGY

Acquired degenerative LSS is characteristically the result of disk degeneration and its sequelae. Loss of disk height, disk bulging, facet joint hypertrophy, thickening and redundancy of the ligamentum flavum, and local osteophyte formation are the typical lesions seen in LSS. The degenerative changes causing LSS are most common at the disk level, and one or several vertebral motion segments may be involved. Central stenosis can cause compression of the NRs of the cauda equina, whereas lateral stenosis typically causes compression of the exiting spinal NRs. The L5 NR is most commonly involved (75%), followed by the L4 (15%), L3 (5.3%), and L2 (4%) NRs. The capacity of the lumbar spinal canal is significantly larger during flexion than during extension, and the symptoms of LSS are therefore characteristically worse during lumbar extension. The spinal degenerative changes analogous to LSS are prevalent in older adults and have been shown to frequently be present in asymptomatic individuals. Direct compression or ischemia of the neural structures is thought to be primarily responsible for the clinical manifestations of LSS. In contrast to HD, the role played by inflammatory changes in the causation of symptoms from LSS is less clear. Degenerative changes that result in spinal stenosis can also give rise to spinal instability (degenerative spondylolisthesis) and spinal deformities (degenerative scoliosis), which can contribute further to spinal narrowing.

CLINICAL CONSIDERATIONS

- **Neurogenic claudication**: The typical manifestations of neurogenic claudication include pain radiating to both lower extremities—posteroslateral aspect of the thighs and legs—that is worse with walking and lumbar extension and is relieved by sitting down. The pain is often associated with numbness and heaviness or weakness of the lower extremities. It is essential that these symptoms be distinguished from claudication of vascular origin. The latter possibility must be entertained in the presence of any sign of vascular insufficiency. In contrast to vascular claudication, the pain of neurogenic claudication continues to be present with standing and is eased by walking in a flexed position, such as pushing a walker or a shopping cart.
- **Radicular pain**: Unilateral radicular symptoms unrelated to any activity are a sign of NR involvement; they usually reflect lateral stenosis and can be present with or without symptoms of neurogenic claudication.
- **Axial pain**: Axial pain is more reflective of disk, facet joint, or sacroiliac joint pathology and may indicate spinal instability; it is unlikely to be an exclusive symptom of LSS.
- **Clinical signs**: Patients with LSS tend to walk with a stooped forward gait and often maintain this position while standing—stooped posture—with loss of lumbar lordosis and decreased range of lumbar extension. Because of the slow and chronic nature of progression of the disease, the SLR test is infrequently positive and the sensorimotor deficits are less pronounced. In a study of patients with LSS, a sensorimotor deficit in the lower extremity was seen in 30% of patients (most commonly in the L5 NR distribution), a decreased or absent plantar reflex was present in 43%, and a diminished patellar reflex was noted in 18% of the patients; the SLR test was positive in only 10% to 25%.
DIAGNOSIS

MRI is the most common imaging modality used to detect the pathologic lesions of LSS. It provides the best visualization of the IVDs, ligamentum flavum, central canal, and neural foramina. CT provides better details of the bony abnormalities, especially facet pathology, and superior visualization of the lateral recesses. Lumbar CT-myelography is the imaging technique of choice when MRI is contraindicated or is not available. The value of EMG/NCV and plain radiologic films in detecting LSS is similar to their application for other types of LRS and was discussed earlier. Because of the frequent presence of radiologic abnormalities in asymptomatic individuals with LSS and their common occurrence in older adults, it is crucial to correlate the radiologic abnormalities with the clinical findings to make this diagnosis.

NATURAL HISTORY AND TREATMENT OPTIONS

Though at first thought to be unrelentingly progressive, the natural history of LSS is interspersed by intermittent flare-ups and is relatively unchanged over time. Because of its seemingly progressive nature and poor prognosis, LSS was treated by early surgical intervention in the past. However, nonsurgical treatments have been shown to be effective and can prevent progression of the patient’s symptoms. Surgical treatment of LSS typically provides superior control of the symptoms initially, but the benefits seem to decline over time. The prevalence of this condition in older adults is expected to reduce loads across the lumbar spine and may provide symptomatic relief. Nonetheless, to avoid muscle deconditioning and back stiffness, any such braces should be worn for short periods only.

NONOPERATIVE TREATMENT OF LUMBAR SPINAL STENOSIS

Nonoperative treatments are particularly useful for the acute flare-ups of LSS and include medications, modifications of activity, bracing, physical therapy, and ESI.

• Medications: Acetaminophen and NSAIDs are often helpful in providing symptomatic relief during acute flare-ups. However, because this condition is chronic, the use of opioid pain medications should be limited to acute exacerbations. Calcitonin has been found to be beneficial in spinal stenosis and is particularly effective for LSS resulting from Paget’s disease.

• Modification of activity: Avoidance of aggravating activity and relative rest are suggested during acute flare-ups. Nevertheless, because of the potential for deconditioning, strict bed rest is no longer advocated for the treatment of LSS. Rigid lumbar braces extend the spine and may worsen the symptoms of LSS. Lumbar binders are expected to reduce loads across the lumbar spine and may provide symptomatic relief. Nonetheless, to avoid muscle deconditioning and back stiffness, any such braces should be worn for short periods only.

• Physical therapy: Flexion-based exercises (e.g., stationary bicycle and inclined treadmill) increase the cross-sectional area of the spinal canal and may improve microcirculation of the neural elements. Such exercises may therefore allow patients to tolerate the exercise programs better and may promote weight loss and cardiovascular fitness. Aquatic therapy is also useful because it stretches the hip flexors and hamstrings and strengthens the core abdominal and trunk muscles.

• Epidural steroid injection: IL-ESIs have been shown to be effective, especially in the short term, and may provide symptomatic control of acute exacerbations of neurogenic claudication. Fluoroscopically guided TF-ESIs appear to be better suited for radicular symptoms secondary to LSS and have been shown to have both short- and long-term efficacy.

OPERATIVE TREATMENT

Wide laminectomy, performed at the stenotic levels, is the standard procedure for surgical decompression of LSS. It involves broad removal of the spinal laminae and ligamentum flavum extending laterally from pedicle to pedicle. Extensive removal of the posterior spinal elements can result in spinal instability, which can be avoided by preservation of the pars interarticularis and lateral half of the facet joints. Extensive decompressive surgery, as is typically indicated for complex stenosis and degenerative spondylolisthesis, may result in significant spinal instability. The post-decompressive instability may be avoided by spinal fusion, performed with or without instrumentation. Lately, surgical techniques involving minimal decompression, such as laminotomy, fenestration, and laminoplasty, are increasingly being used to preserve spinal stability and avoid post-decompressive fusion. However, these minimally decompressive techniques are accompanied by higher rates of restenosis.

INTERNAL DISK DISRUPTION

Although the role of a herniated IVD as a cause of pain is well established, pain originating from the disk itself is poorly understood and has remained controversial. The various terms used for pain of discal origin have included discogenic pain, internal disk disruption, and painful degenerative disk disease (DDD). Changes within the disk that are linked to pain may well be a variant of age-related and non-painful degenerative disk changes. It is therefore vital to understand basic disk anatomy and physiology and normal age-related degenerative disk changes before pathologic changes within the disk that are attributed as being painful are examined.

BASIC INTERVERTEBRAL DISK ANATOMY AND PHYSIOLOGY

The IVD is grossly compartmentalized into the inner NP and the outer rim of the AF. This distinction is most obvious at the lumbar levels and decreases with advancing age. Both the NP and AF are sparsely populated by very distinct cell types that maintain normal disk function and integrity. The NP is inhabited by chondrocyte-like
cells that are found in clusters, whereas the AF is populated by fibrocyte-like cells.102 The composition of the expansively present intercellular matrix is also very different for the NP and AF; the matrix in the NP is jelly-like and has a high concentration of water and proteoglycans, whereas the matrix in the AF is firmer and has a high collagen content. The collagen fibers in the AF are arranged as interlacing lamellae that are firmly attached to the adjacent vertebral bodies.102 A healthy IVD is able to sustain a substantial amount of physical strain.105 These compressive forces are borne directly by the NP and are equally distributed to the AF as tensile force.104 The incompressibility exhibited by a normal NP is largely due to its high water content, maintained in turn by the hydrostatic pressure generated by its high proteoglycan content.102 A delicate balance exists between the anabolic activities of the NP cells and the catabolic activities of the matrix proteolytic enzymes—matrix metalloproteinases (MMPs)—involved in maintaining the normal NP proteoglycan content.109 A normal IVD is scantily innervated and is the largest avascular structure in the body. The IVD is innervated by mechanoreceptors, which, like its vascularity, are limited exclusively to the outer third of the AF. A normal NP is completely lacking in innervation and blood supply.102,106 The outer third of the AF is innervated by plexuses along the anterior and posterior longitudinal ligaments (see Fig. 21.10). The posterior plexus receives its input from the sinuvertebral nerve and gray rami communicans; the latter also contributes mainly to the anterior plexus. The sinuvertebral nerve receives its contributions from the ventral rami and gray rami communicans.107 A normal disk therefore has rich autonomic connections, which may explain the diffuse and nonspecific nature of pain originating from the disk. The metabolic requirements of the cells in the NP and inner AF are met almost entirely by diffusion to and from capillary plexuses in the adjacent vertebral bodies across the cartilaginous end plate and the outer AF.108 This arrangement is at best tenuous, and cells in the NP function in a precarious anaerobic environment.109 Because the IVD also lacks scavenger cells, degradative products of disk macromolecules accumulate over time, which can alter the normal cell and matrix interactions.110 The state of hydration and thus the compressibility of the NP can therefore be altered by a host of factors that can influence the metabolic activities within the NP and AF.

**Figure 21.10** Schematic representation of normal intervertebral disk components and innervation. AF, annulus fibrosus; NP, nucleus pulposus.

### Pathophysiology of Degenerative Disk Disease
Degenerative changes within the disk are commonly seen in asymptomatic individuals, especially with advancing age; however, extensive and often isolated degenerative disk changes are also seen in younger patients with considerable LBP (see Fig. 21.7).111 Degenerative disk changes may therefore be painless and represent the physiologic consequence of aging, or they could be painful and may be pathologic in nature.112 A host of factors have been shown to predispose to early and progressive disk degeneration, including genetic predisposition, diminished blood supply from causes such as smoking and vascular insufficiency, increased mechanical stress from repeated heavy lifting, contact sports, obesity, and traumatic injury to the cartilaginous end plate.113-117 These risk factors may promote degenerative changes within the NP by a host of factors such as dysfunction and decline in viable NP cells,118 enhanced MMP activity,119 and increased NP cytokine and proinflammatory mediator content.120 A reduction in NP proteoglycan content may be followed by diminished NP water and hydrostatic pressure. These changes would make the NP more compressible and expose the AF to direct axial compression.104 Along with the axial stress, the AF may undergo concomitant degenerative changes with loss of annular collagen. These alterations in the AF would eventually lead to stress failure of the collagen fibers and the development of AF fissures that spread outward toward the periphery.121 These NP and AF structural changes affect the biomechanical properties of the entire disk and cause it to shrink and become less plastic.122 Changes in disk dynamics also increase stress on structures adjacent to the disk and may lead to sclerosis, hypertrophic new bone formation, and arthritic changes in the adjacent joints. The various spinal and paraspinal changes have been described as Modic changes in the adjacent vertebral bodies,123 accelerated degeneration of adjacent disks, hypertrophy and arthritis of the facet joints, sacroiliac joint dysfunction, and paraspinal myofascial syndrome.124 In addition, stenotic changes within the spinal canal and intervertebral foramina may follow and can cause NR and spinal cord compressive symptoms.125 Nonetheless, the presence of spinal degenerative changes correlates poorly with the pain experienced by patients.126
PATHOLOGY OF INTERNAL DISK DISRUPTION
AND DISCOGENIC PAIN

A positive painful response on provocative diskography is subjective in nature, is confounded by a host of psychosocial and somatization influences, and has been a subject of controversy for some time.\textsuperscript{127} Yet the pain of positive diskography has been linked to a host of disk lesions and is considered indicative of IDD.\textsuperscript{129-135} It is uncertain whether IDD is a distinct disease entity or represents painful, early-onset, and progressive DDD. It is likely that the factors that predispose to early and progressive DDD are also central to the pathologic changes of IDD. Disks from patients with concordant pain on diskography have been shown to contain vascularized granulation tissue zones or fissures that extend from the NP to the outer AF (Fig. 21.11).\textsuperscript{133-135} These granulation tissue zones have been correlated with the annular fissures seen on post-diskography CT scans\textsuperscript{133} and the high-intensity zones seen on MRI.\textsuperscript{134} As mentioned previously, innervation and vascularity in a normal disk are limited to fissures seen on post-diskography CT scans\textsuperscript{133} and the high-resolution tissue zones have been correlated with the annular of the inner AF and NP, and inflammatory mediators and nociceptors.\textsuperscript{129,130} These zones of granulation tissue also show an abundant mononuclear cell infiltrate and exhibit strong expression of nerve growth factors, which may contribute to nerve ingrowth and accelerate degeneration of the disk.\textsuperscript{132,135} These disks also produce a significant amount of proinflammatory mediators,\textsuperscript{131} which can sensitize the neonociceptors and thus maintain a state of hyperalgesia within the affected disk. These hyperalgesic disks can cause chronic pain that is worse with mechanical stress (axial loading) and produce a painful response with minimal stimulation on diskography (i.e., a chemically sensitized disk).\textsuperscript{136} The presence of annular fissures, nociceptive innervation of the inner AF and NP, and inflammatory mediators and cells, along with the abundance of sympathetic connections at the spinal cord level, provide a substrate for the origin of discogenic pain.

HISTORICAL BACKGROUND

The concept of the IVD as a source of pain is relatively old and was espoused as early as 1947.\textsuperscript{137} The term internal disk disruption, however, was not used until 1986\textsuperscript{138} and was based on the observation that disks that produce pain on diskography—initially used exclusively to demonstrate an HD—often appear morphologically intact on plain x-ray imaging. The diagnosis of IDD was initially based almost entirely on a subjective pain response generated during provocative diskography. The validity of a positive provoked pain response on diskography, however, was seriously challenged in a study published by Holt in 1968 that showed a false-positive rate of 37%.\textsuperscript{139} Although the methodology of Holt’s study was later seriously criticized\textsuperscript{140} and a study by Walsh and associates showed a false-positive rate of 0%,\textsuperscript{141} Carragee and colleagues\textsuperscript{127} have continued to criticize the diagnostic significance of a positive pain response on diskography. More stringent criteria for positive diskograms were later adopted to reduce the false-positive rates; such criteria included a concordant pain response, the presence of at least one disk level with no pain on disk provocation (“control disk”), and evidence of disk disruption on post-diskography CT (i.e., one or more tears extending to the outer annulus).\textsuperscript{142} Pressure diskography using manometry during disk provocation was also introduced to identify disks that are painful with minimal stimulation. This technique has been suggested to improve the specificity of diskography.\textsuperscript{143} However, no test is available to date that can objectively detect the aforementioned pathologic lesions of IDD.

CLINICAL FINDINGS

Pain originating from the disk can be acute or chronic, either from an acute tear of the disk or from the chronic lesions characteristic of IDD. A study performed by Schwarzer and colleagues\textsuperscript{144} showed that in a group of patients with axial chronic LBP, the incidence of IDD was as high as 40% when all the criteria of discogenic pain suggested by the International Spine Intervention Society\textsuperscript{142} were fulfilled. These authors also claimed that the study population represented the general public and therefore advocated that the incidence of IDD was significantly higher in patients with chronic axial LBP. In another study by Hyodo and associates,\textsuperscript{145} 73% of the patients with severe acute LBP obtained greater than 70% pain relief after the intradiscal injection of local anesthetic. This study also proposed that the incidence of discogenic pain was equally high in patients with severe acute LBP. In both studies the incidence of discogenic pain was highest in patients who were younger than 40 years and when the pain was located primarily in the low back and buttock region. It has also been proposed that pain of discogenic origin is precipitated by a torsion injury in the low back region and exacerbated by axial loading, such as occurs with prolonged sitting and standing. Moreover, the pain is often referred to the lower extremities in a nondermatomal distribution.\textsuperscript{146}

Figure 21.11 Schematic depiction of lesions of internal disk disruption. AF, annulus fibrosus; NP, nucleus pulposus; SC, spinal cord.
**DIAGNOSIS**

Spinal imaging frequently shows degenerative disk changes in asymptomatic individuals and is therefore of limited value in the diagnosis of IDD. IDD is frequently referred to as “black disk disease,” which is due to the loss of signal intensity on T2-weighted MRI and signifies desiccation of the NP (see Fig. 21.7). However, it is a change representative of early DDD and may not be painful. A high-intensity zone on MRI of the posterior disk annulus (Fig. 21.7) has been shown to indicate the presence of a tear in the posterior disk annulus and has been correlated closely with the pain of diskography and pathologic IDD lesions. Several authors have attempted to correlate the results of diskography with the radiologic features of DDD, and concordance has ranged from 55% to almost 100%. A concordant pain response to disk provocation, in the presence of a nonpainful or non-concordant pain response at another disk level and coupled with morphologic abnormalities seen on the post-diskography CT scan (i.e., tears extending to the outer third of the AF), currently remains the only means of diagnosing IDD.

**TREATMENT**

Treatment of IDD and painful DDD is mainly palliative in nature, similar to that described for HD and LSS. Among the many minimally invasive treatment options available, several disk-heating modalities have been introduced. Among these, IDET has attained significant attention. IDET involves thermal lesioning of the posterior disk annulus by a percutaneously placed heating coil. This technique was founded on shrinkage of collagen by the application of heat to the joint capsule and ligaments during arthroscopy. The mechanism of proposed IDET effect is contraction of the annular collagen and coagulation of the nociceptive fibers. The true nature of IDET and its reported benefits, however, is unknown. Outcome studies of IDET are also mixed, with efficacy reported as ranging from minimal benefit to highly successful. Complete removal of the painful disk and arthrodesis of the adjacent vertebral bodies—spinal fusion—should theoretically relieve the pain of discogenic origin. However, the results of spinal fusion for discogenic pain are mixed, and serious doubts have been raised about its efficacy. Spinal fusion has also been linked to loss of spinal mobility and accelerated adjacent spinal level disk degeneration. Artificial disk replacement surgery, or disk arthroplasty, was introduced to obviate some of the problems associated with spinal fusion surgery. The initial outcome studies of disk arthroplasty showed that the results were no better than those of spinal fusion surgery, and several unanswered questions remain regarding device longevity, complication rates, and long-term effects. Currently available treatments of discogenic pain are therefore mainly symptomatic, with questionable efficacy and several possible associated complications. These treatments are also generally unable to restore or prevent further deterioration of disk architecture and function.

**FUTURE DIRECTIONS**

The future for the diagnosis and treatment of pain of discogenic origin is uncertain. Although understanding of the pathologic processes responsible for discogenic pain has improved, accurate knowledge of the differences between a painful and a painless degenerated disk remains indefinite, and early and objective diagnosis of IDD remains elusive. Biologic treatments such as gene therapy, tissue engineering, and stem cell transplantation, though currently being investigated, are experimental, with diminutive clinical application. To be successful, early application of treatment modalities that can retard further disk degeneration and therefore development of the related spinal syndromes is needed.

**LUMBAR FACET SYNDROME**

**ANATOMY**

The lumbar facet joints (LFJs), or lumbar zygapophyseal joints, are synovial joints with an articular surface, synovial membrane, fibroadipose meniscoid, and fibrous capsule. These paired joints are located dorsally at the junction of the lamina, pedicle, and base of the transverse process. Each joint is composed of two—superior and inferior—articular processes stemming from the corresponding vertebrae. The orientation of facet joints is distinct at the lumbar, thoracic, and cervical levels. The medial branch (MB) of the posterior primary ramus courses over the base of the superior articular process (SAP) at its junction with the transverse process to innervate the facet joint at the same vertebral level and from the vertebral level below. Each facet joint therefore receives innervation from the MB at the same vertebral level and from the vertebral level above (Fig. 21.12). The course of the MB is relatively fixed as it originates from the dorsal ramus, proximally at the base of the SAP, and as it passes under the mamillo-accessory ligament, at the caudal edge of the SAP. The L5 dorsal ramus passes over the sacral ala at the base of the sacral SAP. The fibrous capsule and the synovium of the facet joints are richly innervated by nociceptive fibers.

**HISTORICAL BACKGROUND**

Goldthwait first proposed LFJs as a potential source of pain in the early 1900s, and the term facet syndrome was introduced by Ghormley as early as 1933. Several investigators...
have since reproduced pain in the low back and proximal leg region by injecting hypertonic saline (a physiologic irritant) into the facet joints. Relief of pain in patients with chronic LBP by intra-articular injections of local anesthetic and steroids was first reported by Mooney and Robertson in 1976.

**PATHOPHYSIOLOGY**

The exact cause of pain originating from LFJs is often undetermined. Pathologic lesions such as systemic inflammatory arthritides (e.g., rheumatoid arthritis and ankylosing spondylitis), synovitis, synovial cysts, and infections (Box 21.4) are rare known causes of pain originating from LFJs. Microtrauma, including microfractures and capsular and cartilaginous tears, have been observed on postmortem studies but are undetected by routine imaging studies. The role of these injuries in causing chronic LBP, however, remains unknown. Meniscoid and synovial entrapment and joint subluxation have also been proposed as potential causes of pain. Degenerative arthritic changes are often accepted as a frequent source of LFS, but these changes are observed in symptomatic and asymptomatic individuals with equal frequency, and their correlation with diagnostic facet joint injections is poor. Degenerative changes in the facet joints frequently accompany degenerative changes in the disks and neural canals, and their contribution to patients’ overall pain is often undetermined.

**DIAGNOSIS**

The typical features of LFS include unilateral or bilateral LBP, which is frequently referred to the groin, hip, or thighs but infrequently radiates below the knee joints (Box 21.5). Pain is often exacerbated by arching or twisting movements and with prolonged standing or sitting and is reportedly relieved by forward flexion, rest, and walking. Painful limitation of low back extension, lack of neurologic findings, a negative SLR test, and localized tenderness over the facet joints have all been described as typical findings on physical examination. Other investigators, however, report lack of consistent clinical findings in patients who respond positively to diagnostic facet joint injections. Although correlation between arthritic findings on imaging studies and pain relief from diagnostic injections has been suggested, no imaging findings or radionuclide scans reliably predict facet joints as a source of pain. Though controversial, the analgesic response to targeted, low-volume, intra-articular local anesthetic injections or MB blocks (MBBs) currently remains the only accepted standard for diagnosing pain originating from the LFJs.

**DIAGNOSTIC INJECTIONS FOR LUMBAR FACET SYNDROME**

The suspected painful joints typically injected are either the joints found most tender on physical examination or, in the absence of any localizing signs, the lowermost LFJs—L5/S1 and L4/5—because these joints are deemed most commonly affected. Fluoroscopic guidance with use of a coaxial needle insertion technique is considered essential for intra-articular needle placement. The injectate volume is generally kept lower than 2 mL. Larger injectate volumes can cause capsular injury, and leakage of contrast material into the neural foramina and epidural space may result in loss of diagnostic specificity. Before injection of a local anesthetic, a small volume of contrast medium (0.2 to 0.3 mL) may be injected to adequately delineate the joint space and to localize the correct intra-articular needle tip position. MBBs are performed by injecting a small volume (<1 mL) of local anesthetic at the junction of the transverse process and the SAP—the “eye of the Scottie dog” (Fig. 21.13)—and have been shown to have equal diagnostic sensitivity. Injection of a small volume of contrast medium is often done before injection of local anesthetic for an MBB to confirm correct needle placement and to rule out intravascular needle tip location. MBBs are especially useful if joint entry cannot be obtained, as is often the case with severely degenerated joints and in patients after spinal surgery. MBBs are also the preferred diagnostic injections before RF MB rhizotomy because they allow direct testing of the nerves targeted for subsequent neurotomy. Avoidance or use of only short-acting systemic analgesics and resumption of routine activities after the diagnostic injection facilitate evaluation of the pain response from the procedure. The use of local anesthetics of different duration on two separate occasions—double comparative blocks—with the patient reporting pain relief that corresponds to the duration of the local anesthetic used, is considered to be a more specific diagnostic test. The prevalence of LFS in patients with chronic LBP as determined by a single set of diagnostic injections has been reported to vary from 7.7% to as high as 75%. Prevalence rates of
15% to 40% are reported when more stringent double comparative blocks are used. In addition to the wide variation in prevalence, a placebo response rate of almost 40% is reported when single diagnostic blocks are used. Double comparative blocks are therefore highly recommended for appropriate diagnosis of LFS and to avoid the unacceptably high false-positive response rate obtained with single blocks.

**THERAPEUTIC LUMBAR FACET JOINT INJECTIONS**

Therapeutic lumbar facet joint injection (LFJI) of steroids and local anesthetics is a commonly performed pain management procedure. Based on the practice of intra-articular injection of steroids into painful knees and shoulders, intra-articular lumbar facet steroid injections were first performed by Mooney and Robertson in 1976. However, no scientific studies have documented capsular inflammation in LFS, and the use of steroids, along with the typical dosages used—20 to 30 mg of methylprednisolone per joint—is entirely empirical. Confirmation of LFS by using diagnostic blocks before therapeutic LFJI is rarely practiced. Observational studies report long-term (greater than 6 months) success rates of therapeutic LFJI to be in the range of 18% to 63%. Long-term pain relief, however, is also reported after intra-articular facet injections of local anesthetics and saline. The few prospective controlled trials conducted on this topic have been seriously criticized and have failed to show the efficacy of therapeutic LFJI.

**FACET DENERVATION**

Facet denervation, also referred to as facet rhizotomy, neurotomy, or ablation, is accomplished by lesioning of the MB at the same vertebral level and one vertebral level above (see Fig. 21.12). Although chemical neurolysis and cryoablation have been used, thermal RF ablation is the most frequently used technique for facet rhizotomy. Because the distal circumferential radius of the RF lesion generated is shorter than the more proximal circumferential radius, an RF lesion is performed by placing the electrode along the path of the nerve, parallel to the base of the SAP. Optimal electrode position is confirmed radiologically and by sensory and motor testing before creation of the lesion. The size of RF electrodes used has varied from 22 to 18 gauge, with temperatures ranging between 80° C and 90° C, and the duration of RF lesioning has varied between 60 and 90 seconds. Larger probe size and longer duration of lesion creation tend to produce larger lesions with a greater likelihood of thermally injuring the target nerve. Routine use of 18-gauge electrodes with a 1-cm exposed tip and a lesioning duration of 120 seconds at 80° C has been recommended by some authors. Apart from the several observational studies reporting the efficacy of RF ablation for LFS, three RCTs of its efficacy are available. Two of these trials demonstrated improvement in chronic LBP following the procedure, whereas the third showed no such benefit.

**SUMMARY**

- Syndromes causing low back and radicular pain include herniated disk, spinal stenosis, internal disk disruption, facet syndrome, sacroiliac joint dysfunction, and myofascial pain syndrome.
- “Red flags” in the medical history of a patient with low back pain may indicate serious pathology and include age younger than 20 or older than 50 years, history of trauma, constitutional symptoms, and systemic illness.
- Most patients with a herniated disk experience significant resolution of their symptoms.
- Nonoperative treatment, including epidural steroid injections, should be tried initially in patients with a herniated disk. Although the initial results from surgery are promising, the long-term results appear to be similar to those of nonoperative treatment.
- Transforaminal epidural steroid injections (TF-ESIs) are associated with central nervous system injuries, including paraplegia. Digital subtraction angiography and nonparticulate steroids should be used for cervical TF-ESIs. For lumbar approaches, either a nonparticulate steroid or a steroid with smaller particles should preferably be used.
- Neurogenic claudication, the hallmark of spinal stenosis, should be distinguished from vascular claudication. Conservative management should be used since the benefits from surgical treatment appear to decrease with time.
- The presence of a high-intensity zone indicates an annular tear. The role of diskography is controversial, and the indication for intradiscal electrothermal therapy is limited.
• Facet denervation after diagnostic medial branch blocks may be an effective treatment of facet syndrome.
• The complexity of low back pain could also be attributed to the frequent presence of psychosocial issues in these patients and the lack of adequate diagnostic tests and effective treatments.
• A thorough clinical evaluation with recognition of the specific signs and symptoms of the different low back pain syndromes, their correlation with findings from available diagnostic tests, and the application of proven therapeutic interventions could provide relief for patients with low back pain and help reduce costs.

Neurosurgeons have a long history of surgically treating pain, particularly cancer pain. The notion that sectioning pain pathways could achieve pain control was first introduced by Spiller and Martin in 1912. This was followed by the development of a whole array of surgical procedures aimed at interrupting ascending pain signals throughout different parts of the central nervous system.

Two approaches are used when targeting the brain or spinal cord to treat pain. The first, a nondestructive approach, uses either electrical stimulation of brain targets, which is thought to modulate the process of pain perception, or pharmacologic agents, which are introduced into the ventricular or intrathecal spaces to target pain-modulating receptors. Targets for electrical stimulation include the peripheral nerves, spinal cord, thalamic nuclei, periventricular gray (PVG) matter, periaqueductal gray (PAG) matter, and motor cortex. Currently, the pharmacologic agent of choice for intrathecal or intracerebroventricular (ICV) injection is morphine or other opiates. In general, nondestructive procedures are used for non–malignant-type pain; however, intrathecal opioids are also used for the treatment of cancer pain.

The second, a destructive approach, is used with the goal of interrupting signals that lead to perception of pain at various levels. Neuroablation can be performed on cellular complexes, such as nuclei or gyri, or on tracts with the aim of either disrupting the ascending sensory signals or destroying the limbic pathways involved in the emotional processes associated with pain. Neurosurgical procedures for pain can be performed at the level of the nerve, spinal cord, brainstem, or cerebrum and are considered ablative or neuromodulatory. Spinal cord neuromodulatory procedures fall into two subcategories: electrical and pharmacologic. These procedures are performed by anesthesiologists and neurosurgeons and are discussed elsewhere in this textbook.

We present three broad categories of neurosurgical procedures for pain: (1) cerebral neuroablation (e.g., dorsomedial thalamotomy and the caudalis dorsal root entry zone [DREZ] procedure), (2) spinal neuroablation (e.g., cordotomy, extralaminiscal myelotomy, and trigeminal tractotomy), and (3) cerebral neuro modulation (electric: motor cortex stimulation [MCS] and deep brain stimulation [DBS]; and pharmacologic: ICV opioids).

**CEREBRAL NEUROABLATION**

Historically, many procedures fall into this category, including mesencephalotomy, pontine tractotomy, and hypophysectomy. We focus on procedures that we believe are more than what could be considered of purely historical significance.

**MEDIAL THALAMOTOMY**

Stereotactic thalamic neuroablative surgery for pain is relatively safe with respect to deep brainstem structures, and because of the wide involvement of many thalamic nuclei in pain processing, it has been considered a part of the pain surgery armamentarium. The first structure targeted for neuroablation was the ventral caudal (Vc) nucleus, as defined by Hassler; however, it was soon recognized that neuroablation of the Vc nucleus was associated with significant deafferentation pain phenomena. The work of Mark and colleagues led to the belief that targeting the medial thalamic nuclei was more effective in managing pain. Nuclear targets for neuroablative medial thalamotomy are (1) the centralis lateralis, (2) centrum medianum, and (3) parafascicularis. Several pain syndromes, including cancer pain, central and peripheral deafferentation pain, spinal cord injury, malignancy, arthritis, and the neurogenic pains associated with Parkinson’s disease, have been successfully treated by medial thalamotomy. Frank and coauthors reported the overall success rate of medial thalamotomy to be 52%, with cancer pain being the main condition treated. Jeanmonod and coworkers and Young and colleagues used radiofrequency and Gamma Knife treatment, respectively, and reported a 60% success rate in achieving pain control. The ideal target lying between the three main medial thalamic nuclei (listed above) has yet to be determined, although the centrum medianum nucleus is the most frequently targeted. DBS of the medial nuclei does not usually produce a conscious sensory response, and lesioning does not induce sensory loss. The published literature on medial thalamotomy is inconsistent regarding the target, guidance technique, patient population, and lesioning method used. Therefore, the actual success rate of medial thalamotomy is difficult to assess. However, in general, the procedure is considered to be effective in treating nociceptive pain, with recent data pointing to some success in relieving neuropathic pain.

**STEREOTACTIC CINGULOTOMY**

Cingulotomy refers to stereotactic lesioning of the anterior cingulate gyrus. Le Beau performed the first open cingulotomy to treat intractable pain in 1954. It is believed that cingulotomy causes relief by altering a patient’s emotional reaction to painful stimuli through interruption of the...
Papez circuit\textsuperscript{10} and increasing tolerance to the subjective and emotional feelings of pain.\textsuperscript{11,12} Cingulotomy is performed with standard stereotactic protocols, usually under general anesthesia. Bilateral lesions are made in the anterior aspect of the cingulate gyrus, and success of the procedure is directly related to the extent of ablation of the cingulum (Fig. 22.1).\textsuperscript{1} A suitable stereotactic cingulotomy candidate is a terminally ill patient with widespread metastatic disease that has extended to the musculoskeletal system, where intrathecal or intraventricular administration of opiates is difficult. Emotional factors associated with pain would favor selection of a stereotactic cingulotomy procedure. Of note, stereotactic cingulotomy has been used to treat non-malignant pain with a success rate of approximately 25\%.\textsuperscript{13} Stereotactic cingulotomy involves the ablation of sufficient anterior cingulate gyrus volume, which is usually achieved by producing at least two lesions with a wide–surface area, uninsulated tip electrode. The procedure is generally safe with few and minor side effects. Pillay and Hassenbusch reported on a series of 12 patients in which 7 had satisfactory pain relief.\textsuperscript{14} Cingulotomy is rarely used today, mainly because of its narrow indication, advances in the medical management of terminal cancer patients, and the widespread use of neuroaugmentive procedures.

**CAUDALIS DORSAL ROOT ENTRY ZONE (BRAINSTEM LEVEL)**

Following the introduction of stereotaxis in the 1960s, the use of open ablative brain and brainstem surgery was almost abandoned. Siqueira first reported performance of the caudalis DREZ procedure in two patients.\textsuperscript{15} Gorecki, Nashold, and colleagues at Duke University\textsuperscript{16,17} later adopted the technique and expanded its indications. In the caudalis DREZ procedure, the caudal portion of the spinal trigeminal nucleus, along with the overlying trigeminal tract, is destroyed. Similar to spinal DREZ surgery, the objective is to destroy the cells of second-order neurons thought to be hyperactive in trigeminal deafferentation pain, thereby achieving pain relief (see Fig. 22.1). The main indications for the caudalis DREZ procedure are ophthalmic post-herpetic neuralgia and trigeminal anesthesia dolorosa. In cases of neuropathic facial pain in which all other medical and surgical modalities are ineffective, the caudalis DREZ procedure may represent a last resort. The procedure is rarely performed, and potential risks include ipsilateral limb ataxia and weakness.

**SPINAL NEUROABLATION**

The first report of surgical disruption of spinal pain pathways was presented by Spiller and Martin in 1912.\textsuperscript{1} They sectioned the anterolateral quadrant of the spinal cord with the intention of interrupting transmission of pain signals via the spinothalamic tract (anterolateral system) and relieving pain on the contralateral side of the body, caudal to the lesion.\textsuperscript{1}

Several decades ago, open surgical sectioning of the spinothalamic tract (anterolateral cordotomy) to control pain.
was a common procedure in many neurosurgical centers. The procedure was used mainly to treat somatic nociceptive pain, usually from cancer. However, factors such as the debilitating state of cancer patients resulting in poor tolerance of open spinal cord surgery, together with high complication rates, meant that the procedure was not an ideal solution to the problem of cancer pain.

Currently, spinal cord targets for destructive procedures to treat pain include (1) the spinothalamic tract (anterolateral column), where destruction can alleviate somatic nociceptive pain below the level of the neck (e.g., anterolateral cordotomy); (2) trigeminal spinal nucleus, which is disrupted to treat trigeminal neuropathic pain (e.g., trigeminal tractotomy-nucleotomy (“caudalis DREZ”)); (3) midline ascending polysynaptic visceral pain pathway, which is used to treat visceral pain, particularly pelvic pain (i.e., midline myelotomy); and (4) the DREZ, primarily to treat deafferentation pain in the upper extremity (i.e., DREZ procedure) (see Fig. 22.1). The role of each of these procedures in contemporary surgical pain management will be reviewed.

ANTEROLATERAL CORDOTOMY

Anterolateral cordotomy refers to lesioning, sectioning, or other disruption of the lateral spinothalamic tract (LST), which is located in the anterolateral quadrant of the spinal cord. The procedure was historically performed in the upper thoracic spine via an open posterior approach and, less commonly, high in the cervical spine. The spinal cord anterolateral ascending pain transmission system carries information about pain and temperature from one side of the body. The tract is formed by the central processes of nociceptive neurons in the dorsal horn that cross the spinal cord in the anterior commissure, ascend in the anterolateral column to the brainstem, and relay in the thalamus. Lesions of the anterolateral tract produce a contralateral deficit in pain and temperature sensation two to five segments below the level of the cordotomy. Fibers in the LST have a somatotopic arrangement, with the sacral segments arranged posterolaterally and the cervical segments anteromedially. The corticospinal (pyramidal) tract lies posterior to the LST with white matter in between. The ventral spinocerebellar tract overlays the LST, and a lesion that damages the spinocerebellar tract may cause ipsilateral ataxia of the arm. Autonomic pathways for vasomotor and genitourinary control and reticulospinal fibers that subserve ipsilateral automatic respiration are also part of the anterolateral quadrant of the spinal cord. A patient with hemibody somatic cancer pain localized caudal to the region of pain. CT-guided cordotomy has a higher success rate than do more traditional approaches, as well as fewer complications. Control of cancer pain is reportedly achieved in more than 95% of cases. Procedural complications may include weakness, hypotension, dysesthesia, mirror-image pain, ataxia, incontinence, and sleep apnea. However, contemporary CT-guided cordotomy complications tend to be both minor and transient.

A recent evidence-based review concluded that the case for cordotomy is somewhat unique among all cancer pain procedures in that it has the most supportive evidence. In that review the GRADE system of recommendation was used, and a recommendation for cordotomy was given. The GRADE system produces recommendations that are independent of the level of evidence.

TRIGEMINAL TRACTOTOMY-NUCLEOTOMY (SPINAL LEVEL)

Sensory information from the 5th, 7th, 9th, and 10th cranial nerves is carried by the trigeminal tract and branches into the trigeminal tract spinal nucleus and extended caudally into the spinal cord to C2. The trigeminal tract is considered a target for surgically treating facial pain, and the history of procedures directed to this target is similar to
cordotomy in that initial open procedures evolved toward less invasive stereotactic operations. Crue and colleagues and Hitchcock developed a stereotactic technique to lesion the trigeminal tract and nucleus via radiofrequency that was named trigeminal nucleotomy. As with CT-guided cordotomy, CT is used when performing the trigeminal tractotomy-nucleotomy (TR-NC) procedure today. Indications include anesthesia dolorosa, post-herpetic neuralgia, neuropathic facial pain, facial cancer pain, and either glossoharyngeal or geniculate neuralgia. The procedure can be considered, in some ways, a mini–caudalis DREZ procedure. The nucleus caudalis DREZ operation involves the same concept as the TR-NC procedure but includes destruction of the substantia gelatinosa (Rexed laminae II and III) of the nucleus caudalis. Pain relief from TR-NC is reported to be complete or satisfactory in 80% of cases. Complications include ataxia from injury to the spino-cerebellar tract (usually temporary) and contralateral hypoalgesia if the spinothalamic tract is included in the lesion.

**EXTRALEMNISCAL MYELOTOMY**

The extralemniscal myelotomy (ELM) procedure was first described by Hitchcock, who initially aimed to destroy the deccussating fibers of the spinothalamic tract in the anterior commissure of the spinal cord to control pain in the neck and both arms. ELM was achieved by creating a lesion in the central medullary region at the cervicomедullary junction. Unexpectedly, it was noted that the ELM procedure also seemed to control pain caudal to the level of the lesion. Schwarz added the term “extralemniscal” to “myelotomy” because of the contention that the lesion incorporated an ascending polysynaptic nociceptive pathway. Subsequently, the presence of such a tract has been confirmed anatomically. Several authors have now presented reports of midline “punctuate” ELM via open procedures to interrupt this pathway at various spinal cord levels. The polysynaptic ascending pathway is thought to carry visceral nociceptive information and lies deep to the midline dorsal column. The concept of CT guidance, previously applied to cordotomy and TR-NC procedures, has also been applied to ELM by Kanpolat and colleagues, thus developing the image-guided ELM procedure used today.

ELM is currently conceived as a pain control procedure for pain of visceral origin, including patients with pelvic malignancy, or for cancer pain in the lower part of the trunk and lower extremities with a predominant visceral pain component. The procedure appears to be safe; however, pain relief results are not as good as those achieved with cordotomy and TR-NC procedures.

**DORSAL ROOT ENTRY ZONE LESIONS**

With introduction of the gate control theory in the 1960s, attention was drawn to the spinal dorsal horn as the initial physiologic substrate for pain modulation. The dorsal horn and DREZ were then reconsidered as targets for both neuromodulation (spinal cord stimulation) and neuroablation. In 1972, Sindou first attempted cervical DREZ destruction for neuropathic deafferentation pain in the upper extremity secondary to brachial plexus avulsion. Nashold and associates soon followed and introduced the use of radiofrequency lesions to perform DREZ disruption. Laser and ultrasound have also been used to damage the DREZ. When large-fiber afferents (touch, position sense) in peripheral nerves or dorsal roots are altered, there is a reduction in the inhibitory control of the dorsal horn. This situation is presumed to result in excessive firing of the dorsal horn neurons, which is thought to be the cause of deafferentation pain and hence able to be controlled by DREZ lesioning. The technical details of the procedure and its variants are beyond the scope of this chapter, but DREZ lesioning is performed as an open surgical procedure under general anesthesia and oftentimes accompanied by intraoperative neurophysiologic monitoring. Surgical candidates are patients with brachial plexus avulsion, Pancoast’s tumor with brachial plexus invasion combined with a good general condition and reasonable life expectancy, pain caused by spinal cord or cauda equina lesions, and pain accompanying spasticity after plexus or cord injury. A general prerequisite for the DREZ procedure is a lack of functional use of the limb where the DREZ procedure is performed since complete sensory denervation of the limb will render it functionless even if there is residual motor power. When patients are carefully selected and the lesions accurately performed, the success rate can be as high as 90% (with follow-up success rates reported for up to 4 years). Complications and side effects include cerebrospinal fluid (CSF) fistula, meningitis, ataxia, increased neurologic deficits, and dysesthesias.

**CEREBRAL NEUROMODULATION**

**ELECTRICAL NEUROMODULATION**

**DEEP BRAIN STIMULATION**

Pool first observed and reported on the analgesic effects of septal stimulation in the frontal and lateral fornical columns while performing psychosurgery in the 1950s. Heath and Mickle and Pool and colleagues subsequently reported the pain-relieving effect of septal and near-septal stimulation in nonpsychiatric patients. Mazars and coauthors and Reynolds first reported pain relief from thalamic stimulation in 1960. Neurostimulation of the brain to relieve pain was thus introduced decades before what has become the main contemporary indication for DBS—treatment of movement disorders. However, these early reports only set the stage for the eventual applications of DBS for pain relief. In the mid-1960s, Melzack and Wall’s gate theory provided the logical rationale for DBS of the sensory thalamus to control pain. Shortly afterward, Reynolds reported on the analgesic effect of focal brain stimulation in rats (stimulation-produced analgesia). In the early 1970s, Hoshobuchi and associates and Richardson and Akil were the first to report on stimulation of the human thalamus and PVG and PAG matter for pain control. Even though stimulation of the thalamic sensory nuclei produced paresthesias in painful areas, consistent pain relief was not achieved. Similar results were produced by stimulation of the internal capsule. Stimulation of the PVG and PAG typically did not produce paresthesias but did induce a
sense of “warmth.” Higher-intensity PVG/PAG stimulation produced unpleasant and sometimes overwhelming sensations such as impending doom or terror. The centromedian-parafascicular complex was also targeted by Andy as a stimulation site to treat pain, and this stimulation likewise did not produce paresthesias.

Despite reports describing the use of DBS to treat chronic pain in the 1970s and early 1980s, data to support the technique never reached contemporary evidentiary standards. The use of DBS for pain control has failed to gain much acceptance in the neurosurgical community, and the use of DBS electrodes as pain control implants has never achieved U.S. Federal Drug Administration (FDA) approval. The lack of data to support the procedure is due, in part, to the small number of patients treated, inconsistent target localization, heterogeneity of the pain diagnoses treated, and failure to mount a prospective randomized trial that was sufficiently powered to answer the question of efficacy. The mechanism of pain relief by DBS is poorly understood but appears to be dependent on the site. The thalamus and PVG/PAG were the most commonly targeted sites for DBS implants for pain. Hosobuchi and colleagues suggested that the pain-relieving effect of PVG and PAG stimulation might involve endogenous opioid receptors based on their studies in which it was found that the pain-relieving effect of DBS could be reversed by naloxone. Evidence to support this mechanism of action of PAG/PVG DBS is inconsistent. Some investigators supported the concept whereas others disagreed. Currently, it is postulated that the pain-relieving effect of PAG/PVG DBS is due to activation of multiple supraspinal descending pain modulatory systems, both opioid and nonopioid. Pain relief resulting from stimulation of the ventral posterolateral (VPL) nucleus and ventral posteromedial (VPM) nucleus (Vc nucleus in the European Hassler terminology), the major sensory nuclei of the thalamus, is poorly understood. Inhibition of spinothalamic tract neurons and activation of dopaminergic mechanisms have both been proposed. The most accepted hypothesis is that thalamic stimulation activates the nucleus raphe magnus of the rostroventral medulla, which results in activation of a suprasegmental descending endogenous pain inhibition system.

Meticulous patient selection, with classification of the pain (i.e., nociceptive or neuropathic) combined with informed DBS target selection, should help improve the outcome of DBS for pain. Clinical case series (class III evidence) observations suggest that PVG/PAG stimulation seems to be more effective in treating somatic nociceptive pain. This is consistent with the proposed opioid-mediated effect of PAG/PVG stimulation. It has also been suggested that VPL and VPM (Vc) stimulation is more effective in treating neuropathic pain, a gate theory-based concept. In the absence of controlled trials to prove efficacy, any definitive conclusions regarding the ideal target for any particular pain syndrome remains elusive. Furthermore, many patients have mixed neuropathic/nociceptive pain, which suggests that the DBS target to control pain should be individualized according to the patient. Some authors have even suggested placing two electrodes simultaneously in the sensory thalamic nucleus (Vc) and in the PVG. For some pain syndromes (e.g., thalamic infarction–induced pain), target selection is simpler given that thalamic stimulation is not possible.

Chronic neuropathic pain conditions treated by DBS have included anesthesia dolorosa, post-stroke pain, thalamic pain, brachial plexus avulsion, post-herpetic neuralgia, post-cordotomy dysesthesia, spinal cord injuries, and peripheral neuropathy pain. Nociceptive pain conditions treated by but not limited to DBS have included failed back surgery syndrome, osteoarthritis, and cancer pain.

DBS for chronic pain is similar to DBS for other indications (movement disorders) in that surgeons have a number of targets that are applicable to the general problem (see Fig. 22.1). DBS target locations are often indirectly derived from the Schaltenbrand and Bailey atlas or measured directly from the patient’s CT or magnetic resonance imaging scans. The location of these targets can be confirmed intraoperatively by microstimulation, microelectrode mapping, or intraoperative imaging. To best judge the benefits of stimulation and help fine-tune stimulation parameters following final electrode implantation, a trial period of approximately 1 week is often a prerequisite. Complications of DBS for pain relief are similar to those for movement disorders. Typically, they are related to either (1) brain injury from bleeding or inadvertent trauma as a result of electrode insertion, (2) infection, (3) hardware failure, and (4) transient site-specific side effects related to overstimulation or unintentional stimulation of neighboring areas. The later might produce diplopia, seizures, nausea, paresthesias, or headaches.

Overall, DBS surgery is a safe procedure with a relatively low chance of complications or unintended neurologic sequelae. However, data to support its efficacy are sparse. Currently, DBS for pain control is an extraordinary treatment that may be applicable to only a few chronic pain conditions. DBS implantable hardware is not approved by the FDA for pain control procedures, and many insurance carriers will not authorize implantation. Given the tremendous interest in and application of DBS for movement disorders, whether DBS for pain will be substantially resurrected at some point remains to be seen.

**MOTOR CORTEX STIMULATION**

In 1954, Penfield and Jasper observed that stimulation of the precentral (motor) gyrus elicited sensory responses when the corresponding portion of the adjacent postcentral gyrus had previously been resected. They treated burning pain on one side of the body by postcentral gyrectomy, and when the pain recurred, they performed precentral gyrectomy, which then controlled the pain. Independently, in 1955 White and Sweet attempted surgical resection of the postcentral gyrus for relief of central pain and reported 13% pain relief. It was not until 1971, after publication of the gate theory in 1965, that Lende and coworkers re-explored the motor cortex as a potential site for pain control. In an attempt to treat central neuropathic facial pain they performed two cases of precentral and postcentral gyrectomy of the facial cortex. These reports formed the basis for establishing a linkage between the precentral postcentral areas and pain control surgery.

By the 1980s, the cumulative failure of other procedures, both modulatory and destructive, to fundamentally alter neuropathic pain made it clear that the development of an innovative methodology to surgically treat pain was critically needed. Exploration of the motor area as a target
site was well under way. Hardy and associates stimulated the rat medial prefrontal cortex with a resultant significant elevation in nociceptive response latency. Hoshbushi implanted electrodes in subcortical somatosensory areas for control of dysesthetic pain, and from this study it was concluded that somatosensory stimulation could be effective in the treatment of leg pain. In 1991, Tsubokawa and coworkers first introduced epidural stimulation of the motor cortex as an option to treat central deafferentation pain. His group had tried postcentral gyrus (sensory) stimulation and found that it was either ineffective or exacerbated the pain. They demonstrated that epidural MCS inhibited abnormal thalamic neuronal burst activity and increased regional blood flow to the cortex and thalamus. Primarily, Tsubokawa and colleagues used MCS for central deafferentation pain syndromes such as post-stroke pain. The mechanism of action of MCS is still poorly understood; however, the work of Garcia-Larrea, Peyron, and coworkers has shed some light on its mechanism of action. Positron emission tomography and electrophysiologic studies have demonstrated that MCS increases blood flow to the ipsilateral thalamus, cingulate gyrus, orbitofrontal cortex, insula, and the brainstem, with some correlation between increased thalamic and brainstem blood flow and efficacy of pain relief. The increased blood flow to the ipsilateral sensory thalamus was greater than that to the motor (ventrolateral) thalamus. It did not appear that an intact somatosensory system was absolutely necessary for the clinical benefits to be realized, an important discovery allowing the use of this technology for stroke and other deafferentation states. As with many forms of chronic stimulation, habituation seems to occur, which is more likely with the use of high-frequency stimulation. The patient selection process for MCS is of paramount importance (as it is for all pain-relieving surgeries), and in this case, the debate continues. Neuropathic pain is more responsive than nociceptive pain to this form of therapy. Attempting to predict the best candidates for MCS can be challenging, and Yamamoto and colleagues introduced a pharmacologic classification of post-stroke patients based on their pain relief response to escalating doses of both intravenous thiamylal and morphine. They concluded that patients with a good response to thiamylal or ketamine and a poor response to morphine were the best candidates for MCS. Several neurogenic pain syndromes have been treated by MCS, including thalamic pain, bulbar post-stroke pain (which typically occurs with “Wallenberg’s syndrome”), facial neuropathic and deafferentation pain, and phantom and brachial plexus avulsion pain. Treatment of central post-stroke pain following thalamic infarction or thalamic or putaminal bleeding by MCS was reported by Tsubokawa and colleagues to achieve good to excellent pain control in 65% of cases (follow up >12 months), with no seizures observed. Katayama and associates extended the indications to include bulbar pain secondary to “Wallenberg’s syndrome” and reported on four patients initially treated by VPL thalamic stimulation that resulted in increased pain. Three other patients were later treated by MCS, with greater than a 60% reduction in pain in two patients and greater than 40% in one patient. Treatment of neuropathic facial pain appears to be one of the most promising indications for MCS, which may be related to the breadth of facial representation over the motor cortex. Several reports include neuropathic facial pain treatment by MCS. Raslan, Ebel, Herregodts, Meyerson, Nguyen, Rainov, and their colleagues all treated trigeminal neuropathic pain with MCS and reported pain relief in approximately 60% of patients for periods of up to 12 months. Peripheral deafferentation pain, as well as brachial plexus avulsion pain, has also been treated by MCS, with variable results. Movement disorders are an active area of ongoing MCS research. MCS has been shown to produce improvement in the symptoms of thalamic hand syndrome, action tremors, intention myoclonus, and Parkinson’s disease.

MCS involves the implantation of epidural electrodes over the motor cortex (see Fig. 22.1), which can be localized by either (1) radiologic landmarks of the central sulcus, (2) intraoperative somatosensory evoked potentials with observation of “phase reversal” over the central sulcus, (3) intraoperative stimulation of the cortex with concurrent electromyographic monitoring of the relevant muscle groups contralaterally, and more recently, (4) use of neuronavigation systems to localize either the central sulcus or the precentral gyrus. Some authors even recommend the use of functional magnetic resonance imaging for targeting, especially with infarctions involving the motor cortex. A trial period of MCS is usually required followed by implantation of a permanent system if the trial produces adequate relief. Complications of MCS include intraoperative seizures, stimulator pocket infection, epidural bleeding, subdural effusion, and “tolerance” to stimulation with diminished analgesia over time.

CEREBRAL NEUROMODULATION: PHARMACOLOGIC

INTRAVENTRICULAR OPIOIDS

Studies showing the direct analgesic effects of opioids applied in the ventricular region and around the medulla of the central nervous system led to the work of Leavens and coworkers in 1982, in which human ICV use of morphine was first reported. The profound analgesic response to intrathecal morphine coupled with its widespread clinical use for lower body pain suggested the need for more rostral injection sites to control pain involving the head, neck, and upper extremity regions. Even though cervical intrathecal opioid injection sometimes resulted in respiratory depression, it was possible to deliver a small amount of ICV morphine without respiratory dysfunction or dysautonomia. Opioid receptors are abundant around the wall of the third ventricle and aqueduct, as well as in the PVG and PAG. In Leavens and colleagues’ 1982 report, 1 mg of morphine was used to treat patients with intractable cancer pain and resulted in profound analgesia and no respiratory depression or neurologic changes. In a report on 82 patients, Lazarth and associates recommended nine specific guidelines for the ICV use of morphine: (1) chronic pain secondary to inoperable malignant tumors in patients with terminal cancer; (2) pain not relieved by medical treatment and, in particular, the development of serious side effects from using oral or systemic morphine; (3) intractable bilateral, midline, or diffuse pain not appropriate for percutaneous

CHAPTER 22 — NEUROSURGICAL APPROACHES TO PAIN MANAGEMENT
Neurosurgical procedures to treat intractable pain have gone through an evolutionary process, dictated in part by technological advances, scientific discovery, and changes in the survival rates of chronic pain patients, especially those with cancer pain. Irreversible ablative procedures are used much less frequently today, yet on occasion they remain the procedures of choice. Depending on the physiologic substrate and pain topography, multiple brain and spinal cord regions can be targeted to treat chronic pain. Today, neuromodulation by either electrical stimulation or pharmacologic manipulation is generally the preferred approach to treat chronic pain.
Cancer pain is a result of cancer growth in human tissues or the pain produced by any of the therapies implemented to treat it. Ideal management starts with a thorough assessment via the history and physical examination, as well as the judicious use of diagnostic testing in an attempt to define the pathophysiologic components involved in the expression of pain to implement optimal analgesic therapy. Adequate pain control can be achieved in the great majority of patients with the implementation of aggressive pharmacologic treatment consisting of the use of opioids and adjuvants.\(^1\,\text{,}\,^2\) With the implementation of these strategies, 90% to 95% of patients may achieve adequate pain control.\(^3\) Consequently, 5% to 10% of patients will need some form of invasive therapy. Thus, when following specific guidelines, the great majority of patients with cancer-related pain may expect adequate pain control in the 21st century. Control of pain and related symptoms is a cornerstone of cancer treatment in that it promotes an enhanced quality of life, improved functioning, better compliance, and a means for patients to focus on matters that give meaning to life.\(^4\) In addition to their salutary effects on quality of life, mounting evidence suggests that good pain control influences survival.\(^5\,\text{,}\,^6\)

**ASSESSMENT OF PAIN INTENSITY**

Questionnaires have been used to aid in standardizing patients’ assessment. Ideally, this assessment is completed by patients before their evaluation. The Wisconsin Brief Pain Inventory (BPI)^22 and the Memorial Pain Assessment Card\(^23\) are becoming increasingly well accepted. The characteristics of the different assessment tools are noted in the following outline:

1. *Wisconsin BPI*:
   a. It is a fifteen-minute questionnaire that can be self-administered.
   b. It includes several questions about the characteristics of the pain, including its origin and the effects of previous treatments.
   c. It incorporates two valuable features of the McGill Pain Questionnaire, a graphic representation of the location of the pain and groups of qualitative descriptors. Severity of pain is assessed by a series of visual analog scale (VAS) scores that quantify pain at its best, worst, and on average. The perceived level of interference with normal function is quantified with a VAS also.
   d. Preliminary evidence suggests that the BPI is cross-culturally applicable and is useful, particularly when patients are not fit to complete a more thorough or comprehensive questionnaire.

**EPIDEMIOLOGY**

Approximately 6.35 million new cases of cancer are diagnosed annually worldwide, half of which originate in developing nations\(^7\) and 1.04 million occur in the United States alone.\(^8\) Mortality is high; one in five deaths in the United States is a result of cancer, which means about 1400 cancer-related deaths per day.\(^9\,\text{,}\,^10\) The morbidity is equally concerning inasmuch as up to 50% of patients undergoing treatment of cancer and up to 90% of patients with advanced cancer have pain.\(^11\) Most (65%) cancer pain is due to involvement of organic structures by tumor, notably bone, neural tissue, viscera, and others. Up to 25% of cancer pain is due to therapy, including chemotherapy, radiotherapy, and surgery, and the rest of “cancer pain” is accounted for by common chronic pain syndromes, including back pain and headaches, which might have been exacerbated by the ongoing growth or treatment of cancer.\(^12\) As new therapeutic regimens are introduced for the treatment of cancer, it is expected that cancer patients will be living longer and potentially experiencing pain as a result of cancer disease itself or therapies implemented for its control for longer periods.

Anorexia, fatigue, and pain are the most common symptom associated with cancer.\(^13\,\text{,}\,^14\) Significant pain is present in up to 25% of patients undergoing active treatment and in up to 90% of patients with advanced cancer.\(^11\,\text{,}\,15\text{–}\,19\) According to several studies, including a survey of oncologists in the Eastern Cooperative Oncology Group (ECOG) and a survey of 1103 consecutive admissions to a U.S tertiary care cancer hospital, 73% of patients in active treatment admitted to having pain, with 38% reporting severe pain.\(^20\) Despite the availability of simple, cost-effective treatments,\(^21\) inadequately controlled pain remains a significant problem. This is important because of the negative influence of pain on patients’ performance status.

Performance status, as measured by the ECOG and Karnofsky scales (Table 23.1), is a global rating of patients’ overall functional status. When performance status is low, as is often the case when pain is severe, patients may find it difficult to tolerate the chemotherapy recommended; indeed, they may not be considered candidates for chemotherapy. Further benefits of good pain management often include improvement in nutrition, rest, and mood, all of which contribute to quality of life and have the potential to influence the outcome of antineoplastic therapy.
2. **Memorial Pain Assessment Card:**
   a. It is a simple, efficient, and valid instrument that provides rapid clinical evaluation of the major aspects of pain experienced by cancer patients.²³
   b. It is easy to understand and use and can be completed by experienced patients in 20 seconds.
   c. It consists of a two-sided, 8.5- × 11-inch card that is folded so that four separate measures are created.
   d. It features scales intended for measurement of pain intensity, pain relief, and mood and a set of descriptive adjectives.

3. **Edmonton staging system:**
   a. It is performed by health care providers.
   b. It was developed to predict the likelihood of achieving effective relief of pain in cancer patients.²⁴,²⁵
   c. The system’s originators provided validation that treatment outcome can be accurately predicted according to five clinical features (neuropathic pain, movement-related pain, recent history of tolerance to opioids, psychological distress, and a history of alcoholism or drug abuse).
   d. Staging requires only 5 to 10 minutes and no special skills are needed to complete it.
   e. Its value lies in prospective identification of potentially problematic patients, thereby further legitimizing clinical research on control of symptoms by introducing better standardization and improving our ability to critically assess the results of various therapeutic interventions in large population of patients.

4. **Pediatric cancer pain assessment:** This includes Beyer’s The Oucher, Eland’s color scale–body outline, Hester’s poker chip tool, McGrath’s faces scale, and others.²⁶-²⁹

5. **Numerical rating scale (NRS) or VAS:**
   a. Pain is often assessed on an 11-point NRS from 0 (no pain) to 10 (worst pain imaginable).
   b. The VAS is a 10-cm line without markings from no pain to worst pain; patients mark their pain score and a measurement in centimeters defines their level of pain.

Evaluation of pain should be integrated with a detailed oncologic, medical, and psychosocial assessment. The initial evaluation should include an evaluation of the patient’s feelings and attitudes about the pain and disease, family concerns, and the patient’s premorbid psychological history. A comprehensive but objective approach to assessment instills confidence in patients and family that will be valuable throughout treatment. A comprehensive evaluation of patients with cancer pain includes the following:

- The **reason for the visit** is determined to ensure appropriate triage (e.g., patients with severe pain because of bowel obstruction may need to be sent to the emergency center for urgent treatment).
- An **oncologic history** is obtained to gain knowledge of the context of the pain problem and includes diagnosis and stage of the disease; a history of therapies implemented, including a list of the chemotherapeutic agents used, types of surgery, site of radiotherapy, and outcome (including side effects); and the patient’s understanding of the disease process and prognosis.
- The **pain history** should include any premorbid chronic pain and, for each new pain site, its onset and evolution, site and radiation areas, pattern (constant, intermittent, or unpredictable), intensity (best, worst, average, current)

on VAS scales, quality, exacerbating and relieving factors, interference of the pain with usual activities, neurologic and motor abnormalities (including bowel and bladder continence), vasomotor changes, and current and past analgesics (use, efficacy, side effects). Previous analgesic use, efficacy, and side effects should be cataloged. Prior treatments of pain should be noted (radiotherapy, nerve blocks, physiotherapy, etc.).

- The medical record and radiologic studies should be reviewed. Many of the treatments of cancer may cause pain themselves (chemotherapy- and radiotherapy-induced neuropathy or postoperative pain syndromes such as post-thoracotomy and post-mastectomy pain syndrome), and many specific cancers may cause well-established pain patterns as a result of known probable sites of metastasis, including (1) metastasis of breast cancer to long bones, the spine, chest wall, brachial plexus, and spinal cord; (2) metastasis of colon cancer to the pelvis, hips, lumbar plexus, sacral plexus, and spinal cord; and (3) metastasis of prostate cancer to long bones, the pelvis, hips, lung, and spinal cord.

- The psychosocial history should include marital and residential status, employment history and status, educational background, functional status, activities of daily living, recreational activities, support systems, health and capabilities of the spouse or significant other, and past history of (or current) drug or alcohol abuse.

- The medical history (independent of the oncologic history) should include coexisting systemic disease, exercise intolerance, allergies to medications, medications in use, previous illness and surgery, and a thorough review of systems, including the following:
  - General (anorexia, weight loss, cachexia, fatigue, weakness, insomnia)
  - Neurologic (sedation, confusion, hallucination, headache, motor weakness, altered sensation, incontinence)
  - Respiratory (dyspnea, cough, pneumonia)
  - Gastrointestinal (dysphagia, nausea, vomiting, dehydration, constipation, diarrhea)
  - Psychological (irritability, anxiety, depression, dementia)
  - Genitourinary (urgency, hesitancy, hematuria)

- The physical examination must be thorough, although at times it is appropriate to perform a focused examination of particular problems. In patients with spinal pain and known or suspected metastatic disease, a complete neurologic examination is mandatory.

- A care team meeting should be arranged if applicable.

- The need for further studies should be determined.

- Formulate a clinical impression (diagnosis). Multiple diagnoses usually apply, and it is optimal to use the most specific known diagnosis, such as somatic pain from a vertebral metastasis, severe pain in a patient with metastatic non-small cell carcinoma of the lung, and neuropathic pain from a paravertebral mass invading the nerve root as it exits the vertebral foramen. Nausea and vomiting with severe weight loss and fatigue, as well as constipation, should be identified.

- Formulate recommendations (plan) and alternatives for each problem. For instance, with respect to the examples just presented in formulating a clinical impression, one could perform magnetic resonance imaging (MRI) of the spine, add a controlled-release opioid administered daily and transmucosal fentanyl citrate for breakthrough pain, implement therapy with a combination of a tricyclic antidepressant and an anticonvulsant with instructions on titration, prescribe an antiemetic before meals and as needed for nausea, prescribe a bowel stimulant and bulk-forming compound twice daily for constipation, and evaluate in 2 weeks to determine the need for a short course of steroid therapy.

- Call an oncologist or the primary care provider, or both, if applicable. Have a discussion with the referring physician, primary care provider, and/or oncologist to establish short- and long-term plans.

- Conduct an exit interview.
  - Explain the probable cause of the symptoms in terms that the patient can understand.
  - Discuss the prognosis for relief of symptoms, management options, and specific recommendations. In addition to writing prescriptions, oral and written instructions must be provided. Educational material regarding medications, pain management strategies, or procedures should also be provided. Potential side effects and their management should be discussed.
  - Arrange for follow-up with clinic contact information.
  - Dictate a summary of the evaluation to the referring and consulting physicians.

### CLASSIFICATION OF CANCER PAIN

#### TIME RELATED

**ACUTE PAIN**

Acute pain is frequently associated with sympathetic hyperactivity and heightened distress. It is often temporally associated with the onset or recrudescence of primary or metastatic disease, and its presence should motivate the clinician to aggressively seek its cause and adjust the pharmacologic therapeutic scheme.

**SUBACUTE PAIN**

Some patients experience subacute pain for 4 to 6 weeks after a major surgical procedure. This type of pain is largely undertreated and deserves special attention because it may affect the patient’s ability to perform activities of daily living after discharge from the hospital.

**CHRONIC PAIN**

Treatment of pain of a chronic nature mandates a combination of palliation, adjustment, and acceptance. With time, biologic and behavioral adjustment to the symptoms occurs, and hopefully the associated symptoms will be blunted. Chronic pain with superimposed episodes of acute pain (breakthrough pain) is probably the most common pattern observed in patients with ongoing cancer pain.

#### INTENSITY

Consistent use of measurements of pain intensity aids in monitoring a patient’s progress and may serve as a basis for interpatient comparisons. High pain scores may alert the clinician to the need for more aggressive treatment or hospitalization (or both) for rapid control of symptoms via...
intravenous patient-controlled analgesia (IV PCA) or for antineuropathic medications with a rapid titration protocol.

PATHOPHYSIOLOGY

A mechanistic approach is useful when formulating the initial treatment plan, as suggested in the example above.

Somatic pain is described as a constant, well-localized pain often characterized as aching, throbbing, sharp, or gnawing. It tends to be responsive to opioids and nonsteroidal anti-inflammatory drugs (NSAIDs—cyclooxygenase-2 inhibitors) and amenable to relief by interruption of proximal pathways via neural blockade when indicated.

Visceral pain originates from injury to organs. This pain is transmitted by fibers that travel along the sympathetic nervous system. Visceral pain is characteristically vague in distribution and quality and is often described as a deep, dull, aching, dragging, squeezing, or pressure-like sensation. When acute, it may be paroxysmal and colicky and can be associated with nausea, vomiting, diaphoresis, and alterations in blood pressure and heart rate. Mechanisms of visceral pain include abnormal distention or contraction of smooth muscle walls (hollow visceras), rapid capsular stretch (solid visceras), ischemia of visceral muscle, serosal or mucosal irritation by algesic substances and other chemical stimuli, distention and traction or torsion on mesenteric attachments and the vasculature, and necrosis.

The viscera, however, are insensitive to simple manipulation, cutting, and burning. Visceral involvement often produces referred pain (e.g., shoulder pain of hepatic origin). Neuropathic pain is defined as pain caused by injury or irritation to some element or elements of the nervous system. Examples of neuropathic pain syndromes include tumor growth around nerve structures; postsurgical pain syndromes such as post-thoracotomy, post-mastectomy, post-radical neck dissection, and post-hepatectomy pain; or pain induced by chemotherapeutic agents affecting peripheral nerve structures. Chemotherapeutic agents associated with this problem include vinca alkaloids (vincristine, vinblastine), cisplatin, paclitaxel (Taxol), docetaxel (Taxotere), vinorelbine (Navelbine), and bortezomib (Velcade). Neuropathic pain is often resistant to standard analgesic therapies and frequently requires an approach using combinations of opioids, tricyclic antidepressants, anticonvulsants, oral or topical local anesthetics, corticosteroids, N-methyl-D-aspartate (NMDA) blockers, and others.

TEMPORAL ASPECTS OF PAIN

CONSTANT PAIN

Such pain is most amenable to drug therapy administered around the clock, contingent on time rather than symptoms. It is best managed by long-acting analgesics or, in selected cases, infusion of analgesics.

BREAKTHROUGH PAIN AND INCIDENT PAIN

Breakthrough pain that is related to a specific activity, such as eating, defecation, socializing, or walking, is referred to as incident pain. Incident pain is best managed by supplementing the preventive around-the-clock regimen with analgesics that have a rapid onset of action and a short duration. Once a pattern of incident pain is established, escape or rescue doses of analgesics can be administered in anticipation of the pain-provoking activity. Breakthrough pain that occurs consistently before the next scheduled dose of around-the-clock opioids is called end-of-dose failure (plasma concentrations fall below minimum effective analgesic concentrations) and is ideally managed by reducing the intervals between doses. In contrast, increasing the doses of long-acting opioids under these circumstances may increase the incidence of side effects. Under a strict definition, breakthrough pain is pain that may occur at any time during the day; it increases to a high intensity very rapidly and has duration of 30 to 45 minutes. Consequently, it is important to recognize the differences among these three types of breakthrough pain to implement adequate therapy.

INTERMITTENT PAIN

This type of pain is very unpredictable and can best be managed by the administration of potent analgesics with a rapid onset and short duration as needed.

SPECIFIC CANCER PAIN SYNDROMES

METASTASES

Bone tumor infiltration or bone metastasis is cited as the most common cause of cancer pain and is most often seen with stage IV carcinoma of the prostate, breast, thyroid, lung, or kidney. The pain is usually constant, dull, achy or deep, and often intense with movement or weight bearing. Approximately 25% of patients with bone metastases experience pain. Pressure and chemical irritation of nerve endings in the periosteum may cause pain. It is noteworthy that greater than 50% decalcification must occur before osseous lesions are visible on plain radiographs. Thus, a bone scan (isotope scanning, scintigraphy) is preferred for detecting most bone metastases. Nonetheless, with primary bone tumors, thyroid cancer, and multiple myeloma, plain films are considered to be more sensitive. Neoplastic changes must be differentiated from changes related to infection, trauma, or degeneration because treatment differs, even in patients with cancer.

Prostaglandin E2 (PGE2) and other cytokines are elaborated by osseous metastases. These cytokines are thought to contribute to pain by sensitization of peripheral nociceptors. NSAIDs and steroids are postulated to reduce pain from bony metastases by inhibition of the cyclooxygenase pathway of arachidonic acid breakdown, thus decreasing the formation of PGE2. As deposits enlarge, stretching of the periosteum, pathologic fractures, and perineural invasion contribute to the pain, and requirements for analgesics increase. Palliative radiation therapy is used successfully to relieve pain emanating from bony metastases. However, pain relief may not be seen in 100% of cases. Thus, other forms of therapy may need to be implemented.

Vertebral body metastases are associated with carcinoma of the lung, breast, and prostate. Localized paraspinal, radicular, or referred pain within the dermatomal distribution of the affected nerve structure is usually the first sign of metastasis to the spine. It is often manifested as severe local, dull, steady, aching pain and is frequently exacerbated by movement and weight bearing. On physical evaluation, local
midline tenderness may be present, as well as corresponding neurologic changes associated with either nerve compression or epidural–spinal cord compression. Invasion of the second cervical vertebra may result in pain referred to the occiput, and C7-T1 invasion may produce interscapular pain.41

BASE OF SKULL METASTASIS

Metastasis to the base of the skull is usually accompanied by headache and a spectrum of neurologic findings, especially when the cranial nerves are involved. Symptomatic metastasis to the skull is usually, but not always, a late finding.32 Plain radiography, scintigraphy, and computed tomography (CT) are helpful for the diagnosis of bony disease, whereas MRI and lumbar puncture are useful in evaluating soft tissues and detecting leptomeningeal disease, respectively.43

Musculoskeletal pain in the form of myofascial pain is frequently seen in cancer patients.44 Patients with bone metastases and those with post–radical neck dissection syndrome are frequently affected by this condition. Stress, anxiety, muscle overuse to compensate for the lack of bone support, or the absence of other muscles resected during cancer surgery may play an important role in the development of this condition. Thus, treatment should be multidisciplinary and include pharmacologic therapy, trigger point injections, and physical rehabilitation with the use of orthotic devices as needed.

LEPTOMENINGEAL METASTASIS, MENINGEAL CARCINOMATOSIS

These conditions are frequently seen with primary malignancies of the breast and lung and with lymphoma and leukemia; it is secondary to diffuse infiltration of the meninges. About 40% of patients have headache or back pain, presumably caused by traction on the pain-sensitive meninges or traction on cranial or spinal nerves or secondary to raised intracranial pressure.45,46 Headache is the most common initial complaint; it is characteristically unrelenting and may be associated with nausea, vomiting, mucal rigidity, and changes in mental status.46 Neurologic abnormalities may include seizures, cranial nerve deficits, papilledema, hemiparesis, ataxia, and cauda equina syndrome. The diagnosis may be suggested by the T2 phase of MRI, and it is usually confirmed via lumbar puncture and cerebrospinal fluid (CSF) analysis, which typically shows elevated protein and decreased glucose, as well as malignant cells.47 The natural history of patients with leptomeningeal metastasis is a gradual decline and death over a period of 4 to 6 weeks, although survival is often extended to 6 months or more when radiation therapy or intrathecal chemotherapy (or both) is instituted.48 Steroids may be useful in the management of headache,43 as well as the neuropathic pain associated with spinal cord and nerve involvement.

SPINAL CORD COMPRESSION AND PLEXOPATHIES

Plexopathies are the result of tumor growth around nerve plexuses in the upper or lower extremity. Cervical plexopathy is most commonly due to local invasion by head and neck cancer. Symptoms include aching preauricular, postauricular, or neck pain. Brachial plexopathy is most commonly caused by upper lobe lung cancer (Pancoast syndrome or superior sulcus syndrome), breast cancer, or lymphoma. Pain is an early symptom that usually precedes the neurologic findings by up to 9 months.50,51 The lower cord of the plexus (C8-T1) is affected most frequently, and pain is usually diffuse and aching and radiates down the arm, often to the elbow and medial (ulnar) aspect of the hand.52,53 When the upper part of the trunk is involved (C5-6), pain is generally found in the shoulder girdle and upper portion of the arm and radiates to the thumb and index finger. Horner’s syndrome, dysesthesias, progressive atrophy, and neurologic impairment (weakness and numbness) may occur. Brachial plexus invasion may be associated with contiguous spread to the epidural space.49,54-56 Lumbosacral plexopathy may be due to local soft tissue invasion or compression from tumors of the rectum, cervix, or breast, sarcoma, and lymphoma; pain is usually the initial symptom in 70% of such patients.57 The pain is usually described as aching or pressure-like and only rarely is dysesthetic.57 Depending on the level involved, pain is referred to the low back region, abdomen, buttock, or lower extremity.57,58 This medical problem must be differentiated from spinal cord invasion or cauda equina syndrome, for which urgent diagnosis and treatment are mandatory. Clinical experience shows that brachial plexopathies respond better to medical therapy with opioids, tricyclic antidepressants, and anticonvulsants, whereas lumbosacral plexopathies may require early intervention with intrathecal opioid, bupivacaine, and clonidine therapy.

PAIN ASSOCIATED WITH CANCER TREATMENT

Oral mucositis typically occurs within 1 to 2 weeks of the initiation of chemotherapy. This condition is most common with the use of methotrexate, doxorubicin, daunorubicin, bleomycin, etoposide, 5-fluorouracil, and dactinomycin.59 Mucositis is often most severe when chemotherapy is combined with radiation treatments involving the head and neck region. Treatment may require hospitalization for IV PCA opioid therapy. Ambulatory care may necessitate transdermal opioids, local anesthetics, or doxepin swishes.

Painful polyneuropathy occurs most commonly with vincristine (motor and sensory involvement), vinblastine, paclitaxel, doctetaxel, a platinum derivative (predominantly sensory involvement), vinorelbine, and bortezomib.60 Symptoms commonly include burning dysesthetic pain in the hands and feet. The majority of these patients will respond to medical therapy with opioids, tricyclic antidepressants, and anticonvulsants. However, the small number of patients who do not achieve adequate pain control with this strategy will usually show a significant response to the use of spinal cord stimulation.

Postvascular chronic pain syndromes are most common after mastectomy, thoracotomy, radical neck dissection, nephrectomy, and amputation.61 The clinical characteristics generally include aching, shooting, or tingling pain in the distribution of peripheral nerves (e.g., intercostobrachial, intercostals, cervical plexus), with or without skin hypersensitivity. One study suggested that the incidence of
post-mastectomy pain was higher after conservative surgery than after modified radical mastectomy (33% vs. 17%). In this same study, 25% of patients experienced postoperative phantom breast pain. The exact incidence of postsurgical pain syndromes is unclear but appears to be in the 25% to 50% range by some estimates. Medical therapy with opioids, tricyclic antidepressants, and anticonvulsants is successful in the great majority of patients. Those who fail pharmacologic therapy will benefit from intrathecal therapy (post-thoracotomy, post-mastectomy syndromes), spinal cord stimulation (post-thoracotomy, post-mastectomy syndromes), or even peripheral subcutaneous nerve stimulation (post-radical neck dissection, post-thoracotomy syndromes).

Headache is present in 60% of patients with a primary or metastatic brain tumor, half of whom classify it as their primary complaint. It is typically steady, deep, dull, and aching with moderate intensity and is rarely rhythmic or throbbing. It is usually intermittent and may be worse in the morning and with coughing or straining. Symptoms often improve with radiation therapy, NSAIDs, or corticosteroids.

Cervicofacial pain syndromes are most common in patients with head and neck cancer. The head and neck are richly innervated by contributions from cranial nerves V, VII, IX, and X and the upper cervical nerves, so the pain varies in character. When cranial nerves are involved, the symptoms represent those of trigeminal, glossopharyngeal, or intermittent neuralgia, with sudden, severe lancinating pain radiating to the face, throat, or ear, respectively. The pain may be accompanied by dysesthesias, trigger points, and altered sensation to light touch. When cranial nerves are involved, the pain varies in character. When cranial nerves are involved, the symptoms represent those of trigeminal, glossopharyngeal, or intermittent neuralgia, with sudden, severe lancinating pain radiating to the face, throat, or ear, respectively.

The World Health Organization has developed a three-step ladder approach to the management of cancer pain that relies exclusively on the administration of oral agents and is usually effective. However, this approach lacks the mechanistic approach that may be more effective in decreasing the side effects of drugs that may not necessarily be effective against some types of pain, such as anticonvulsants as first-line agents for neuropathic pain syndromes. When more conservative therapies produce inadequate results, escalating doses or alternative therapies should be sought. The role of more invasive forms of analgesia, ranging from parenteral analgesics to neural blockade or neuro-modulation, should be considered judiciously.

Before initiation of therapy, assessment of problems and setting realistic goals that are acceptable to the patient should be established along with a treatment plan and contingencies.

**TREATMENT**

The goal of treatment of cancer pain is to relieve the pain by modifying its source, interrupting its transmission, or modulating its influence at brain or spinal cord sites. This can be achieved with single therapy or combinations of the following available modalities:

A. Antineoplastic treatment
B. Pharmacologic management
   1. NSAIDs
   2. Opioids
   3. Adjuvant analgesics
      a. Antidepressants
      b. Anticonvulsants
      c. Oral local anesthetics
      d. Corticosteroids
   e. NMDA antagonists
   f. α-2-adrenergic antagonists
   g. Topical analgesics
4. Interventional pain management
   a. Continuous parenteral infusion of opioids
   b. Neuraxial analgesia—epidural or intrathecal infusions
   c. Vertebroplasty or kyphoplasty
   d. Nerve blocks: local anesthetic nerve blocks and neurolytic nerve blocks
   e. Spinal cord stimulation, peripheral nerve stimulation, or peripheral subcutaneous nerve stimulation
5. Behavioral pain management
6. Other interventions such as aromatherapy, relaxation, and herbal medications
7. Home-based and hospice care

**ANTEOPLASTIC TREATMENT**

The most effective form of treatment of any cancer-related pain is treatment of the cancer itself, which in the majority of cases will reduce or eliminate the pain. Once diagnosed, the pathologic process responsible for pain can often be altered by surgical resection, external beam radiation therapy (targeted fractioned or single-dose therapy, hemibody or total-body irradiation), radionuclide (e.g., strontium 89, samarium) chemotherapy, hormonal treatment, and even whole-body or limb hyperthermia. The majority of patients require some form of primary analgesic therapy even when pursuing antitumor therapy.

**PHARMACOLOGIC MANAGEMENT**

Control of pain involves three basic principles: modifying the source of the pain, altering the central perception of pain, and blocking transmission of the pain to the central nervous system. In addition, any new pain in a patient with cancer is assumed to be progression or recurrence of disease until proved otherwise.

Oral analgesics are the mainstay of therapy for patients with cancer pain. An estimated 70% to 95% of patients can be rendered relatively free of pain when straightforward guideline-based principles are applied in a thorough, careful manner.

The World Health Organization has developed a three-step ladder approach to the management of cancer pain that relies exclusively on the administration of oral agents and is usually effective. However, this approach lacks the mechanistic approach that may be more effective in decreasing the side effects of drugs that may not necessarily be effective against some types of pain, such as anticonvulsants as first-line agents for neuropathic pain syndromes.
The noninvasive route should be maintained as long as possible for reasons that include simplicity, maintenance of independence and mobility, convenience, and cost. Treatment should be directed toward relief of pain and suffering, which includes consideration of all aspects of function (e.g., disturbances in sleep, appetite, mood, activity, posture, and sexuality), and attention should be paid not only to the physical but also to the emotional, psychological, and spiritual aspects of suffering.

For a specific description of the different agents that may be used for pharmacologic noninvasive therapy, please refer to Chapters 36 to 42.

INTERVENTIONAL PAIN MANAGEMENT

When a comprehensive trial of pharmacologic therapy fails to provide adequate analgesia or leads to unacceptable side effects, consideration should be given to alternative treatments.

CONTINUOUS SUBCUTANEOUS INFUSION OF OPIOIDS

This modality was frequently used in the past and proved to be effective. However, the advent of IV PCA therapy and long-term IV lines such as peripherally inserted indwelling central catheter (PIC) lines have made it somehow obsolete in this population of patients.

INTRAVENOUS INFUSION OF OPIOIDS WITH PATIENT-CONTROLLED ANALGESIA DEVICES

The most frequent indication for this form of therapy is severe pain and the need to rapidly titrate opioids in the hospital setting to achieve adequate pain control. Moreover, in the ambulatory setting, this modality is indicated for patients in whom the oral route is not available because of gastrointestinal obstruction, malabsorption, uncontrolled nausea and vomiting, or dysphagia or when the requirement for opioids is large because of tolerance. Some modifications in the implementation of this therapy have been used once the patient is no longer able to control the device. Thus, nurse- or family-controlled analgesia is an acceptable alternative in these circumstances. Consequently, patients will need to be treated in a controlled environment such as hospice or at home with the help and monitoring of family members. In such circumstances visiting nursing services will be required.

INTRASPINAL ANALGESIA

Neuraxial analgesia is achieved by the epidural or intrathecal administration of an opioid alone (very rarely) or in combination with other agents such as bupivacaine, clonidine, or ziconotide. With the use of neuraxial analgesia, pain relief is obtained in a highly selective fashion without motor, sensory, and sympathetic effects, thus making these modalities highly adaptable to the home care environment. At its inception, the principle of neuraxial opioid therapy was that introducing minute quantities of opioids in close proximity to their receptors (substantia gelatinosa of the spinal cord) achieves high local concentrations. Thus, neuraxial analgesia was potentially superior to that achieved when opioids were administered by other routes, and since the total amount of drug administered is reduced, side effects were minimized. Currently, the biggest advantage is the ability to use multiple agents to target neuropathic, somatic, and visceral components.

In general, patients with a survival expectancy of longer than 3 months are candidates for intrathecal therapy with a permanent intraspinal catheter and an implanted subcutaneous pump. Conversely, patients with a survival expectancy of less than 3 months will require epidural therapy with an implanted system (the Du Pen epidural catheter or the Sims epidural Port-a-Cath) connected to an external pump with PCA capabilities. Either way, patients will need a trial with an epidural catheter placed at the site where nociception is being processed in the spinal cord. At Roswell Park Cancer Institute, we conduct this trial on an outpatient basis, and if successful, we proceed to implant the permanent device. For this purpose, we suggest the following protocol:

Epidural Trial

- Catheter position: dermatomal specific under fluoroscopic guidance
  1. Opioids:
     - Morphine: 0.1 (60 mg) to 0.2 (120 mg) mg/mL
     - Hydromorphone: 0.03 (20 mg) to 0.12 (80 mg) mg/mL
  2. Bupivacaine: 1 to 2 mg/mL
  3. Clonidine: 3 to 5 µg/mL
  4. Total volume: 600 mL
- Determining epidural opioid doses:
  1. If the patient is receiving more than 300 µg/hr of fentanyl, 1200 mg/day of morphine sulfate (MS), 600 mg/day of oxycodone, or 160 mg/day of methadone:
     - Hydromorphone: 0.12 mg/mL
  2. If the patient is receiving between 100 and 300 µg/hr of fentanyl or equivalent dose:
     - Hydromorphone: 0.06 mg/mL
  3. If the patient is receiving less than 100 µg/hr of fentanyl or equivalent dose:
     - Hydromorphone: 0.03 mg/mL
- Basal infusion: 2 mL/hr
- No bolus during the first 72 hours, then 2 mL every 10 minutes
- The goal is to determine patient requirements
- Trial for 7 days as an outpatient

If the patient had a successful trial, defined as a reduction in pain of greater than 80%, we proceed to implant an intrathecal system if indicated by the survival expectancy. We suggest the following protocol to achieve a success rate higher than 80%:

- Conditions for success:
  1. Place the tip of the intrathecal catheter in the dermatome corresponding to the area of nociception
  2. For severe somatic pain, combinations of local anesthetics and an opioid will be needed
  3. For neuropathic pain:
     Place the tip of the catheter below L3-4: initial therapy with an opioid and clonidine
     Place the tip of the catheter above L1-2: initial therapy with an opioid and bupivacaine
The doses and drugs that we use in our practice are as follows:

<table>
<thead>
<tr>
<th>Drug</th>
<th>Range of Doses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Morphine</td>
<td>1.0-20 mg/day</td>
</tr>
<tr>
<td>Hydromorphone</td>
<td>0.5-25 mg/day</td>
</tr>
<tr>
<td>Sufentanil</td>
<td>10-100 µg/day</td>
</tr>
<tr>
<td>Bupivacaine</td>
<td>6-20 mg/day</td>
</tr>
<tr>
<td>Clonidinide</td>
<td>250-2000 µg/day</td>
</tr>
</tbody>
</table>

Thus, compounding by a trained pharmacist will be needed. The goal is to concentrate these drugs to twice the daily dose so that the pumps may be programmed to deliver 0.5 mL/hr. In this way, patients will need pump refills monthly, and it will not be a burden on their quality of life by having to come frequently to the pain specialist’s office. The steps that we use to implement the therapy are as follows:

1. **Step 1:**
   - Opioid plus bupivacaine:
     - MS, 3 to 25 mg/day, or hydromorphone, 0.5 to 15 mg/day (25 mg of MS per day = 4 mg of hydromorphone per day)
     - Bupivacaine: 6 to 20 mg/day
   - Opioid plus clonidinide:
     - Clonidine: 250 to 2000 µg/day
2. **Step 2:** Opioid plus bupivacaine plus clonidine
3. **Step 3:** At this point, ziconotide
4. If the patient’s insurance does not pay for hydromorphone, bupivacaine, or clonidine, the use of morphine plus ziconotide may be an alternative. However, limitations include the following:
   1. Trials are unpredictable because ziconotide may not be administered in the epidural space. Consequently, the patient will need to undergo a trial once the implanted system is in place
   2. Patients may not allow you to carry out a titration protocol over a 4- to 6-week period:
      - The starting dose is 2.4 µg/day with weekly increases of no more than 2.4 µg/day
      - Therapeutic effects are not usually seen until a dose of 10 µg/day is reached
5. **Other issues to consider when initiating ziconotide include the following:**
   3. Rinse the pump with 2 mL of the 25-µg/mL solution three times
   4. Start low and go slow:
      - Slower titration is tolerated better
      - Initiate therapy at a dose of 2.4 µg/day (0.1 µg/hr) and titrate to patient response
      - Titration increments should not be more than 2.4 µg/day and ideally should be implemented every week
      - Maximum recommended dose: 19.2 µg/day (0.8 µg/hr)

If triple therapy with an opioid, bupivacaine, and clonidine at optimal doses is not working, troubleshooting the system is a must. In doing so, consider the following:

1. **Catheter:** A myelogram will be needed to determine whether obstruction is present and the position of the tip of the catheter. When performing a myelogram through the diagnostic port of the pump, remember that this port accommodates only a 25-gauge Huber needle. Moreover, consider the following:
   1. The dead space of the catheter when injecting contrast medium
   2. The need for a bolus dose after the study is completed

In a recently published multicenter prospective randomized clinical trial by Staats and coauthors in which intrathecal therapy was compared with continued medical management, a slight trend toward better analgesia was noted in the intrathecal group (not statistically significant), but an improved side effect profile and increased survival were seen in the intrathecal group. There is also a report from the MD Anderson group in abstract form in which significant improvement in pain scores (NRS score of 7.6 to 4.8) and oral intake (morphine equivalent drug dose [MEDD] of 300 vs. 80) was documented following intrathecal opioid pump implantation.

The cost of implementing intrathecal therapy is initially high because of equipment acquisition cost. In contrast, the cost of implementing long-term epidural therapy is low. Two studies evaluated the cost of implementing therapy with these two modalities. These analyses show a “break-even” point at approximately 3 months. Thus, epidural therapy becomes very expensive after 3 months, which is one of the reasons to limit its use in patients with survival expectations of less than 3 months.

A consensus panel published current practice data on intrathecal medication management. A survey of 413 physicians managing 13,342 patients showed a variety of medications being used in the intrathecal pump, including morphine (48%); morphine and bupivacaine (12%); hydromorphone (8%); morphine and clonidine (8%); hydromorphone and clonidine (8%); morphine, clonidine, and bupivacaine (5%); morphine and bupivacaine (3%); and others (<3%). Other drugs mentioned included fentanyl, sufentanil, ziconotide, meperidine, methadone, ropivacaine, tetracaine, ketamine, midazolam, neostigmine, droperidol, and naloxone.

**NERVE BLOCKS**

**LOCAL ANESTHETIC NERVE BLOCKS**

Local anesthetic injections can be implemented for diagnostic or therapeutic purposes, or for both.

**Diagnostic blocks** help characterize the underlying mechanism of pain (nociceptive, neuropathic, sympathetically mediated) and discern the anatomic pathways involved in pain transmission. Their main indication is as a preliminary intervention conducted before a therapeutic nerve block or other definitive therapy. This helps the clinician determine the potential for subsequent neurolysis if indicated. Although the results often have good predictive value, they are not entirely reliable.

**Therapeutic injections of local anesthetics,** with or without a corticosteroid, into trigger points may provide lasting relief of myofascial pain. Epidural steroid–local anesthetic injections are unlikely to provide long-lasting relief for neuropathic pain of neoplastic origin. However, they will produce significant angesia in...
patients who may not tolerate rapid titration of antineuropathic medications.

Local anesthetic injections administered into sympathetic ganglia may contribute to lasting pain relief in patients with complex regional pain syndrome (CRPS) type 2, a condition frequently seen in cancer patients.93-95 This syndrome may arise as a result of tumor invading into nervous system structures (e.g., brachial or lumbosacral plexopathy), postsurgical pain syndromes, or chemotherapy-induced peripheral neuropathy. Local anesthetic blockade of the stellate ganglion or lumbar sympathetic chain has been used with some success to temporarily relieve pain in these patients.

NEUROLYTIC BLOCKS

Neurolytic blocks have played an important role in the management of intractable cancer pain. This modality should be offered when pain persists despite the implementation of aggressive comprehensive medical management or when drug therapy produces unwanted and uncontrollable side effects. Patient selection is essential, and some of the important variables to consider include (1) the severity of the pain, (2) pain that is expected to persist despite chemotherapy or radiotherapy, (3) pain that cannot be modified by less invasive or risky means, (4) a clinical picture that the pain is somatic or visceral in origin, and (5) a short life expectancy.

Alcohol and phenol are the two agents commonly used to produce chemical neurolysis. Ethyl alcohol is a pungent, colorless solution that readily can be injected through small-bore needles and is hypobaric with respect to CSF. For peripheral and subarachnoid blocks, alcohol is generally used undiluted (referred to as 100% alcohol, dehydrated alcohol, or absolute alcohol), whereas a 50% solution is used for celiac plexus blocks. The alcohol should not be exposed to ambient room temperature for a long period because absorbed moisture dilutes it. Alcohol injection is typically followed by intense burning pain and occasionally erythema along the targeted nerve distribution.

Phenol is fairly unstable at room temperature. Its shelf half-life is about 1 year when refrigerated and kept away from light. Phenol can be used in 3% to 15% concentrations with saline, water, and glycerol or radiologic contrast agents. It is relatively insoluble in water, and as a result, concentrations in excess of 6.7% will result in a suspension at room temperature without adding glycerin to increase its solubility in water. Phenol with glycerin is hyperbaric in CSF but is so dense that even when warmed, it is difficult to inject through needles smaller than 20 gauge. Phenol has a biphasic action: its initial local anesthetic action produces subjective warmth and numbness, which usually gives way to chronic denervation over a day’s time. The hypoalgesia after phenol is not as dense as after alcohol, and the quality and extent of analgesia may fade slightly within the first 24 hours of administration, particularly when used for epidural neurolysis.

The use of subarachnoid (intrathecal) injections of alcohol or phenol for the management of intractable cancer pain has significantly decreased in the United States since polypharmacy intrathecal analgesia was implemented. Because alcohol and phenol destroy nervous tissue indiscriminately, careful attention to selection of the injection site, volume and concentration of injectate, and selection and positioning of the patient are essential to avoid neurologic complications,98,99 a risk that is responsible for the decrease in its use. Most authorities agree that neither alcohol nor phenol offers a clear advantage except to the extent that variations in baric properties may facilitate positioning of the patient.100,101 With the exception of perineal pain treatment, alcohol is usually preferred for intrathecal neurolysis since most patients are unable to lie on their painful side, as required for intrathecal phenol neurolysis. In an analysis of 13 published series documenting treatment with intrathecal rhizolysis in more than 2500 patients, Swardlow reported that 58% of the patients obtained “good” relief, “fair” relief was observed in an additional 21%, and in 20% of patients “little or no relief” was noted.102 The average duration of relief is estimated to be 3 to 6 months, with a wide range of distribution. Reports of analgesia persisting 1 to 2 years are fairly common.102 In representative series using alcohol (n = 252) and phenol (n = 151), a total of 407 and 313 blocks were performed, respectively.103,104 In these two series, neither motor weakness nor fecal incontinence occurred, and of eight patients with transient urinary dysfunction, incontinence persisted in just one.

Subarachnoid neurolysis can be performed at any level up to the midcervical region, above which the risk for spread of drug to the medullary centers and the potential for cardiorespiratory collapse increase.105 A hyperbaric phenol saddle block is relatively simple to perform and is particularly suitable for many patients with a colostomy and urinary diversion.

Until recently, epidural neurolysis was performed infrequently. The results were inferior to those obtained with subarachnoid blockade, presumably because the dura acts as a barrier to diffusion, thereby resulting in limited contact between the drug and targeted nerves.102,106

PERIPHERAL AND CRANIAL NERVE BLOCKS

Peripheral nerve blockade has a limited role in the management of cancer pain.97 Blockade of the ganglion of Gasser, within the foramen ovale at the base of skull or its branches, may be beneficial for facial pain.107 However, the indications in patients with tumor-related pain are truly minimal because a neuropathic pain component is usually present. Thus, the risk for deafferentation pain is significantly increased with chemical neurolysis. Again, the use of intraspinal therapy by means of an implanted cervical epidural catheter or intraventricular opioid therapy has become a better option for these patients.108,109

VERTEBROPLASTY

Many cancer patients with metastatic vertebral compression fractures (VCFs) or osteoporotic VCFs have movement-related back pain. Percutaneous vertebroplasty (PV) is a minimally invasive procedure that involves injection of bone cement (usually polymethylmethacrylate [PMMA]) into the fractured vertebral body to alleviate the pain and hopefully enhance structural stability. This procedure is performed by placing needles under biplanar fluoroscopic guidance via a unipedicular or bipedicular approach. PMMA mixed with sterile barium is injected in a careful, controlled manner to avoid unintended spread of cement into the spinal canal or into veins within the affected vertebra. Injection is stopped as soon as cement starts approaching the posterior third of the vertebral body. Four studies evaluated the efficacy of PV in patients with vertebral fractures. Two of them found no differences between the treatment and placebo.
groups. The third study reported better pain relief on the first postoperative day, but no difference from placebo thereafter, and the fourth study reported significant pain control at 1 week and 1 month, but not at 3, 6, and 12 months. It therefore appears that PV is a questionable alternative for patients with vertebral fractures.

**SPINAL CORD STIMULATION**

This technique has been used successfully for refractory neuropathic chronic pain states in patients with chronic nononcologic pain. There is a lack of studies evaluating its use for cancer pain states. However, at Roswell Park Cancer Institute we have used it successfully in patients with CRPS type 2, such as those with postsurgical pain syndromes, chemotherapy-induced peripheral neuropathy, and postradiation nerve injury. Patient selection is very important in the cancer population because MRI at this point is contraindicated after this device is placed and medical oncologists rely on this study to monitor the progress of disease in these patients.

**NEUROSURGICAL PALLIATIVE TECHNIQUES**

Neurosurgical palliative techniques have fallen into less favor as more medications and reversible, titratable, lower-risk techniques have largely replaced these procedures. Pituitary ablation entails destruction of the gland by injecting a small quantity of alcohol through a needle positioned transnasally under light general anesthesia. This technique is effective in relieving pain originating from disseminated bony metastases, particularly those secondary to hormone-dependent tumors (breast and prostate). Commissural myelotomy has been reported to be efficacious in relieving cancer pain refractory to more conservative therapy. Percutaneous cordotomy produces a thermal lesion within the substance of the spinal cord and reliably relieves unilateral truncal and lower limb pain. As with pituitary ablation, a high degree of skill and expertise is necessary, but the pain relief is often profound and the rigors of a major neurosurgical procedure are avoided.

**BEHAVIORAL INTERVENTIONS**

Several behavioral pain management techniques have been used in patients with cancer, including hypnosis, relaxation, biofeedback, sensory alteration, guided imagery, and cognitive strategies. Relaxation and imagery training significantly reduce VAS scores in patients in whom mucositis develops after bone marrow transplantation. This training is probably most effective for patients who have no significant psychological or psychiatric problems and for insightful psychology-minded patients.

**HOME-BASED AND HOSPICE CARE**

For years, hospice has been regarded as a place where people go to die, but in its purest form, it is a philosophy of care that is “a blend of clinical pharmacology and applied compassionate psychologic care.” In the United States, hospice care has been developed primarily as a home-based service, with a minority of institutions offering short inpatient stays to stabilize refractory symptoms and provide respite for overwhelmed families.

The principles of home-based pain management are in most respects similar to those that apply to ambulatory and inpatient pain management. Differences generally relate to the recognition that further curative therapy is futile rather than that care is being provided at home. No compromise in quality of care based on where it is delivered is justified.

Hospice care is comfort oriented and focuses specifically on alleviating symptoms rather than necessarily treating their underlying cause. Factors that influence the selection of home treatment are advanced incurable disease, realization and acceptance of the appropriateness of palliative care (care directed at preserving comfort and quality of life rather than curing the tumor and extending life), and a desire to die in familiar surroundings. Many difficulties associated with providing intensive palliative care at home can be reconciled by education and orientation of the family, and such care can be performed in coordination with health care institutions, home care nursing, and laboratory and pharmacy services.

**SUMMARY**

Acute and chronic pain is highly prevalent in cancer patients. Inadequate assessment and treatment of pain and other distressing symptoms may interfere with antitumor therapy and markedly detract from quality of life. Even though a strong focus on control of pain is important independent of disease stage, it is a special priority in patients with advanced disease who are no longer candidates for potentially curative therapy.

Through rarely eliminated, pain can be controlled in the vast majority of patients with the implementation of an aggressive comprehensive medical management strategy. In the small but significant proportion of patients whose pain is not readily controlled with noninvasive analgesics, a variety of alternative invasive and noninvasive measures, when selected carefully, are also associated with a high degree of success. To this end, it is very reassuring to conclude that at this point we have the appropriate tools to adequately treat cancer-related pain in close to 100% of patients.

**KEY POINTS**

- Uncontrolled acute or chronic pain still affects 40% to 45% of patients afflicted with cancer. Despite the availability of a multitude of simple cost-effective pain treatments, inadequately controlled pain remains a significant problem in cancer patients.
- Cancer-related pain is mostly due to invasion of organic structures by the tumor (directly or by metastasis), is related to cancer treatment (surgery, chemotherapy, radiation therapy), or in a small minority, is due to chronic pain syndromes.
- Various standardized questionnaires can be used in pain clinics to assess pain intensity. Furthermore, a comprehensive patient assessment can be done by performing a thorough history and complete physical examination, along with subsequent analysis of diagnostic studies, which will lead to an appropriate diagnosis in virtually all patients.
CHAPTER 23 — CANCER PAIN

SUGGESTED READINGS

KEY POINTS—cont’d

• Cancer pain can be classified on the basis of various pain parameters, such as time, intensity, pathophysiology of the pain, and temporal aspect of the pain or by the evolution of various cancer pain syndromes.

• Cancer pain can be adequately controlled in the majority of patients (≈95%) with aggressive pharmacologic treatment, with only a minority requiring invasive therapy. Treatment of cancer pain should be directed toward relief of pain and suffering and improvement in function and the psychological aspects of cancer diagnosis and pain.

• Oral and transdermal opioid analgesics are the mainstay of therapy for pain in cancer patients. Other adjuvant analgesics can be added to oral opioids for adequate control of pain if neuropathic pain is present. When oral pharmacotherapy fails, alternative modalities can be considered, including subcutaneous opioid infusion, intravenous patient-controlled analgesia with opioids, neuraxial opioids, and invasive procedures such as intrathecal pump implantation, peripheral nerve radiofrequency lesions, and neurolytic procedures.

• Patients with a survival expectancy of longer than 3 months are generally considered candidates for intrathecal therapy with a permanent intraspinal catheter and an implanted subcutaneous pump. Patients with a survival expectancy of less than 3 months will require epidural therapy with an implanted system. Before either neuraxial procedure, an epidural catheter trial is conducted to assess the need for implantation of the permanent device.

• Behavioral therapy has an important role in the treatment of pain. In patients with advanced or incurable disease, palliative therapy for control of pain and preservation of quality of life with home-based and hospice care can be undertaken.

• Overall, with judicious use of the various modalities available, including noninvasive oral and intravenous pharmacologic therapy combined with invasive therapy when needed, control of cancer pain is possible in the vast majority of patients.

INTRODUCTION

Neuropathic pain comprises a wide range of heterogeneous conditions. Various types of neuropathic pain may have distinct pathophysiologic causes and different clinical signs and symptoms. Despite the diversity of conditions classified as “neuropathic pain,” many potentially share common underlying mechanisms of nociception, including neuronal hyperexcitability, but others may not. This may in part explain why certain analgesic agents are relatively effective for a wide range of neuropathic pain states but why notable exceptions exist that appear to be resistant to conventional “neuropathic” pain therapy. A group has been assembled to address the inconclusive research on “neuropathic” pain and to operationalize and specify definitions and criteria for conditions that are to be referred to as neuropathic pain (Box 24.1). This work should lead to a more reductionist approach to the study of neuropathic pain and to effective therapies for specific disease processes.

In this chapter we focus on some of the more common states of “neuropathic” pain as defined by the sensitive but nonspecific definition of the International Association for the Study of Pain (IASP). These conditions include complex regional pain syndrome (CRPS), post-herpetic neuralgia (PHN), painful diabetic peripheral neuropathy (DPN), and human immunodeficiency virus (HIV) painful sensory neuropathy.

COMPLEX REGIONAL PAIN SYNDROME

The term complex regional pain syndrome, which denotes both types 1 and 2, originated from a history of different names appointed by individuals who made particular observations. In 1864 Silas Weir Mitchell made an important observation of Civil War soldiers when he noticed that they suffered from burning pain and muscle atrophy at the sites of their injuries. He called this “causalgia,” which is derived from the Greek words kausis (burning) and algos (pain). In 1900 at a lecture in Germany, Paul Sudeck stated that this syndrome could not only extend from the initial insult but also had an inflammatory component. The name Sudeck’s dystrophy was applied in his honor. Half a century passed before the discovery that invasive procedures that block the sympathetic nervous system provide further relief of pain symptoms. Because of the success of these methods, Evans renamed the syndrome “reflex sympathetic dystrophy.” Over the years cases arose in which patients lacked a trophic component, sympathetic involvement was absent, or there was no evidence of reflex involvement. These exceptions led to a meeting in 1993 by the IASP at which the term “complex regional pain syndrome” was formulated and subsequently published the following year. The most commonly used clinical diagnostic criteria for CRPS types 1 and 2 are low in specificity but high in sensitivity, which has led to overdiagnosis of the pain syndrome. This in turn has made it difficult to obtain accurate epidemiologic data for CRPS or to perform rigorous studies of the pathologic state. In 2007, research criteria (also known as the Budapest criteria) were published that included objective signs of pathology characteristic of patients with CRPS (Box 24.2). These criteria had good specificity and sensitivity. Although they were initially intended for research use, many physicians prefer them to the less stringent original criteria.

PATHOPHYSIOLOGY

There are two types of CRPS, known as type 1 and type 2 (Box 24.3). They differ in that type 2 has evident nerve injury whereas type 1 assumes an injury to the nerve or nerves. A consistent finding in both types of CRPS is the discrepancy between the severity of the symptoms and the severity of the inciting injury. In addition, symptoms have the propensity to spread in the affected limb in a pattern not restricted to the specific nerve’s area of innervation. CRPS is characterized by intense burning pain with resultant hyperalgesia or allodynia. It may be associated with local edema and autonomic involvement, such as changes in skin color and sweating and increased or decreased skin temperature in the affected area. There may also be trophic changes in the skin, hair, and nails in the affected site (see Box 24.3). Although many questions concerning the pathophysiology...
of this syndrome are still unanswered, three main principles remain at the core of CRPS: abnormalities in both somatosensory and sensory pathways as well as sympathetic nervous system involvement.

SOMATOSENSORY ABNORMALITIES

Inciting injury to either the upper or lower extremity is an important trigger of CRPS. Studies have shown that changes in cutaneous innervation of the injured extremities take place even when no nerve injury is found. In one recent study, skin biopsy samples were obtained from the affected limbs of patients with CRPS type 1. A lower density of C and A fibers was found in the affected limbs than in the unaffected limbs, which led to sensory deficits in the affected limbs.5 Brain plasticity is another important factor found to be associated with somatosensory abnormalities. Data suggest that patients with CRPS have decreased activity in the somatosensory cortex of the affected side.6 These patients also tend to have tactile mislocation because of somatotopic reorganization, which was found to be directly correlated with hyperalgesia.7 Changes occurring within the primary somatosensory (SI) cortex are dependent on pain and have been shown to be reversible after recovery from the pain.8

SENSORY PATHWAYS (CENTRAL NERVOUS SYSTEM SENSITIZATION, PERIPHERAL SENSITIZATION, INFLAMMATION)

Central sensitization occurs when pain perception increases because of constant firing of painful stimuli to the central nervous system. Neuropeptides such as substance P and bradykinin are released in response to nociceptive stimuli and activate N-methyl-D-aspartate (NMDA) receptors, which together lead to hyperalgesia and allodynia.9 Peripheral sensitization is the counterpart of central sensitization. When a nerve injury occurs, multiple proinflammatory factors such as glial cell activation, substance P, bradykinin, tumor necrosis factor-α, interleukin-1β, prostaglandin E2, and nerve growth factor are activated, which results in increased

---

**Box 24.2 Difference between the IASP Criteria and the Budapest Criteria for the Diagnosis of CRPS**

**IASP Criteria for the Diagnosis of CRPS***
1. Presence of an initiating noxious event or reason for immobilization
2. Disproportional pain, allodynia, or hyperalgesia from a known inciting event
3. Sign or symptom of any evidence showing edema, skin changes, blood flow, or abnormal sudomotor activity in the region of the pain
4. No other condition that would otherwise explain the degree of pain or dysfunction

**Budapest Criteria for Diagnosis of CRPS***
1. Presence of continued disproportional pain from the known inciting event
2. Must report at least one symptom in three of the following four categories:
   - Sensory: hyperesthesia, allodynia
   - Vasomotor: temperature asymmetry, changes in skin color
   - Sudomotor/edema: edema, changes in sweating, sweating asymmetry
   - Motor/trophic: decreased range of motion, motor dysfunction (tremor, weakness, dystonia), trophic changes (hair, nail, skin)
3. Must report at least one sign in two or more of the following categories at the time of evaluation:
   - Sensory: hyperalgesia to pinprick, allodynia to touch or joint movement
   - Vasomotor: temperature asymmetry, color asymmetry
   - Sudomotor/edema: edema, asymmetrical sweating, sweating changes
   - Motor/trophic: decreased range of motion, motor dysfunction, trophic changes
4. No other condition that would otherwise explain the degree of pain or dysfunction

*If seen without any major nerve damage, the diagnosis is CRPS type 1; if seen with evidence of nerve damage, the diagnosis is CRPS type 2.

CRPS, complex regional pain syndrome; IASP, International Association for the Study of Pain

**Box 24.3 Difference between CRPS Type 1 and Type 2**

**CRPS Type 1 (Reflex Sympathetic Dystrophy)**
1. The presence of an initiating noxious event or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of the pain
4. This diagnosis is excluded by conditions that would otherwise account for the degree of pain and dysfunction

**CRPS Type 2 (Causalgia)**
1. The presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve
2. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of the pain
3. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction

*Criteria 2 to 4 must be satisfied.
†All three criteria must be satisfied.

CRPS, complex regional pain syndrome.
nociceptive sensitivity and a decreased threshold for firing of nociceptive stimuli. Together, central and peripheral sensitization results in the allodynia and hyperesthesia seen in patients with CRPS. There are other important factors in the inflammatory pathway, such as the role of nuclear factor NFκB upstream in the proinflammatory pathway observed in animal studies.

**ALTERED SYMPATHIC NERVOUS SYSTEM FUNCTION**

Involvement of the sympathetic nervous system is thought to be responsible for the limbs in patients with CRPS becoming cool, blue, and painful secondary to vasoconstriction as a result of excessive outflow from the sympathetic nervous system. In an animal study, rats with chronic posts ischemic pain that had norepinephrine injected into their hind paws experienced increased nociceptive firing, thus supporting the notion that pain can be sympathetically maintained. However, this provides little evidence in support of sympathetic maintenance of CRPS pain. Coupling of sympathetic neurons may occur not only to nociceptive afferents but also to non-nociceptive mechanosensitive or cold-sensitive neurons. Sympathetic afferent coupling, considered the cause of sympathetically maintained pain, occurs in cutaneous and deep somatic tissues, but during the acute event of CRPS, the deep somatic tissues are of greater importance. Although coupling occurs in some patients with CRPS, a subset of patients with clinically identical CRPS have sympathetically independent pain. These patients exhibit little to no response to sympathetic blockade either pharmacologically with phentolamine or via interventional blockade of the sympathetic ganglia.

**EPIDEMIOLOGY**

Multiple studies of CRPS type 1 have shown that the male-to-female ratio ranges between 1:2 and 1:4, thus suggesting that females are at higher risk for development of the syndrome. However, the male-to-female ratio for most other pain syndromes is similar. A retrospective, cross-sectional analysis study showed that the male-to-female ratio was 1:4 and that the most common initiating events were bone fractures, sprains, and trauma. Outcomes of the disease tended to be worse in patients with upper extremity injuries than in those with lower extremity injuries, injuries other than fractures, and “cold” (commonly chronic) CRPS rather than “warm” (acute) CRPS. Other risk factors that contribute to the development of CRPS are age, workplace, and type of injury. The average age of patients ranges between 16 and 79 (median range, 41.6), with a higher incidence in the older population. Patients with motor nerve damage were found to be at higher risk for CRPS than those with sensory nerve damage. Fracture has been reported to be the most common initiating injury. The incidence of job-related injuries leading to CRPS was as high as 76%, which may indicate a psychosocial or secondary gain component in reporting of this pain. Studies report that CRPS develops in patients with a family history of CRPS at a higher incidence and younger age, thus suggesting that CRPS may have a genetic component. Another study showed that siblings of patients in whom CRPS developed before 50 years of age had a threefold increased risk for development of the syndrome. Psychological factors such as depression, personality disorders, and anxiety have no correlation with CRPS patients, which suggests that there is no specific type of CRPS personality.

**CLINICAL FEATURES**

The pain must be greater in proportion to the inciting event. There must be at least one symptom in three of the following four categories: sensory (hyperesthesia/allodynia), vasomotor (changes in temperature or sweating in the affected limb in comparison to the normal limb), sudomotor/edema, and motor/trophic (demonstration of weakness, decreased range of motion, or trophic changes in hair, nails, or skin). At least one sign must be present at the time of evaluation in two or more of the following four categories: sensory, vasomotor, sudomotor/edema, and motor/trophic. There must be no other diagnosis that better explains the patient’s signs and symptoms. This is different from the criteria proposed in 1993 by the IASP (see Box 24.3). A recent study in which the validity of CRPS was evaluated by comparing the Budapest criteria in patients with CRPS and in those with neuropathy showed that the IASP criteria had a sensitivity of 1.0 and a specificity of 0.99 and the Budapest criteria had a clinical sensitivity of 0.96 and a specificity of 0.68. The newly revised criteria are also divided into clinical and research. The research criteria contain more inclusions, which allows a specificity of 0.96.

The current IASP taxonomy also divides CRPS into CRPS 1 (formerly known as reflex sympathetic dystrophy) and CRPS 2 (formerly known as causalgia). The distinction between CRPS 1 and 2 is the presence of a definable nerve lesion in patients with CRPS 2. The signs and symptoms for both conditions are clinically indistinguishable and include sensory changes (allodynia, hyperalgesia, and hypoalgesia), edema, temperature abnormalities, and changes in sweating (see Box 24.3). Pain is the principal feature in both CRPS 1 and CRPS 2. In patients with CRPS the associated clinical signs are typically out of proportion to the inciting injury. Patients describe a burning, deep-seated ache that may be shooting in nature along with associated allodynia or hyperalgesia. Pain occurs in 81.1% of patients meeting the CRPS criteria. Patients also frequently complain of sensory abnormalities such as hyperesthesia in response to the typical mechanical stimuli encountered in day-to-day activities (such as dressing) involving the affected limb.

In CRPS 2 (i.e., CRPS with associated major nerve injury), patients often report hyperesthesia around the injured nerve in addition to electric shock-like sensations, shooting pain, and allodynia. Symptoms indicative of vasomotor autonomic abnormalities (including color changes) occurred in 86.9% of patients; temperature instability occurred in 78.7%. Sudomotor symptoms of hyperhidrosis and hypohidrosis were reported in 52.9%. Trophic changes in skin, nail, or hair pattern were reported in 24.4%, 21.1%, and 18%, respectively. Edema was reported in 79.7%, with decreased range of motion in 80.3% and motor weakness in 74.6%.

**DIAGNOSIS**

There is currently no “gold standard” test for the diagnosis of CRPS. A very thorough history and physical examination are essential for evaluation and diagnosis. Patients with this condition will have the signs and symptoms mentioned previously. Physical examination must be performed to establish the sensory, motor, trophic, sudomotor/edema, and autonomic...
changes. Sensory changes such as allosthenia may be evaluated by light touch and the application of warm/cold temperature to the affected area. Autonomic dysfunction may be confirmed by the presence of asymmetry in temperature and color. Trophic changes may be manifested as changes in skin, nails, and hair in the affected limb. Motor activity may be evaluated by examining motor strength and range of motion. Sudomotor and edema changes may be assessed by dragging a smooth object over the affected and unaffected limb, with the wetter limb allowing a smoother drag than the drier limb. Common diagnostic tools used for diagnosis of CRPS include quantitative sensory testing, tests of autonomic function, and imaging for trophic changes.

QUANTITATIVE SENSORY TESTING
Such testing includes the use of standardized psychophysical tests of the sensory and motor systems, thermal sensation, thermal pain, and vibratory thresholds to assess the function of large-fiber, myelinated small-fiber, and unmyelinated small-fiber afferents. Patients with CRPS may have impaired paradoxical heat sensations, mechanical detection thresholds, mechanical pain thresholds to pinprick stimuli and blunt pressure, allodynia, and pain summation with the use of continuous pinprick stimuli. There is currently no definitive diagnostic sensory pattern in patients with CRPS, but this test can aid in distinguishing other neuropathies from CRPS.

TESTS OF AUTONOMIC FUNCTION
Thermoregulation and sudomotor regulation are the main systems tested in patients with CRPS for disorders in autonomic function. Thermoregulation is tested by using the thermoregulatory sweat test (TST) and infrared thermography or thermometry. The TST assesses calorimetric precipitation from a specific region of the body by adding a solution that changes color when enough heat is generated to produce sweat. Infrared thermography is direct visualization of the change in temperature of the affected site, and in infrared thermometry, a device is used to measure temperature through detection of infrared energy. Changes in temperature in patients with CRPS versus those with other types of pain had a sensitivity of 76% and a specificity of 94%. Sudomotor regulation is tested by using the quantitative sudomotor axon reflex test (QSART), which measures sweat output from various regions of the skin.

TROPHIC CHANGES
Three-phase bone scintigraphy (TPBS) is a very valuable test for detection of CRPS. Although joint and bone alterations are not part of the IASP inclusion criteria, they are very important in the outcome of the syndrome. TPBS detects alterations in periarticular bone metabolism, particularly increased bone metabolism, by detecting increase uptake of a periarticular tracer, which occurs predominantly within the first year. TPBS is low in sensitivity but high in specificity. Magnetic resonance imaging of the affected limb has also been used for detection of CRPS but has high sensitivity (97%) and low specificity (17%).

TREATMENT
Management of CRPS has been complicated by scant knowledge of the etiology of the disease, which has resulted in few targeted therapies. Most of the medications initiated as first-line therapy have been investigated for other non-CRPS neuropathic pain conditions and then applied to the treatment of CRPS, with mixed success. The historical approach to therapy for CRPS still remains a multimodal, multidisciplinary methodology. The predominant therapeutic modalities for the care of CRPS patients include physical therapy, pharmacologic agents, and interventional procedures.

PHYSICAL AND OCCUPATIONAL THERAPY
Physical and occupational therapy for restoration of function and improvement of limbs affected by CRPS has been studied widely. Physical exercises such as isometric strengthening, active range of motion, myofascial release, and stress loading are all tools that aid in restoring functional capacity of the affected limb. Other methods of therapy are currently under study. In a large controlled study in which tactile acuity and pain on application of a tactile stimulus were measured in patients with CRPS and mirror images were used to show the reflection of the unaffected limb during the stimulus, a decreased two-point discrimination threshold and decreased pain acuity were observed. This suggests that therapies that improve functional restoration of the affected limb may improve the outcome of CRPS.

PHARMACOLOGIC THERAPY
Membrane Stabilizers
Medications such as gabapentin and pregabalin have been shown to be effective in relieving neuropathic pain. CRPS is considered neuropathic pain and gabapentin is presumed to be effective in treating it, yet there are very limited studies showing its specific efficacy for CRPS. In a randomized double-blind, placebo-controlled crossover study in which patients were treated for two 3-week periods with 2 weeks in between, gabapentin had minimal effect on pain acuity were observed. This suggests that therapies that improve functional restoration of the affected limb may improve the outcome of CRPS.

Corticosteroids
A large part of the pathophysiology in CRPS is the acute inflammatory process that occurs after an initiating event (see “Pathophysiology”). Because of this inflammatory course, corticosteroids have been used for treatment. In a recent randomized controlled trial comparing prednisolone with piroxicam, patients were given either medication for 1 month, and their shoulder-hand syndrome scores (measuring pain, distal edema, passive humeral abduction, and external rotation) were determined. In the prednisolone group, 83.3% showed improvement, and in the piroxicam group, only 16.7% improved. The shoulder-hand syndrome score in the steroid group was significantly lower than that in the piroxicam group.

Antidepressants
These drugs have not been studied for use specifically with CRPS, but they have been widely studied for the control of neuropathic pain, and because CRPS is considered neuropathic pain, they are used in pain management.
Antidepressants such as tricyclic antidepressants (TCAs) and selective serotonin-norepinephrine reuptake inhibitors (SSNRIs) have been used to control neuropathic pain effectively. In a recent Cochrane review, TCAs were found to be effective in treating neuropathy, with a number needed to treat (NNT) of 3.6 and a relative risk (RR) of 2.1. Venlafaxine, an SSNRI, was also found to be effective, with an NNT of 3.1 and RR of 2.2. Further studies to investigate the drugs’ ability to specifically target CRPS are warranted. A recent study showed that the combination of gabapentin and nortriptyline was a more effective therapy than either medication alone for neuropathic pain (including CRPS).

Opioids
Studies on the effects of opioids directly on CRPS are lacking, although some have shown opioids to improve neuropathic pain when used in high doses. However, a double-blind, placebo-controlled trial studying the efficacy of sustained-release morphine in CRPS patients for a total treatment of 8 days showed that it was ineffective in decreasing pain, but the study had many limitations. Substantial challenges to using opioid therapy for nonmalignant pain include nausea, constipation, cognitive impairment, tolerance, and hyperalgesia, and therefore it should be used only until other therapies can be initiated. Studies of these medications in the CRPS population are lacking, and more are needed to demonstrate the efficacy of opioids.

Ketamine
Ketamine is an NMDA receptor antagonist. The NMDA receptor is a major part of the central sensitization that occurs in patients with CRPS (see “Pathophysiology”). Ketamine can be administered topically, orally, intranasally, or parentally in subanesthetic (analgetic) doses or in high doses to produce ketamine coma. A double-blind, randomized, placebo-controlled, parallel-group trial studying the effects of subanesthetic intravenous dosing of ketamine for 4 days in CRPS patients showed decreased levels of pain, but the pain progressively increased from the 1st week after infusion to the 12th week. In patients undergoing ketamine infusion, minor and rare side effects such as nausea, vomiting, and psychomimetic effects developed. In another nonrandomized open-label trial in which chronic CRPS patients refractory to standard therapies were treated with anesthetic doses of ketamine for 5 days, the pain improved significantly for 6 months, but 79.5% relapsed back to baseline after the 6-month period. The topical form of ketamine has also been shown to decrease allodynia and hyperalgesia in response to pinprick stimuli, but this has not been well validated.

Bisphosphonates
Bone resorption at the site of inflammation in the affected limb contributes to the pain in CRPS. The use of bisphosphonates to decrease osteoclast overactivity has shown promise in its pain-reducing effects. In an 8-week randomized, double-blind, placebo-controlled study, alendronate was used in patients with post-traumatic CRPS type 1. This drug improved spontaneous pain, tolerance to pressure, and extremity range of motion. However, other trials have shown no reduction in CRPS-related pain.

## INTERVENTIONAL TREATMENT

### Sympathetic Nerve Block

The most common sympathetic nerve blocks are the stellate ganglion and lumbar sympathetic blocks for treatment of CRPS of the upper and lower extremities, respectively. Multiple modalities have been studied for their ability to disrupt the sympathetic pathway through these nerve plexuses, including local anesthetics, chemical neurolysis, and radiofrequency ablation. In a study in which both stellate ganglion and lumbar sympathetic blocks were performed with local anesthetic and normal saline on each subject, it was observed that the decreased pain that each experienced was almost identical, but the duration of decreased pain was longer when patients received the local anesthetic block. In a small randomized study in which radiofrequency neurolysis was compared with chemical neurolysis, the pain decreased from baseline, but no significant difference was seen between the two methods. Although sympathetic blocks provide a significant reduction in pain by blocking the sympathetic pathway of the pathophysiologic stages in CRPS, their greatest limitation is that they provide only short-term relief in the vast majority of treated patients. This means that patients must continue to frequently undergo sympathetic blocks, which most often places them on maintenance therapy. This form of therapy should be performed to provide enough pain relief so that patients are able to perform physical therapy exercises for functional restoration and multidisciplinary therapy, but not as a sole therapeutic modality.

### Spinal Cord Stimulation

A spinal cord stimulator is a generator containing leads that are placed in the dorsal aspect of the spinal cord within the level that innervates the area causing pain. Most patients have been managed with standard medical therapy and some treated surgically before undergoing spinal cord stimulation (SCS). In a randomized trial, patients with CRPS were separated into two groups: SCS with physical therapy and physical therapy only. This study showed that SCS provided significant improvement in pain for the first 2 years. Unfortunately, there was no amelioration in quality of life or functionality in the group undergoing SCS with physical therapy, although this study was seriously flawed because of excessive patient dropout. SCS has been used widely for the control of intractable pain, but further research is needed to verify its impact on CRPS.

### Intrathecal Treatments

Baclofen and ziconotide administered intrathecially have been examined for the treatment of CRPS. Baclofen is a γ-aminobutyric acid receptor agonist. It is currently used as a muscle relaxant and has been indicated for muscle spasticity and dystonia. A single-blind, placebo run-in, dose escalation study of CRPS patients with dystonia showed that intrathecal baclofen was very effective in decreasing dystonia and pain, as well as in improving quality of life, as indicated in a 12-month follow-up. Ziconotide is a very potent drug made from the toxin of sea snail venom and works by blocking chemicals that transmit pain signals. Intrathecal administration of this drug has great potential in reducing edema, trophic changes, and pain in these patients. However, it is associated with a nearly 100% side effect profile.
PHN is neuropathic pain that arises from herpes zoster (HZ—shingles) in a dermatome distribution. This form of pain is very debilitating and leads to poor quality of life and poor functional status at home and in society. Control of pain is difficult, with multiple interventions being required. There are multiple risk factors for the development of HZ and subsequent PHN. It is essential to understand the risk factors, pathophysiology, and diagnostic approach to PHN to delve into the various pharmacologic and interventional treatments available.

EPIEDEMILOGICAL RISK FACTORS

Varicella is a viral infection that may lead to varicella zoster (chicken pox) on first exposure and subsequently remains in a latent phase for the majority of lifetimes. HZ develops secondary to reactivation of varicella virus from its latent state. Varicella virus is kept in a latent state by the body's cell-mediated immunity. When there is a decrease in cell-mediated immunity, the risk for reactivation and subsequent HZ increases. Cell-mediated immunity may decrease with age, HIV infection, cancer, and immunosuppressive therapy as used for transplant patients. The incidence of HZ in the United States is approximately 500,000 cases per year, or approximately 2 cases per 1000 persons. The lifetime risk for the development of HZ is 10% to 20%, but this number increases with age. Patients older than 75 years have an incidence of 10 cases per 1000 persons per year. In patients older than 85 years, 50% would have had at least one episode of HZ. PHN pain that persists after the acute phase of the disease is seen in approximately 10% to 20% of patients infected with HZ. The incidence of PHN developing from HZ also increases with age. Patients older than 70 years with HZ have a 50% risk for the development of PHN, whereas it rarely develops in patients younger than 40 years. There are many risk factors for the development of PHN, and among them are increased age, greater severity of the rash during the acute phase, female gender, and greater acute pain severity. In an epidemiologic study of patients with PHN in the Ferrara University Dermatology Unit, Italy, from the years 2000 to 2008, males had an earlier age at onset than females did, and 72% of the patients were older than 45 years. The sites most commonly observed to have been affected were ophthalmic in 32%, thoracic in 16.5%, and facial in 16%. The correlation of PHN developing after the first episode of HZ was reviewed in a prospective study in which patients were monitored for 12 months. It was concluded that 3 months after appearance of the HZ rash, the risk for development of PHN was 1.8%. In patients older than 60 years, the risk for development of PHN and the severity of the pain were higher.

In recent years, administration of varicella vaccine has become very popular. However, some data suggest that these vaccines may lead to an increase in the incidence of HZ secondary to a reduced opportunity for subclinical boosting, which results in an extreme reduction in the incidence of varicella from the immunizations. In contrast, administration of zoster vaccine has been proven to decrease the incidence of HZ and PHN. In a randomized, double-blind, placebo-controlled trial of the zoster vaccine, the incidence of PHN decreased by 66.5% (P < 0.001) and the incidence of HZ decreased by 51.3% (P < 0.001). The zoster vaccine has shown great promise in preventing HZ and PHN in patients older than 60 years.

PATHOPHYSIOLOGY

Varicella zoster is the primary infection that leads to chicken pox. After the primary infection, the virus remains dormant within one of the sensory nerve ganglia, the most common of which are the trigeminal and thoracic ganglia; these are also the sites where most of the cutaneous dermatomes are involved. The cell-mediated immune system keeps the virus dormant in the latent phase. Progression from the latent phase to reactivation of the virus leads to the development of HZ and subsequently PHN in some patients. During the reactivation phase of varicella-zoster virus (VZV), destruction of neurons and satellite cells occurs because this is the site of replication for the virus. VZV traveling along the affected sensory nerves leads to evasion of the host immune system and spreads from cell to cell until its characteristic unilateral dermatome rash is produced. Spread of the virus and its destruction of neurons occurs before development of the rash. Studies in postmortem patients have led to the conclusion that reactivation and replication of VZV result in inflammatory changes within the sensory neurons that it disturbs, which causes pain. This mechanism may help explain the findings of loss of cells, myelin, and axons, fibrosis of the affected ganglion, and atrophy of the dorsal horn in postmortem patients.

The previously mentioned mechanism contributes to the two primary pathophysiologic mechanisms of PHN pain: sensitization (hyperexcitability) and deafferentation. These mechanisms describe not only peripheral nerve pain but also central nerve pain. Following nerve injury, nociceptive receptors in the peripheral and central nervous systems become sensitized, which means that the threshold for firing of action potentials after a certain stimulus is lowered. This causes the nerve to become hyperexcitable and leads to alldynia without sensory loss. Deafferentation pain arises from the neuronal destruction and loss of afferent neurons that occur after the virus reactivates and subsequently produces the inflammatory response within the affected nerve. The loss of afferent neurons leads to spontaneous activity centrally, which results in pain in areas where there is sensory loss. Neural sprouting is initiated in an attempt to reconnect the former C-fiber receptors, a process that leads to hyperalgesia with allodynia. The sympathetic nervous system is also thought to play a role in PHN by stimulating a vasoconstrictive response during the inflammatory process that results in decreased intraneural blood flow, hypoxia, and endoneural edema.

DIAGNOSIS

Post-herpetic neuropathy is principally a clinical diagnosis. The typical clinical scenario involves a patient complaining of persistent pain that is within a certain dermatome and affects the region that the dermatome innervates in a unilateral fashion. The acute phase of HZ is characterized as a maculopapular vesicular rash that crusts over after 1 to 2 weeks and results in a burning sensation, hyperesthesia, itching, and severe pain. Prodromal symptoms that may occur 1 to 5 days before the rash include headache, fever, malaise, abnormal skin sensation, and photophobia.
PHN may occur 2 weeks after the presence of HZ and is the chronic form of the disease. This is a very debilitating pain that consists of burning, dysesthesia, pruritus, and allodynia or paresthesia of the affected dermatomal region. The pain usually decreases or resolves within 6 months after exposure, but in some cases it may last years.70

**TREATMENT**

Therapy for HZ can be separated into the acute phase (shingles) and the chronic phase (PHN). In the acute phase of the disease process, the first-line medications that have proved to significantly decrease the length of disease are antiviral medications such as acyclovir, famciclovir, and valacyclovir. Three randomized controlled trials that measured the efficacy of these agents when initiated within the first 72 hours of disease onset concluded that they were all effective in increasing the rate of healing and decreasing pain.71-73 Another study showed that valacyclovir resulted in faster complete resolution than acyclovir did (44 vs. 51 days, respectively).74 In addition, a study comparing famciclovir with valacyclovir showed no statistically significant difference.71 When deciding which agent to use, it is important to consider the amount of administration and cost (Table 24.1). Unfortunately, data on the administration of antiviral medications for prevention of PHN are inconsistent. Other medications that may be used to control the pain of acute HZ are acetaminophen, nonsteroidal anti-inflammatory agents, tramadol, and opioids.54 Studies and randomized trials comparing opioids, TCAs, and membrane stabilizers for treatment of the acute pain from HZ are lacking, but they are still recommended as adjunctive therapy for refractory severe pain.54 The addition of corticosteroids with antiviral medications has proved effective in relieving the intensity of the pain of shingles, but not the duration of the disease process.75 Furthermore, corticosteroid administration did not aid in preventing the development of PHN, as shown in a recent Cochrane review study.76 Interventional therapy for the treatment of acute HZ has proved effective in relieving the pain but not in preventing the development of PHN. A randomized trial in which patients older than 50 years with HZ were given standard therapy versus standard therapy and one epidural injection of methylprednisolone, 80 mg, with bupivacaine, 10 mg, showed that after 1 month, patients in the epidural injection group experienced a significant reduction in pain.77

**ANALGESIC THERAPY**

PHN is a neuropathic pain historically refractory to many forms of therapy. PHN therapies have been separated into analgesic medications (e.g., topical, membrane stabilizers, opioids), interventional procedures (such as sympathetic blocks, intrathecal injections, or surgical interventions), and preventive therapy with the zoster vaccine. Nontraditional PHN therapies such as cognitive and physical therapy have also proved beneficial. As with most other chronic pain disorders, a multimodal therapeutic plan leads to an optimal chance of success.

Medications such as gabapentin, pregabalin, tramadol, and topical lidocaine are considered first-line treatments because they have been shown to be most well tolerated by the (commonly elderly) patient population. Other medications shown to help in patients with PHN are TCAs and SSNRLs, opioids, and topical capsaicin cream (Table 24.2).

The therapeutic modality chosen is patient specific and depends on a thorough history and physical examination.

Topical Medication
A 5% lidocaine patch and 4% to 10% lidocaine cream are widely used topical forms. A randomized, two-treatment period, vehicle-controlled, crossover study showed that a lidocaine patch is effective in controlling PHN pain from allodynia. At the end of the study, 78.1% of subjects enjoyed the lidocaine patch treatment phase and only 9% liked the placebo patch treatment phase. The lidocaine patch is also very safe because of minimal systemic absorption. It is also used safely with other medications based on studies showing no significant drug-drug interaction. The most common side effect reported has been mild skin irritation.

Topical capsaicin in cream or high-concentration patch form has shown promise in treating PHN pain. The first application of the cream leads to exacerbation of the burning sensation, but with time, application leads to desensitization of the nerve root endings and decreases the hyperalgasia. In a 4-week, double-blind study, patients were randomized to receive a high-concentration topical capsaicin patch or placebo. The study showed that the high-strength capsaicin patch relieved pain in 64% of patients at the 6-week mark as compared with 25% taking placebo.

Anticonvulsants
Gabapentin has been used widely as a first-line therapeutic agent for PHN. A quantitative systematic review of randomized controlled trials indicated that the pooled NNT for gabapentin was approximately 4.4. Another study, a randomized, double-blind, parallel-group trial of 9 weeks’ duration, showed that gabapentin was just as effective as nortriptyline but was tolerated better. The pain score after 9 weeks of gabapentin treatment declined by 43% and sleeping scores improved by 52%. The dosage may be titrated up to 1800 mg/day to a maximum of 3600 mg/day. Pregabalin has an identical site of action as gabapentin and is as efficacious in the treatment of PHN. It has the drawback of being on patent (and therefore more expensive) but can be better tolerated by patients because of its greater bioavailability, which results in twice-a-day dosing in comparison to the three-times-daily dosing required for gabapentin.

Antidepressants
TCA medications have been the first-line therapy for neuropathic pain. In a recent randomized, double-blind, parallel-group trial of 9 weeks’ duration, patients with PHN who received nortriptyline had a 47.6% reduction in pain with sleeping scores improved from baseline. A quantitative systematic review of analgesic therapy for PHN noted a significant analgesic benefit with TCAs for the treatment of PHN pain, with the pooled data showing an NNT of 2.6 (95% confidence interval = 2.1 to 3.5). The efficacy of amitriptyline in providing relief of pain in patients with PHN was studied by comparing nortriptyline with amitriptyline. The results showed that both these drugs provided adequate pain relief in 67% of patients. Although they are both equally effective, patients tolerated nortriptyline better because of its fewer side effects.

Venlafaxine is another antidepressant medication with good potential. It is classified as an SSNRI and provides relief of neuropathic pain by increasing the amount of serotonin and norepinephrine and inhibiting their reuptake. This drug has been shown to have fewer side effects than TCAs. Venlafaxine has yielded improvements in neuropathic pain such that 56% of patients had greater than a 50% reduction in pain in comparison to a placebo group (34%: \( P < 0.01 \)) in a double-blind, randomized, placebo-controlled trial. Venlafaxine must be used in doses exceeding a total daily dose of 200 mg/day to inhibit norepinephrine reuptake; doses below this level will only inhibit serotonin reuptake and have no analgesic benefit.

Opioid Medications
Although opioids are considered effective in overall pain management, their efficacy in controlling neuropathic pain is still controversial. In a double-blind, crossover, 4-week study of sustained-release oxycodone, 20 to 60 mg, for moderate to severe pain in patients with PHN, the response rate for pain relief was 58% versus 18% for placebo. Another study reported that the administration of 10 mg oxycodone to a patient already taking pregabalin did not enhance the pain relief obtained, thus demonstrating that oxycodone at low doses is not as effective as administration at higher doses. Morphine was also found to be beneficial in managing the pain of PHN. It was shown that a combination of morphine and gabapentin improved neuropathic pain in patients with PHN more than did either one of them alone. These data suggest that opioids at high doses are of therapeutic value in relieving pain in patients with PHN.

Tramadol
Tramadol is a weak \( \mu \)-receptor agonist medication with properties that increase release of serotonin and inhibition of norepinephrine reuptake. This medication has been effective in treating neuropathic pain with an NNT of 4.8. In a multicenter, randomized, double-blind, parallel-group study involving 127 outpatients treated with tramadol or placebo for 6 weeks, the tramadol group showed significantly reduced pain in compared to the placebo group. Quality of life in the tramadol group was also improved.

Combination Therapy
Many studies have combined medications to achieve the greatest efficacy with the least dosage and increased tolerability of the medications. In a double-blind, double-dummy, crossover trial in which patients with neuropathic pain took gabapentin or nortriptyline as monotherapy or combination therapy, combination therapy was shown to be better than monotherapy, although each medication was effective in relieving neuropathic pain. The combination of gabapentin and morphine has also been widely researched. Gabapentin in combination with morphine was more effective than either medication alone.

INTERVENTIONAL THERAPY
Interventional therapy for the pain of PHN includes nerve blocks, intrathecal injections, and SCS. Interventional therapies are not considered to be a first-line choice, but they should be considered in a multimodal management approach for the treatment of PHN.
Sympathetic Nerve Blocks

The role of sympathetic nerve blocks is to provide relief of pain during the development of HZ, provide relief of PHN pain, and prevent the development of PHN from HZ. Unfortunately, most of the data attempting to prove the efficacy of sympathetic nerve blocks in these three main roles come from retrospective studies and are consequently limited. Thus, the use of sympathetic nerve blocks remains controversial. In a small, randomized study based on retrospective data in which bupivacaine was compared with saline solution, there was evidence of reduced duration of acute HZ pain in patients with sympathetic nerve blocks.68 Another retrospective study concluded that sympathetic nerve blocks provided temporary short-term pain relief in 41% to 50% of patients with PHN.92

Neuraxial Blocks

Epidural injections, paravertebral injections, and intrathecal steroid injections have all been used for temporary relief of pain from PHN, with successful short-term results. Epidural steroid injections have been proved to effectively reduce pain in the acute phase of PHN, but most research has focused on its effects in preventing progression of HZ to PHN. In a study performed in Italy, 600 patients older than 55 years with HZ were administered bupivacaine and methylprednisolone through an epidural catheter versus intravenous administration of prednisolone and acyclovir until they were pain free. After 1 year, the incidence of PHN was 22% in patients receiving intravenous prednisolone and acyclovir as opposed to 1.6% in those receiving bupivacaine and methylprednisolone through an epidural catheter.93 The efficacy of paravertebral blocks in preventing PHN was assessed in a single-center randomized study of patients with HZ given either the standard therapy of oral antivirals and pain medications or a series of four paravertebral injections with bupivacaine and methylprednisolone in addition to standard therapy. The study concluded that after 12 months, the incidence of PHN with standard therapy alone was 16% as compared with 2% in the paravertebral block group. Although it seems that paravertebral blocks are effective in preventing PHN, larger multicenter trials are still required.94 Another promising procedure for the relief of PHN pain is intrathecal methylprednisolone. A study in which 279 patients with intractable PHN pain for more than 1 year were given either intrathecal methylprednisolone with lidocaine, lidocaine alone, or no therapy concluded that the group receiving methylprednisolone with lidocaine experienced a significant reduction in pain in comparison to the groups receiving lidocaine alone or no therapy.95 Unfortunately, these data have never been replicated and clinical experience has not corresponded to the positive results that the authors obtained. Although this method of management of intractable PHN may have been effective in this single study, its association with adhesive arachnoiditis has and should limit its application.

Spinal Cord Stimulation

A study followed 28 patients refractory to conservative therapies after placement of a spinal cord stimulator. Twenty-three of the 28 patients had significant improvement in pain, and many stopped using their adjuvant oral medications. The pain relief was long lasting.96 Further trials, including cost-effectiveness data, are needed to determine the role of SCS in the treatment of PHN pain.

DIABETIC NEUROPATHY

EPIDEMIOLOGY AND RISK FACTORS

The definition of diabetic neuropathy as proposed by the San Antonio Consensus Statement is “demonstrable disorder, either clinically evident or subclinical in the setting of diabetes without other causes of peripheral neuropathy.”97 The diabetic neuropathies are collectively considered a diverse, complex disease that affects many components of the nervous system and exhibits varied clinical manifestations. They can be classified into two main categories: generalized neuropathies versus focal or multifocal neuropathies. Generalized neuropathies include acute sensory neuropathy, chronic sensorimotor distal polyneuropathy (DPN), and autonomic neuropathy. Focal and multifocal neuropathies include cranial, truncal, focal limb, and proximal motor neuropathy (amyotrophy), as well as chronic inflammatory demyelinating polyneuropathy.98

The prevalence and incidence of DPN have been very difficult to verify given the inconsistencies in clinical diagnostic criteria, variability in patient populations, and wide range of physiologic techniques. The World Health Organization estimated that 150 million people had diabetes in the year 2000, and this number was expected to increase to 366 million by the year 2030.99 It has been estimated that approximately 56% of patients with DPN will complain of pain that affects their quality of life.100 In earlier studies, the prevalence of lower limb pain ranged from 6% to 27%, and DPN affected men and women equally.101 A study conducted in the United Kingdom involved 356 diabetic patients, most of whom had type 2 diabetes, and included a structured questionnaire with physical examination. Chronic sensorineural diabetic peripheral neuropathy (CSDPN) was diagnosed in almost half the patients, but only a third of them complained of pain that had been present for at least 1 year. The prevalence rate for DPN in this study was 16% as opposed to 5% for chronic neuropathic pain in a similar population without diabetes. It is also important to note that in this study 12.5% of patients with DPN did not report symptoms to their physicians and the 39% who reported pain did not obtain treatment of their pain, which suggests that DPN is undertreated.102 A cross-sectional descriptive study reported the prevalence of DPN in patients with diabetes mellitus type 2 to be 26%. The prevalence of diabetic patients suffering from CSDPN was found to be 44%.103 A multicenter study recently conducted in Belgium included 1111 diabetic patients, types 1 and 2, and estimated the prevalence of CSDPN and DPN.104 The study was performed with the NeuroPEN device, which tests for pain and monofilament perception, and based on studies is able to identify CSDPN with confidence.105 The duration of diabetes in this population was greater in patients with type 1 than in those with type 2, 16 versus 11 years, respectively. The study concluded that the prevalence of CSDPN was 43% and was higher with type 2 (51%) than with type 1 (26%) diabetes. The prevalence of lower limb neuropathic pain was 14%, again higher with type 2 (18%) than with type 1 (6%).104 According to these
and other studies, the prevalence of DPN may be estimated to be 15% to 20% in type 2 diabetics and approximately 5% in type 1 diabetics with an incidence rate of 2% per year. Risk factors for DPN have been widely studied in an effort to prevent its development. The most commonly reported risk factors are age and duration of diabetes. Other risk factors associated with DPN are arterial hypertension and impaired glucose tolerance (IGT). In a study examining patients with neuropathy of unknown origin, 36% of patients had IGT, 77% of whom had painful neuropathy. Other risk factors shown to have a relationship with the presence of DPN are obesity with low high-density lipoprotein cholesterol and high plasma triglyceride levels. Genetic factors are also considered risk factors based on a study by Galer and colleagues, 56% of patients with DPN also had first- or second-degree relatives suffering from DPN.

**PATHOPHYSIOLOGY**

Diabetic neuropathy is theorized to occur by three mechanisms: the polyol pathway, microvascular damage, and glycosylation end-product theories. These three models most likely act simultaneously, but there may also be some overlap between them. Neurotrophic factors and neuronal membrane ion channel dysfunction may likewise play a role in DPN.

The polyol pathway theory proposes that increased blood glucose leads to elevated glucose concentrations within nerve endings. Through a series of reactions, the glucose is converted into sorbitol via the polyol pathway involving aldose reductase and elevation of the fructose level. The high sorbitol and fructose levels subsequently lead to a decrease in sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) activity. Activation of the aldose reductase--depleting cofactor NADPH (reduced nicotinamide adenine dinucleotide phosphate) leads to decreased nitric oxide and glutathione, which inhibits the buffer against oxidative injury and vasodilation and results in chronic ischemia. In the microvascular damage theory, thickening of the capillary basement membrane along with endothelial cell hyperplasia leads to neuronal ischemia and infarction. The glycosylation end-product theory proposes that interference in axonal transport results in decreased nerve conduction velocity because of chronic hyperglycemia, which results in deposition of advanced glycosylation end products around peripheral nerves. These end products may also produce NADPH (which activates NADPH oxidase) and thereby contribute to the formation of hydrogen peroxide and increased oxidative stress. Nerve growth factors are important in the repair of nerve structure and function after an injury. Low levels of these neurotrophic factors correlate with diabetic neuropathy in animal models. Other factors associated with diabetic neuropathy are abnormal calcium channel activity contributing to cellular injury and death and sodium channel dysfunction playing a role in the genesis of painful neuropathy.

**CLINICAL FEATURES**

Acute sensorimotor neuropathy often occurs in association with periods of poor metabolic control such as uncontrolled glycemic levels or the development of ketoacidosis. This form of neuropathy is very rare. The most common form of peripheral neuropathy is CSDPN, as seen in more than 80% of patients with DPN. Patients with CSDPN typically complain of distal, symmetrical burning pain that usually involves the feet initially and gradually moves upward in a symmetrical fashion. This is due to damage to longer nerves, a phenomena known as length-dependent diabetic polyneuropathy.

DPN causes neuropathic pain as a result of the involvement of small nerve fibers, and diagnosis is achieved through a diligent history and physical examination. One study showed that clinical neurologic examination, including questionnaires, was 23% sensitive and 93% specific in diagnosing DPN. Another recent study concluded that development of the DN4 questionnaire has improved diagnostic performance, with a sensitivity of 83% and specificity of 90% in patients with a neuropathic pain score greater than 4 out of 10. The initial symptoms in up to 50% of patients with DPN are highly nociceptive and include burning pain, electric or stabbing sensations, paresthesias, hyperesthesia, and deep aching pain, which are typically worse at night. Upper extremity involvement is rare. Physical examination of the lower limbs typically shows sensory loss of vibration, pressure, pain, and temperature perception and absent ankle reflexes. Loss of touch and pin sensation typically occurs before loss of proprioception and vibration and is caused by the involvement of large-diameter fibers. This is evaluated with 10-gauge monofilament and tuning fork tests. Gait ataxia may occur with severe neuropathy. In addition, signs of peripheral autonomic dysfunction can be observed, including a warm or cold foot, distended dorsal foot veins, dry skin, and calluses under pressure-bearing areas. It is important to note that the diagnosis of DPN is a diagnosis of exclusion and that multiple pathologies may mimic this form of neuropathy. The differential diagnosis should include peripheral vascular disease, restless legs syndrome, Morton’s neuroma, vitamin B₁₂ deficiency, hypothyroidism, and uremia.

Autonomic neuropathy is a common pathology that may occur in patients with chronic diabetes types 1 and 2. This form of neuropathy may be present at any stage of the disease, but it most often affects patients who have had the disease for more than 20 years. The parasympathetic, sympathetic, and enteric nerves are affected, and myelinated and unmyelinated nerves are affected and damaged. The condition is considered to be irreversible, but cardiac sympathetic denervation has been shown to revert with tight glucose control. It affects multiple organ systems, including the cardiovascular, genitourinary, sudomotor, gastrointestinal, and endocrine systems. Some clinical manifestations include resting tachycardia, orthostatic hypotension, distal anhidrosis, bladder dysfunction, erectile dysfunction and female sexual dysfunction, severe constipation, diarrhea, and dysmotility syndrome. In addition, because of the loss of sympathetic tone, vasodilation occurs and leads to pooling of blood in the lower extremities. This has been proposed to cause osteopenia and is related to the development of Charcot’s neuroarthropathy.

Multifocal neuropathies comprise a wide spectrum of neuropathies, including diabetic amyotrophy, truncal neuropathies, cranial neuropathies, and mononeuropathies. Diabetic amyotrophy most often occurs in type 2 diabetics and is characterized by subacute pain and asymmetrical
weakness and atrophy of the proximal lower limb muscles. There may also be involvement of the upper limb muscles and distal end of the lower extremity, but this is rare.\textsuperscript{120} Mononeuropathies most commonly involve the ulnar, median, and common peroneal nerves secondary to nerve ischemia because these nerves are more susceptible to injury from compression. Cranial nerve involvement may be present but is extremely rare.\textsuperscript{120}

**TREATMENT OPTIONS**

Treatment of DPN has been widely studied and includes the use of TCAs and SSNRIs, anticonvulsants, opioids, and other modalities. Treatment options can be viewed as approaches either to prevent the development of DPN or to alleviate its symptoms. As is true for all chronic pain syndromes, a multimodal approach is the most effective therapy for DPN, with the primary aim often focusing on protecting the lower limbs from damage caused by sensory loss or on relieving pain to enhance the quality of life and functionality of each patient.

**GLYCEMIC CONTROL**

Hyperglycemia and insulin deficiency are associated with the pathogenesis of DPN. It appears that glycemic control is one of the most effective treatments to slow progression of the disease and delay its onset.\textsuperscript{1} In a study conducted by the Diabetes Control and Complications Trial Research Group, a total of 1441 patients with insulin-dependent diabetes mellitus (726 of whom had no retinopathy and 715 had mild retinopathy) were monitored for 6.5 years after random assignment to intensive external insulin pump therapy or three or more daily insulin injections. The study concluded that in the group without retinopathy, intensive therapy reduced the risk for development of DPN by 76% in comparison to conventional therapy. In the retinopathy group, intensive therapy decreased progression by 54%. The study also showed that progression of microalbuminuria in both groups was reduced by 39%, albuminuria by 54%, and clinical neuropathy by 60% with intensive insulin therapy.\textsuperscript{121} Thus, tight glycemic control contributes to a delayed onset and slowed progression of DPN.

**ANTICONVULSANTS**

Gabapentin has been used as first-line therapy for neuropathic pain and has been shown to provide mild relief of pain in patients with DPN. In a randomized, double-blind, placebo-controlled, 8-week trial comparing gabapentin and placebo, it was concluded that daily pain in the gabapentin-treated patients decreased from 6.4 to 3.9 versus a decrease in the placebo group from 6.5 to 5.1. Patients in the gabapentin treatment group also had improved sleep.\textsuperscript{122} Another trial comparing the efficacy of gabapentin for DPN used three different forms of recording pain, including the visual analog scale (VAS), present pain intensity (PPI), and McGill Pain Questionnaire (MPQ) completed before and after therapy. Only the MPQ showed statistical improvement in pain with gabapentin treatment versus placebo.\textsuperscript{123} Gabapentin has an NNT of 3 for overall neuropathic pain. Use of gabapentin for DPN had no effect on quality of life, but it did yield improvements in sleep and mental health.\textsuperscript{123} A systematic review of the literature on the treatment of DPN from 1960 to 2008 recommended that pregabalin be used if medically appropriate before gabapentin. Gabapentin and valproic acid should be considered as alternative therapies for DPN.\textsuperscript{124} A randomized controlled trial comparing pregabalin with placebo in patients with DPN for 1 to 5 years showed that 46% of the patients taking a dosage of 300 mg/day, 48% taking 600 mg/day, and 18% taking placebo had greater than a 50% reduction in pain.\textsuperscript{125} In a 12-week randomized, double-blind, multicenter, placebo-controlled trial using a fixed dose of 100 mg/day for 1 week and 600 mg/day for 11 weeks in one group and flexible doses of 150, 300, 450, and 600 mg/day in the other group concluded that both treatments were superior in reducing neuropathic pain in comparison to the group receiving placebo.\textsuperscript{126} The NNT is 4 for a 50% reduction in pain at a dosage of 600 mg/day. Thus, pregabalin has been shown to be effective in providing relief of neuropathic pain in patients with DPN.

**ANTIDEPRESSANTS**

Multiple antidepressant medications, including TCAs and SSNRIs, have been used for general neuropathic pain with positive results. In one study in which nortriptyline and fluoxetine were given in combination and compared with placebo, the group receiving combination therapy had 63% more patients with greater than a 50% reduction in VAS scores for pain.\textsuperscript{127} The NNT for TCAs in patients with DPN was 1.3, as recorded by five randomized trials that established its effectiveness in treating neuropathic pain in those with DPN.\textsuperscript{38} In addition, combination therapy with gabapentin has increased the effectiveness of treating PHN and DPN pain.\textsuperscript{39} In a multicenter, double-blind, randomized, placebo-controlled study in which patients were treated with venlafaxine, those patients taking low dose venlafaxine (75mg) had 32% reduction from their baseline VAS scores after 6 weeks, and those taking high dose venlafaxine (150-225mg) had 50% reduction after 6 weeks with an NNT of 4.5.\textsuperscript{80} Duloxetine is another SSNRI that has shown promise in relieving neuropathic pain from DPN. Multiple studies have demonstrated duloxetine to be more effective than placebo.\textsuperscript{128,129} In a randomized, double-blind, crossover clinical trial comparing duloxetine with amitriptyline after a 6-week treatment concluded that both were effective in treating DPN. The duloxetine group had a 59% reduction in VAS scores with good pain relief, a 21% reduction with moderate pain relief, and a 9% reduction with mild pain relief. Duloxetine was also better tolerated than amitriptyline.\textsuperscript{130}

**OPIOIDS AND TRAMADOL**

Many studies have shown that opioid medications decrease pain in patients with DPN. The fear of dependency on and addiction to these drugs warrants close observation; opioid medication should be administered only if the patient’s condition is unresponsive to nonopioid therapy (Fig. 24.1). Of these agents, tramadol, morphine sulfate, and oxycodone consistently decrease pain from DPN. An open, randomized comparative study of gabapentin versus tramadol and acetaminophen showed that the combination of tramadol and acetaminophen was just as effective in relieving DPN pain as gabapentin.\textsuperscript{34} In a randomized, double-blind, placebo-controlled crossover study using tramadol, the group receiving tramadol experienced relief from polyneuropathy symptoms such as pain, allodynia, and paresthesia (NNT of 4.3).\textsuperscript{151}
Oxycodone has also been shown to be effective in treating neuropathic pain in patients with DPN. In a multicenter, randomized, double-blind, placebo-controlled study comparing controlled-release oxycodone with placebo, it was concluded that pain scores in the groups receiving oxycodone and placebo were 4.1 and 5.3, respectively. This suggests that oxycodone is mildly effective in relieving neuropathic pain in patients with DPN. Another study that added oxycodone to the regimen of diabetic patients already taking gabapentin for neuropathic pain concluded that use of the combination of these drugs relieved pain more than when gabapentin was used alone. There are limited data on the use of morphine monotherapy in diabetic patients with neuropathy. A crossover study investigating morphine and gabapentin used as either monotherapy or combination therapy showed that the addition of morphine to gabapentin was more effective with lower doses of each medication.

**NMDA RECEPTOR ANTAGONISTS**

The NMDA receptor plays an important role in processing nociceptive and chronic pain. Thus, antagonizing its actions may reduce neuropathic pain. One of the most common NMDA receptor antagonists is dextromethorphan. This drug has been examined in past studies, and it was shown to be efficacious in providing relief of pain in diabetic patients suffering from neuropathy. One study demonstrated that the pain in DPN patients had been reduced by 33% and that 68% of patients receiving dextromethorphan had more than moderate pain relief. A study comparing dextromethorphan with placebo showed a 27% reduction in neuropathic pain in diabetic patients, with higher efficacy achieved with increased doses. Also, it is worthwhile to note that both these studies showed efficacy of dextromethorphan for DPN but not for PHN.

**OTHER INTERVENTIONS**

Topical anesthetics have been deemed safe to use because of their lack of drug interactions, decreased side effects, and lack of titration required. Capsaicin cream (0.075%) has been shown to decrease neuropathic pain with an NNT of 6.6. In addition, 5% lidocaine–medicated plaster has been demonstrated to be as effective as capsaicin, amitriptyline, gabapentin, and pregabalin, as shown in a systemic review study comparing the efficacy of each of these drugs in patients with DPN. Because oxidative stress may play an important role in the pathogenic mechanisms of diabetic neuropathy, the use of antioxidants such as α-lipoic acid may have some beneficial effect in the treatment of diabetic neuropathy. A meta-analysis showed that treatment with α-lipoic acid, 600 mg intravenously for a 3-week course, provided effective relief of neuropathic pain and improved neurologic deficits. A more current study reported significant improvement in neuropathic pain with a 600-mg daily intravenous dose for 5 weeks (NTT of 2.7). Other treatment forms have been suggested for DPN based on its pathophysiology, such as glycation inhibitors, aldose reductase inhibitors, and growth factors, but further research in these areas is necessary.

**HIV-RELATED PAIN SYNDROMES**

**EPIDEMIOLOGY**

It is estimated that more than 65 million people worldwide are infected with HIV. With the development and widespread use of highly active antiretroviral therapy (HAART) and the resultant decrease in opportunistic infections of the central nervous system, polyneuropathy has become the most prevalent neurologic complication associated with HIV infection. This disease affects the patient’s immune and nervous systems. As the patient progresses through different stages of the disease, a variety of neurologic complications arise that are directly or indirectly related to HIV infection. Although symptomatic neuropathy occurs in 10% to 35% of individuals seropositive for HIV, pathologic abnormalities exist in almost all those with end-stage acquired immunodeficiency syndrome (AIDS). A systematic review in which multiple studies were compiled in the hope of determining the incidence and prevalence of neuropathy in HIV-infected patients found a high level of variation across all the studies. The prevalence of neuropathy ranged from 1.2% to 69.4%. The rate of development of neuropathy per 100 person-years in HIV patients ranged from 0.7 to 39.7, with a greater risk for neuropathy in older patients and those with more advanced disease.
Multiple neurologic deficits occur with HIV infection, but the two most common forms of HIV-related sensory neuropathy (HIV-SN) are distal sensory polyneuropathy (DSP) and antiretroviral toxic neuropathy (ATN). DSP is due to the viral infection itself, whereas ATN is due to medical treatment of the viral disease. The more common of the two disorders is DSP. The most common risk factors for the development of HIV-SN before the introduction of HAART were older age and advanced disease states (such as high plasma viral load and low CD4+ cell count). After initiation of HAART, risk factors for the development of neuropathy became more ambiguous and included older age, CD4+ count lower than 50 cells/mm, nutritional deficit, use of dideoxynucleoside reverse transcriptase inhibitors, and exposure to protease and alcohol.

**CLINICAL FEATURES**

Although these HIV-SN disorders may represent two distinct entities, the clinical syndrome and pathophysiologic manifestation of the two disorders are almost indistinguishable. The time course of the illness and, in the case of ATN, the temporal relationship to commencement of antiretroviral therapy represent the primary differentiating characteristic. The onset of DSP can occur in either the subacute or chronic phase or following the development of an AIDS-defining illness. The clinical manifestations of ATN can appear within the first week to 6 months after the initiation of antiretroviral therapy and may subside after its cessation. The clinical features of HIV-SN are dominated by painful dysesthesia, allodynia, and hyperalgesia. Its onset is often gradual, and it most commonly begins with bilateral lower extremity involvement. The neuropathy progresses in a length-dependent fashion with a worsening gradient of disease from distal structures to those more proximal. The dysesthesia commonly involves the soles of the feet first and progresses proximally; when the symptoms encompass the dermatomes of the knee, the patient will frequently report finger involvement. The first symptoms noted are often numbness or burning sensations following a diurnal cycle, with the pain being worse at night. Shortly thereafter, patients will report allodynia (a stimulus previously not found to be noxious is perceived as painful) and hyperalgesia (a lower pain threshold) of the involved structures. As a result, wearing shoes and walking become painful and the patient’s gait becomes antalgic. There is minimal subjective or objective motor involvement, and pain is typically limited to the intrinsic muscles of the foot. In addition to the sensory findings, physical examination reveals a diminution or loss of ankle reflexes.

**DIAGNOSTIC STUDIES**

There is currently no gold standard for the diagnosis of DSP. In addition, the optimal combination of diagnostic studies has yet to be defined. The disease process remains primarily a clinical diagnosis. The neuropathy may be secondary to many other physiologic processes for which blood work must be obtained for exclusion, such as vitamin B12 deficiency, diabetes mellitus, hypothyroidism, IGT, and syphilis. In a nonrandomized, cross-sectional study, HIV patients with axonal peripheral neuropathy who were taking neurotoxic nucleoside analogues had their acetylcarnitine serum levels measured. Patients suffering from neuropathy while taking nucleoside analogue medications had a deficiency in acetylcarnitine and were nutritionally deficient. Although the level of acetylcarnitine may be used for the diagnosis of ATN, more studies are necessary. Nerve conduction studies are not necessary for the diagnosis of DSP and will show an axonal, length-dependent, sensory polyneuropathy. Needle electromyograms are of no great benefit because the findings are usually normal, but they may show chronic denervation and reinnervation. Punch skin biopsy specimens from the distal end of the calf and proximal part of the thigh may be used to detect small-fiber neuropathy by measuring intraepidermal nerve fiber density. The lower the intraepidermal density, the greater the likelihood of DSP symptoms developing and the greater the neuropathic pain level. Epidermal nerve fiber density may be used as a quantitative marker in clinical trials of neurodegenerative agents and also to predict the likelihood of symptoms developing in an asymptomatic patient. Dorsal root ganglion (DRG) neuronal loss has been reported, although the reduction is more modest than distal axon loss.

**PATHOPHYSIOLOGY**

DSP and ATN are clinically similar but have a distinct pathophysiology. The exact mechanism of the disease process is not fully understood, but it is hypothesized that there are multiple mechanisms at work that eventually cause axonal injury. The peripheral and central nerve toxicity related to HIV infection may be due to cytokine-mediated effects because HIV does not infect axons or Schwann cells. The gp120 protein is an HIV-associated protein thought to play a key role in pathogenesis by way of ligation of chemokine receptors located on glial cells and neurons. It may also play a role on chemokine receptors related to Schwann cell-to-neuron interaction. Damage to axons occurs secondary to the inflammatory reaction in the nerve and surrounding tissues, which eventually leads to the characteristic pain seen in DSP. This hypothesis has been supported by animal studies in which gp120 was found to produce pain in rats when administered epineurally into the sciatic nerve and intradermally into the paw. The indirect causes of DSP pain are thought to be mediated by inflammatory injury. They can be divided into peripheral and central mechanisms. The peripheral hypothesis proposes that the pain results from the spontaneous activity of uninjured pain-transmitting or C fibers after injury to adjacent fibers. Inflammatory mediators released by macrophages may further sensitize these fibers. The central hypothesis involves an alteration in ion channels in the DRG combined with changes in the spinal cord dorsal horn that result in “central sensitization.”

ATN primarily occurs as a result of the use of nucleoside reverse transcriptase inhibitors and typically ensues within a year of beginning treatment or in patients with preexisting peripheral neuropathy. The mechanism for ATN is currently unknown, but mitochondrial dysfunction as a result of abnormal mitochondria in Schwann cells and axons has been shown to play a role. Data have also shown that the depletion of mitochondrial DNA seen in AIDS patients treated with NRTIs leads to increased levels of serum lactate.
A double-blind, multicenter, randomized trial using high-dose capsaicin cream demonstrated pain relief in patients with HIV-SN.\textsuperscript{170}

**SUMMARY**

Despite the diversity of conditions and pathophysiology characterized by neuropathic pain, many of the underlying treatment options are comparable but not identical. Traditional systemic analgesic agents, such as antidepressants, anticonvulsants, local anesthetics, and opioids, are typically the mainstay of treatment of neuropathic pain, although the efficacy of individual classes of agents varies with the specific type of neuropathic pain. Few high-quality trials are available as interventional options for the treatment of neuropathic pain. Clinicians should be aware of the paucity and support the use of traditional interventional options in some cases.

**KEY POINTS**

- The most commonly used clinical diagnostic criteria for complex regional pain syndrome (CRPS) types 1 and 2 have low specificity but high sensitivity, which has led to overdiagnosis of this pain syndrome.\textsuperscript{3}
- In 2007, research criteria (also known as the Budapest criteria) were published that included objective signs of pathology characteristic of patients with CRPS\textsuperscript{4} (see Box 24.2).
- Psychological factors such as depression, personality disorders, and anxiety have no correlation with CRPS patients, which suggests that there is no specific type of CRPS personality.\textsuperscript{20}
- A double-blind, randomized, placebo-controlled, parallel-group trial studying the effects of subanesthetic intravenous dosing for 4 days in patients with CRPS showed decreased levels of pain but a progressive increase in pain from the 1st week after infusion to the 12th week. Minor and rare side effects such as nausea, vomiting, and psychomimetic effects developed in patients treated with ketamine infusion.\textsuperscript{43}
- In a randomized trial patients with CRPS were separated into two groups: spinal cord stimulation (SCS) with physical therapy and physical therapy only.\textsuperscript{49} This study showed that SCS provided significant improvement in pain for the first 2 years.\textsuperscript{50}
- The acute phase of herpes zoster is characterized by a maculopapular vesicular rash that crusts over after 1 to 2 weeks and leads to a burning sensation, hyperesthesia, itching, and severe pain. Prodromal symptoms that may occur 1 to 5 days before the rash include headache, fever, malaise, abnormal skin sensation, and photophobia. Post-herpetic neuralgia may occur 2 weeks after the presence of herpes zoster and is the chronic form of the disease.
- Medications such as gabapentin, pregabalin, tramadol, and topical lidocaine are considered first-line treatments because they have been shown to be most well tolerated by the (commonly elderly) patient population.
KEY POINTS—cont’d

Other medications shown to help in relieving the pain associated with post-herpetic neuralgia are tricyclic and serotonin-norepinephrine reuptake inhibitor antidepressants, opioids, and topical capsaicin cream (see Table 24.2).

- The initial symptoms in up to 50% of patients with painful diabetic peripheral neuropathy are highly nociceptive and include burning pain, electric or stabbing sensations, paresthesias, hyperesthesias, and deep aching pain, which are typically worse at night. Upper extremity involvement is rare.96

- The rate of development of neuropathy per 100 person-years in patients infected with human immunodeficiency virus (HIV) ranged from 0.7 to 39.7, with a greater risk for neuropathy in older patients and those with more advanced disease.144

- Lamotrigine, gabapentin, and topical capsaicin are effective in the treatment of HIV-associated neuropathic pain, but amitriptyline, topical lidocaine, and pregabalin are ineffective.

Chronic pain is an accompaniment of many neurologic disorders. Although chronic pain may be the defining feature in certain neurologic disorders, neurologists and primary care practitioners often focus mainly on treatments aimed at addressing the primary neurologic condition (disease-based treatments). Thus, it is important for pain specialists to acquire a pathophysiologic understanding of the specifics of the pain that accompanies these conditions and embark on treatment strategies to complement disease-based treatments and improve the quality of life of affected individuals. Common neuropathic pain disorders are given specific attention in the chapter on neuropathic pain syndromes (see Chapter 24, which includes discussions on complex regional pain syndrome, post-herpetic neuralgia, and diabetic peripheral neuropathy). Another neuropathic pain syndrome, phantom pain, is specifically addressed in Chapter 26. The neuroanatomic basis and pathophysiology underlying the pain associated with these disorders have been detailed in Chapters 8 through 10.

The pain symptoms accompanying neurologic disorders are remarkably similar despite the varied causes of neurologic conditions. The details of advanced therapeutic strategies are covered in the chapters describing classes of pharmacologic and interventional management techniques. The discussion here focuses on the prevalence, symptoms, and characteristics of a selection of neurologic disorders characterized by or having symptomatic pain as a dominant feature during the course of the illness. Although it is not possible to include every disorder in which pain is a feature, this chapter includes those that pain specialists are likely to encounter at some frequency during the course of their practice in the management of chronic pain. Because of the success that leaders in the field of pain medicine have achieved in the recognition of pain, information on the pain associated with each disorder discussed in this chapter may be worthy of a more detailed dissertation (see the reference list for detailed reviews of each disorder in the literature, when available).

The pain associated with neurologic disorders may be broadly characterized as occurring in two basic forms: (1) neuropathic pain resulting from a pathologic entity or lesions in the central or peripheral nervous system and (2) pain occurring as a secondary feature of the neurologic disorder as a result of nervous system dysfunction. The former category is widely accepted as neuropathic pain, as defined by the International Association for the Study of Pain in 1994. Lesions associated with the development of chronic neuropathic pain typically involve damage or dysfunction along the small-fiber peripheral nervous system, spinothalamic pathways within the spinal cord, medial lemniscus and trigeminal pathways in the brainstem, and thalamocortical pathways to the parietal cerebral cortex of the brain. Thus, the location of the neuropathic pain in a given disorder typically follows the neuroanatomic substrate as defined by the location of the lesion or lesions causing the condition. The pain complaints are characterized by numerous pain descriptors, such as burning, shooting, stabbing, aching, and shocklike, along with accompanying sensory phenomena such as numbness and tingling. The pain accompanying these disorders is often a combination of constant and intermittent pain experiences. Additionally, the pain typically has components of stimulus-dependent and stimulus-independent pain. As defined in Chapter 24, stimulus-dependent phenomena include allodynia, hyperalgesia, and hyperpathia. Attention to the dominant pain description, type, and nature of the evoked (stimulus-dependent) pain subtypes allows the clinician to adjust treatment strategies accordingly.

Secondary pain syndromes that arise from nervous system dysfunction may include components of neuropathic or nociceptive pain. Examples of secondary pain syndromes include myofascial pain secondary to spasticity, muscle cramps, and regional myofascial dysfunction. Musculoskeletal pain may stem from bone and joint disorders precipitated or aggravated by paralysis, falls, generalized immobility, and spasticity. Immobility predisposes to decubitus ulcers, disordered intestinal motility, osteoporosis (vertebral compression fractures), and focal peripheral nerve entrapment. During the clinical evaluation of a neurologic patient with chronic pain, it is important to distinguish pain that is a direct result of the neurologic disorder from pain that may be secondary to the accompanying disability or primary disease process. Prevention and treatment of secondary sources of pain require constant diligence and periodic reassessment by the treating pain specialist. Table 25.1 summarizes the types of pain syndromes common in patients with neurologic disorders.

**PERIPHERAL NERVOUS SYSTEM DISORDERS**

The peripheral nervous system is composed of motor and sensory axons of the anterior horn cells (motor fibers) and dorsal root ganglia (sensory fibers), peripheral autonomic ganglia and their axons, and peripheral ganglia of the gastrointestinal tract. Pain is frequently a dominant symptom in the course of development of peripheral nervous system disorders, especially those that affect the "small fibers" of...
the sensory peripheral nervous system. These fiber types (Aδ and C) are characterized by slower axonal conduction and conveyance of the sensory modalities of nociception, warmth, and cold. Injuries to spinal nerve roots, dorsal root ganglia, and peripheral nerves are characterized by sensory and motor dysfunction according to the site or sites of pathologic involvement. The symptoms of peripheral nervous system disorders are thus characterized by neuropathic pain described as numbness, tingling, and shooting or stabbing pain. Of the most common peripheral neuropathy, diabetic peripheral neuropathy, is delineated in Chapter 24. Table 25.2 includes a general classification of painful neuropathies; a few specific examples are discussed in the following sections.

**AUTOIMMUNE PERIPHERAL NERVOUS SYSTEM DISORDERS**

Autoimmune peripheral nervous system disorders include the neuropathies caused by connective tissue diseases, systemic vasculitis, and autoimmune disorders of peripheral myelin. Neuropathic pain may precede the diagnosis of systemic or focal vasculitis or occur during the course of established disease. When neuropathy precedes the diagnosis of vasculitis, the absence of more severe systemic symptoms may delay the diagnosis. Inflammation leading to ischemia of focal peripheral nerves may result in the clinical syndrome of mononeuropathy multiplex. This syndrome is characterized by pain, numbness, and weakness in the distribution of multiple peripheral nerves. The peripheral nerves most commonly affected include the ulnar, median, and peroneal nerves. Dysfunction in the territories of these nerves will typically occur at sites of peripheral nerve entrapment and at sites distal from locations usually associated with peripheral entrapment. Distal symmetrical polyneuropathy (DSP) may also occur in the setting of vasculitis and connective tissue disease. DSP is characterized by numbness, tingling, and pain in a characteristic symmetrical stocking-glove distribution. Symptoms typically begin in the feet and consist of burning, aching, and dysesthesias. Not uncommonly, asymmetry of progression of DSP leads to a consideration of autoimmune vasculitis and may assist in the clinical diagnosis.
symptom. A review of pain in patients with Guillain-Barré syndrome has highlighted the importance of recognizing the primary components of pain and secondary pain syndromes. Deep aching, throbbing pain in the low back region associated with radiation into the lower extremities is typically the most excruciating and disabling pain during the acute episode. A positive straight-leg raise test may accompany the acute pain. Accompanying the low back and radicular pain, myofascial pain may coincide with the development of muscle spasm, cramping, and muscular tenderness. Stabbing, shocklike, or electric pain may be present in the extremities and face. Ectopic impulses caused by acute nerve root inflammation may be the pathologic mechanism associated with the acute neuropathic pain component in Guillain-Barré syndrome. Chronic neuropathic pain may actually persist beyond treatment of and recovery from the paralytic disorder in a small proportion of patients. The autonomic nervous system dysfunction present in Guillain-Barré syndrome may lead to the development of headaches, cardiovascular instability, and visceral pain secondary to ileus and urinary retention.

Treatment of primary neuropathic pain in Guillain-Barré syndrome includes the use of antineuropathic agents in addition to immune-based therapy for the primary disease. Antineuropathic agents commonly used include tricyclic antidepressants, anticonvulsants, and opioids (oral and parenteral, when necessary). In severe cases, epidurally administered local anesthetics or opioids may be of benefit in the acute stage. Treatments beneficial for secondary pain syndromes include muscle relaxants (e.g., baclofen, tizanidine) for acute myofascial pain and supportive measures for the acute dysautonomia (e.g., intravenous fluid administration, stool softeners, urinary drainage).

**HUMAN IMMUNODEFICIENCY VIRUS–RELATED NEUROPATHIES**

Nervous system complications of human immunodeficiency virus (HIV) type 1 infection have been reviewed by Price. Peripheral neuropathic pain is recognized as a common accompaniment of HIV infection. Neuropathic pain may complicate any stage of the infection and result in disordered sleep and ambulation, disability, and psychosocial distress. It is estimated that 35% of patients infected with HIV experience symptomatic DSP whereas as many as 67% of patients infected with HIV may experience asymptomatic DSP when evaluated neurologically. The peripheral neuropathic pain syndromes characteristic of HIV infection are summarized in Table 25.3.

During the acute course of seroconversion, acute inflammatory demyelinating polyneuropathy may develop and cause numbness, weakness, and peripheral neuropathic pain. The disorder may be the initial manifestation of HIV seroconversion. Its course may be similar to that of Guillain-Barré syndrome, though with a higher incidence of more severe weakness, atrophy, and profound sensory loss. Treatment of moderate to severe cases uses the standard strategies for the treatment of Guillain-Barré syndrome (e.g., immunotherapy, antineuropathic agents, epidural infusions). The acute polyneuropathy associated with seroconversion typically resolves with mild, if any, residual sequelae of neuropathic pain. The chronic form of the disorder, chronic inflammatory polyneuropathy, appears in the intermediate to late stages of the disease, it is manifested as neuropathic pain associated with more severe sensory loss, weakness, and gait disturbance.

With the advent of successful antiretroviral therapy, long-term survival rates for those with HIV infection have increased, and as a result, there has been an associated increase in the incidence of chronic neuropathic pain attributable to the treated disease, as well as the treatments. In addition to the neuropathies associated with primary HIV infection, antiretroviral agents may be neurotoxic. In particular, the dideoxynucleoside family of nucleoside analogue reverse transcriptase inhibitors has been shown to have specific peripheral neurotoxic effects. Antiretroviral-induced neuropathies are manifested by distal dysesthesias, burning, tingling, and shooting pains. This antiretroviral-induced polyneuropathy can be distinguished from HIV polyneuropathy in that it occurs more abruptly with more rapid progression and is often more painful. Antiretroviral polyneuropathy occurs in 26% to 66% of patients, but the symptoms often improve with drug cessation or reduction. Allodynia may be experienced during ambulation and can be debilitating. Difficulty with sleep is a common accompaniment secondary to allodynia and spontaneous dysesthesias.

A distal symmetrical HIV-induced sensory axonal polyneuropathy may occur in the intermediate or late stages of infection. The polyneuropathy is manifested as burning pain, numbness, and evoked dysesthesias beginning in the lower extremities, with variable progression to upper extremity involvement. Similar to the antiretroviral neuropathies, allodynia may impair sleep and ambulation. Another intermediate-stage phenomenon, vasculitic mononeuropathy multiplex, may coexist with other peripheral nervous system symptoms of HIV infection. Symptoms of vasculitic neuropathy are similar to those that characterize the connective tissue disorders. Pain, numbness, dysesthesias, and motor symptoms are multifocal and asymmetrical. They often persist despite treatment of the primary disease.

During the course of the illness, especially if untreated or refractory to treatment, opportunistic infections may

contribute to the neurologic symptoms. Cytomegalovirus infection may give rise to progressive polyradiculopathy or mononeuropathy multiplex, or both. The polyradiculopathy is characterized by the development of pelvic and lower extremity radicular pain and urinary retention and may progress to cauda equina syndrome. Rapid progression with ascending paralysis, central nervous system involvement, and death occurs in untreated cases. Reactivation of other latent nervous system infections such as neurosyphilis, herpes simplex virus, and toxoplasmosis has been well characterized in advanced HIV and may lead to neuropathic peripheral or central pain syndromes.

Treatment of HIV-related peripheral neuropathy and neuropathic pain follows the usual course of management of neuropathic pain syndromes in general. However, in contrast to other neuropathic syndromes, such as postherpetic neuralgia and diabetic peripheral neuropathy, the neuropathic pain associated with HIV and HIV-related neuropathies has proved difficult to treat. In particular, the antiepileptic drug lamotrigine has been shown to be of benefit in refractory cases.

**IDIOPATHIC SENSORY POLYNEUROPATHY**

A significant number of patients will exhibit symptoms of peripheral neuropathic pain in a characteristic stocking-glove distribution without a definable causative agent. The disorder is estimated to occur in approximately 25% of those 65 years and older and in as many as 50% of those 85 and older. In many cases the disorder is characterized by loss of peripheral pain and temperature sensation. However, in a significant proportion of cases, complaints of burning, tingling, and symptoms of restless legs syndrome may predominate. This syndrome may be associated with difficulty ambulating, falls, and a reduction in quality of life. It is hypothesized that age-related changes in the peripheral nervous system may contribute to the development of age-related idiopathic sensory neuropathy. As is true for other sensory neuropathies, the symptoms are typically worse at night. This may lead to disrupted sleep and failed attempts at restoring sleep with therapy aimed toward minimizing insomnia. In most cases, physical examination reveals evidence of loss of pain and temperature sensation distally in the lower extremities. In more severe cases there may be loss of large-fiber sensation, with deficits in vibration and joint position sense. It is imperative to exclude vitamin deficiencies, insulin resistance, and incipient diabetes mellitus in the evaluation of these patients. Therapy is aimed toward achieving restorative sleep and minimizing awakenings secondary to pain. An antineuropathic agent, such as a tricyclic antidepressant or anticonvulsant given at bedtime, represents common first-line therapy. An open-label study using topical 5% lidocaine has demonstrated improvement in symptoms over baseline without significant adverse effects.

**SUBACUTE SENSORY NEURONOPATHY**

Sensory neuronopathy is a rare disorder characterized as an autoimmune response to antigens found on cells in the dorsal root ganglia. The disorder may also result from the effects of drugs or neurotoxins (cisplatin or pyridoxine). It is characterized by ataxia and sensory loss, frequently with painful dysesthesias beginning in the lower extremities and rarely in the upper extremities, trunk, or facial region. This disorder is slowly progressive and may not improve following immunotherapy aimed at removal of paraneoplastic or autoimmune antibodies. Sensory neuronopathy has most commonly been associated with small cell cancer of the lung, Sjögren’s syndrome, and the presence of anti-Hu antibodies. In addition to immunotherapy aimed at treatment of the primary disorder or tumor resection (if relevant), the goal of symptomatic therapy is reduction of the neuropathic pain components and prevention of a secondary pain syndrome through limb protection and ambulatory assistive devices. When the disorder is associated with toxin or drug exposure, treatment is typically limited to supportive measures and treatment of any neuropathic pain components.

**TABES DORSALIS**

Perhaps once the most commonly encountered chronic neuropathic pain condition, neurosyphilitic involvement of the dorsal root entry zone represents a classic neurologic pain disorder. The disorder is characterized by “lightning pain” involving the lower extremities. Similar pain may occur in the trunk, thorax, and abdomen. Tabetic pain may occur for brief periods (seconds or minutes) or last for several days. Occasionally, visceral involvement predominates, known as “visceral crises.” These crises are characterized by attacks of epigastric or pelvic pain accompanied by nausea and vomiting. Physical examination is remarkable for loss of sensory modalities distally in the lower extremities. There may also be significant ataxia, hypotonia, and dysautonomia. The neuropathologic hallmark of tabes dorsalis is inflammatory infiltrates along the dorsal roots with degeneration of the posterior columns. Therapy involves standard antibiotic therapy to eradicate the *Treponema pallidum* organism. Antineuropathic agents such as anticonvulsants and tricyclic antidepressants are used for symptomatic therapy. Argyll Robertson pupils (miotic pupils that are unresponsive to light but react with accommodation) are usually present. Though characteristic of the disorder, the classic finding of Charcot’s joints is the result of deep anesthesia caused by the disorder. Even though it is an important secondary complication of the neurologic syndrome, once the disorder has reached the stage of profound joint hypalgesia, the protective mechanism of pain (and therefore the need for aggressive therapy) has been severely attenuated.

**PAIN ASSOCIATED WITH SPINAL CORD DISORDERS**

Disorders of the spinal cord are commonly associated with pain. The causes and locations of the spinal cord disorders typically determine the need for surgical or medical management of the primary condition. Pain may be a prominent element in the manifestation of certain spinal cord disorders (e.g., acute spinal cord injury) or occur as a late effect of the disease or therapy (e.g., radiation treatment, tumor resection). The characteristics of the pain experience, variable findings, and secondary pain generators are common to all disorders of the spinal cord. In an effort to highlight the aspects of the pain associated with disorders of the spinal
cord, a few selected examples are discussed in the following sections. Table 25.4 summarizes the pain syndromes associated with spinal cord disorders.

**SPINAL CORD INJURY**

The incidence of traumatic spinal cord injury is difficult to establish since rates of 236 to 1009 per million new cases each year have been reported. Cripps and colleagues estimated the incidence of traumatic spinal cord injury in North America to be 39 new cases per million inhabitants per year and 15 new cases per million inhabitants per year in Western Europe. Longitudinal studies of patients with spinal cord injury have noted that 23% of persons with spinal cord injury report pain at 6 weeks; the proportion of patients with pain increases to 41% the year following the initial injury. After the acute injury, pain is commonly located in the areas with sensory loss, there may be deafferentation pain characterized by constant burning and aching. With lesions above the midthoracic level, the presence of pain caused by spasticity in the upper or lower extremities may predominate. Intense muscular spasms, jerks, and hypertonicity will commonly be associated with neuropathic pain complaints. The patient may have numerous regions of ongoing musculoskeletal pain, either resulting from the initial traumatic episode or aggravated by chronic disability.

The pain associated with spinal cord injury impairs quality of life in these individuals. It is significantly associated with disordered sleep, exercise, work, and activities of daily living. It may impair the patient’s ability to engage in social, recreational, and self-care activities. Treatment of pain following spinal cord injury tends to be directed toward the type of pain experience and tolerability of the agent relative to the patient’s medical history. Antineuropathic drugs such as gabapentin and other antiepileptics, tricyclic antidepressants, and topical local anesthetics may be of assistance in amelioration of the symptoms of neuropathic pain. Pain related to spasticity and myofascial pain are usually treated with oral muscle relaxants such as baclofen. In patients intolerant of or resistant to oral baclofen, intrathecal baclofen has proved efficacious in the control of chronic lower extremity spasticity. A retrospective study found the addition of intrathecal morphine to baclofen to have variable results in pain relief. Musculoskeletal pain associated with the initial trauma or with emerging disorders may respond to local anesthetic or corticosteroid injections, nonsteroidal anti-inflammatory drugs, and opioids.

**SYRINGOMYELIA**

Syringomyelia involves cavitation in the central canal of the spinal cord. It may have a post-traumatic (especially following hematomyelia), congenital (associated with Arnold-Chiari malformation), or postinfectious (associated with arachnoiditis) cause or may be associated with intramedullary spinal cord tumors. Post-traumatic syringomyelia involves the presence of new neurologic deficits above a previous level of paraplegia or quadriplegia. Increased levels of sensory loss, spasticity, and progressive atrophy may accompany increasing levels of neuropathic pain. Dissociated sensory loss describes the loss of pain and temperature sensation resulting from involvement of the crossing of spinothalamic second-order neurons, with sparing of dorsal column function. Worsening spasticity is attributable to increasing involvement of the descending corticospinal tracts. Atrophy and fasciculations indicate involvement of the anterior horn cell columns by the syrinx.

The pain associated with syringomyelia is generally neuropathic in nature. Patients with a cervical syrinx will have pain and numbness along multiple cervical root distributions (arm pain and dysesthesia) and often describe burning that may be associated with significant allodynia and hyperalgesia. Pain and temperature sensory loss may be associated with unrecognized trauma. Extension of the syrinx into the upper cervical region may be associated with ipsilateral facial pain caused by involvement of the descending trigeminal tract and nucleus. Thoracic syringomyelia will be manifested as neuropathic pain in a trunk or abdominal distribution, dissociated distal sensory loss, spasticity, and urinary retention. Lower thoracic syringomyelia will exhibit symptoms of
dysfunction of the conus medullaris, with prominent sacral neuropathic pain and urinary retention.

Treatment of syringomyelia may involve neurosurgical drainage of the syrinx or surgical resection of a spinal cord tumor (when present), or both. Syrinx drainage is primarily performed to limit neurologic progression; however, alleviation of central pain following drainage of the syrinx is not uncommon. Medical treatment of the central neuropathic pain associated with syringomyelia is often associated with only partial efficacy and a high frequency of treatment refractoriness. Treatment modalities include anticonvulsants, antidepressants, local anesthetics, spinal cord stimulation, and intrathecal drug administration.

**MULTIPLE SCLEROSIS**

Multiple sclerosis is a relapsing, remitting, and chronic progressive disorder involving central nervous system demyelination. The disease is characterized by acute exacerbations of neurologic deficits. These exacerbations are associated with acute inflammation of central myelin. Areas of prominent involvement include the optic nerves, periventricular white matter, brainstem, and spinal cord. Estimates have suggested that more than 50% of patients who have the chronic form of multiple sclerosis also experience chronic pain. Because of the chronic nature of the disorder and multiple sites of neurologic involvement, a multidisciplinary approach is recommended for optimizing outcomes. Box 25.1 summarizes the pain conditions associated with multiple sclerosis. Trigeminal neuralgia has a well-known association with brainstem demyelination in those with multiple sclerosis. Sharp, lancinating facial pain may occur spontaneously or may be evoked by tactile stimulation. An uncommon finding in the idiopathic disorder, trigeminal sensory loss is more common in patients with multiple sclerosis. During acute exacerbations of multiple sclerosis, patients may have significant axial spine pain or radicular pain caused by demyelination along the dorsal root entry zones. Cervical demyelination may be associated with acute neck pain and electric shock–like pain along the axial spine (Lhermitte’s phenomenon). Following an acute exacerbation, patients may typically be left with a neurologic deficit that could include spasticity, ataxia, and sensory loss. Following acute transverse myelitis, patients with persistent neurologic deficits often have lingering central neuropathic pain. The pattern of the neuropathic pain is similar to that described for spinal cord injury. Elements of deafferentation pain, end-zone pain, and chronic radicular pain may be present concomitantly or individually in a patient with multiple sclerosis.

The types of secondary pain experienced by patients with multiple sclerosis include chronic myofascial pain related to spasticity and sleep deprivation, chronic headaches, and musculoskeletal pain related to disability. With the increasing burden of disease, it is likely that the intensity, locations, and complexity of the pain in multiple sclerosis progress, along with the neurologic disorder. The pain has a significant impact on psychosocial functioning, daily activities, mood, and sleep.

Treatment of chronic pain in multiple sclerosis involves alleviation of the primary neuropathic pain with a contemporary pharmacologic regimen and referral for specific immunotherapy during periods of acute exacerbation. Concomitant myofascial pain may be treated effectively with oral muscle relaxants such asbaclofen and tizanidine. The use of intrathecal baclofen for chronic lower extremity spasticity is recognized as an effective therapy in patients with an incomplete response to oral therapy. When intrathecal baclofen and morphine are combined, the pain and spasticity in multiple sclerosis can be effectively treated long-term. In ambulatory patients, a regular exercise regimen may be of benefit in alleviating diffuse myofascial pain symptoms. Concomitant sleep disorders and depression should be addressed and treated by nonpharmacologic means (e.g., sleep hygiene measures, cognitive-behavioral therapy if required) and pharmacologic modalities when appropriate.

### Box 25.1 Pain Conditions Associated with Multiple Sclerosis

**Neuropathic Pain**
- Acute transverse myelitis
- Acute radicular pain
- Chronic myelopathy (deafferentation pain, transitional pain, radicular pain)
- Focal peripheral neuropathies (secondary to disability)

**Myofascial Pain**
- Spasticity secondary to myelopathy
- Regional myofascial pain (overuse syndromes, posture and gait disorders)
- Diffuse myofascial pain (chronic fatigue, sleep deprivation)

**Musculoskeletal Pain**
- Overuse syndromes (wheelchair-bound patients)
- Accelerated osteoporosis because of immobility

**Headaches**

**PAIN IN NEUROMUSCULAR DISORDERS**

Neuromuscular disorders describe a heterogeneous group of neurologic conditions associated with diseases of the peripheral motor nerves, neuromuscular junction, muscles (muscular dystrophies, myopathies), and anterior horn cells. In a large series of patients with postpolio syndrome, a large proportion of patients (80%) reported muscular and joint pain. The common feature in these conditions is the notable loss of muscle power and tone and the presence of muscular atrophy. Syndromes with slow progression over time are characterized by disorders of ambulation, which may lead to chronic disability and incapacitation. With progression of the disease, there may be concomitant musculoskeletal pain associated with the loss of neuromuscular support of the axial spine and pelvic and shoulder girdles. As is common in other chronic pain syndromes, the pain may be associated with significant psychosocial
distress and with mood and sleep disorders. In patients with neuromuscular disorders, muscle and joint pain predominates. Patients with mixed peripheral nervous system disorders may also have a component of neuropathic pain. In addition, neuropathic pain may be incited by peripheral nerve entrapment, which may be considered to be a secondary pain disorder caused by chronic disability and loss of muscular protection over sites of neural compression.

**BRAIN CENTRAL PAIN SYNDROMES**

In addition to lesions of the spinal cord, lesions of the brain or brainstem may lead to neuropathic central pain. Tumors, vascular malformations, inflammatory diseases (postinfectious encephalomyelitis, meningitis abscess), intracerebral hemorrhage, and stroke may be associated with the development of chronic pain, which therefore depends chiefly on the site of the lesion in the central nervous system, not on the size of the lesion or the specific pathology. The neuroanatomic substrate for brain central neuropathic pain involves a lesion along the somatosensory pathways in the brainstem trigeminothalamic pathways, medial lemniscus, thalamus, thalamocortical projections, and somatosensory cerebral cortex. The classic and most characteristic central neuropathic pain condition is central post-stroke pain.

Central post-stroke pain is estimated to occur in approximately 10% of individuals after the first year following a stroke. Post-stroke pain was characterized by Dejerine and Roussy (in 1906) following lesions of the somatosensory thalamus. Post-stroke pain typically coexists with a concomitant contralateral sensory deficit. The pain may emerge weeks or even months following the initial vascular event. The pain may be described as diffuse burning or aching, interspersed with episodes of spontaneous lancinating or sharp pain. Remarkably, there may be a very mild motor deficit in comparison to the significant pain and hemihypoaesthesia. Patients with brainstem infarctions, particularly lateral medullary infarcts (Wallenberg’s syndrome), may also be affected with central neuropathic pain. Ipsilateral neuropathic facial pain may coexist with contralateral sensory deficits and central neuropathic pain.

Recognition of central neuropathic pain following a lesion of the central nervous system is important to minimize the disability and disruption in quality of life that may accompany a chronic, yet static neurologic disorder. Attention to secondary pain disorders such as a frozen shoulder following stroke, decubitus ulcers, and muscular spasticity is important in assessment of the pain. Pharmacologic management of central post-stroke pain often provides incomplete or partial results. Antidepressants may be indicated for treatment of the neuropathic pain in addition to a concomitant mood disorder. Antiepileptics and tricyclic antidepressants may be of benefit for the relief of lancinating sharp pain and constant burning pain. Centrally acting muscle relaxants such as baclofen or tizanidine are important adjuvant therapies when a concomitant pain syndrome is produced by muscular spasticity. The pharmacologic management of central post-stroke pain has recently been reviewed.

**PAIN IN MOVEMENT DISORDERS**

Movement disorders are characterized as slowly progressive disorders of the motor system that have the primary component of dysfunction in the execution of normal motor function—hence the term movement disorders. Clinical symptoms of movement disorders involve abnormalities in gait, coordination, fine motor control, and muscular tone. Movement disorders may be the result of dysfunction in numerous deep brain regions known as the basal ganglia. These regions include the globus pallidus, putamen, caudate nucleus, substantia nigra, subthalamic nucleus, and motor nuclei of the thalamus. Certain movement disorders are characterized by dysfunction secondary to neuronal loss in specific brain regions, such as the loss of dopamine-producing cells in the substantia nigra in patients with idiopathic Parkinson’s disease. Loss of important components of motor system control in the movement disorders may lead to secondary dysfunction in other deep brain nuclei because of the loss of specific inhibitory or facilitatory neural input. Causes of movement disorders include genetic syndromes, toxin- and drug-induced disorders, post-traumatic states, and post-stroke syndromes. However, the cause of most movement disorders remains elusive, but improved understanding of acquired genetic factors coupled with environmental influences has enhanced our understanding of the pathogenesis of many of the movement disorders.

**PARKINSON’S DISEASE**

First described by James Parkinson in 1817, Parkinson’s disease is a slowly progressive movement disorder characterized by resting tremor, rigidity, and bradykinesia. The incidence of idiopathic Parkinson’s disease ranges from 5 to 20 per 100,000 persons per year. It typically occurs in older individuals with a variable pattern of progression. It may progress over a decade and result in rigid immobility or assume a more indolent course of slow progressive loss of motor control over several decades. The symptoms of Parkinson’s disease have been ameliorated by the advent of dopaminergic agents, which significantly improve the symptoms of bradykinesia and rigidity.

With progression of the disease, patients typically have significant motor fluctuations with “on” periods of relative ease of movement interspersed with “off” periods of rigidity, bradykinesia, and tremor. It is during the off periods when many patients with Parkinson’s disease experience pain. The pain may be described as muscular tightness and cramping. Accompanying pain symptoms may also take the form of restless legs syndrome and peripheral dysesthesias. It is estimated that pain occurs in more than 50% of patients with Parkinson’s disease. Treatment of the underlying pain involves obtaining a careful history of the motor fluctuations and accompanying sensory phenomena. The motor symptoms are best treated with dopaminergic agents, whereas the sensory manifestations may require treatment with antineuropathic agents such as anticonvulsants or tricyclic antidepressants. Secondary pain complaints may be proactively managed by symptomatic treatment of arthralgias, management of concomitant osteoarthritis, and prevention of falls.
DYSTONIA

Dystonia describes a heterogeneous group of movement disorders characterized by disordered control of muscle groups. It is typically related to the simultaneous contraction of agonist and antagonist muscle groups. Dystonias are classified according to the extent of neuromuscular involvement—focal, segmental, multifocal, or generalized. Causes of dystonia include several hereditary syndromes and postinfectious, post-traumatic (usually following peripheral nerve trauma), and idiopathic forms. Clinical examples of syndromes of dystonia include those characterized by abnormal posturing of the trunk (torsion dystonia) or head and neck (cervical dystonia). Pain is a prominent feature of the dystonias and occurs as a result of sustained muscle contraction (intracellular acidosis). In most cases, treatment of dystonia includes dopaminergic agents, anticholinergic agents, muscle relaxants (e.g., baclofen), and benzodiazepines. In focal dystonias, especially idiopathic cervical dystonia, the use of locally injected botulinum toxin has resulted in significant symptomatic benefit and is the first-line therapy.

INTRODUCTION

The phenomenon of phantom limbs has probably been known since antiquity, but the first medical descriptions were not published until the 16th century. Historically, Silas Weir Mitchell (1829-1914) is credited with coining the term **phantom limb**, and more than anyone else, Mitchell brought phantom limbs to the attention of the medical community (for a historical review, see Finger and Hustwit1). Tragically, over the past several decades, wars and land mine explosions in many parts of the world have been responsible for numerous cases of traumatic amputation. In Western countries, the main reasons for amputation are diabetes and peripheral vascular disease in elderly people. The mechanisms underlying pain in amputees are still not fully understood, and although a large number of treatments have been suggested, the results of treatment are often poor. Phantom phenomena may also occur following the amputation of other body parts, such as the breast and rectum, but the present chapter focuses on the clinical characteristics, mechanisms, possible preventive measures, and treatment of phantom pain after limb amputation.

It is useful to distinguish between several elements of the phantom complex:

- **Phantom pain**: painful sensations referred to the missing limb
- **Phantom sensation**: any sensation in the missing limb except pain
- **Stump pain**: pain referred to the amputation stump

There is an overlap between these elements, and in the same individual, phantom pain, phantom sensations, and stump pain often coexist.

CLINICAL CHARACTERISTICS OF PHANTOM LIMP PAIN

### PREVALENCE

The prevalence of phantom pain shows great variability in the literature. Early studies reported figures in the range of 2% to 4%, but most recent studies agree that 60% to 80% of patients experience phantom pain following amputation (see Table 26.1 for details). The prevalence is probably not influenced by age in adults, gender, side, or level and cause (civilian versus traumatic) of the amputation.2,5 However, a recent prospective study of 85 amputees showed that female gender and upper limb amputation were associated with a higher risk for phantom pain.6 Phantom pain is less frequent in very young children and congenital amputees.7,8

### TIME COURSE

Prospective studies in patients undergoing amputation, mainly because of peripheral vascular disease, have shown that the onset of phantom pain is usually within the first week after amputation.3,10-12 The appearance of phantom pain may, however, be delayed for months or even years.13 The prevalence of phantom pain often remains the same over the years, but the severity and intensity of phantom pain attacks generally decrease with time.

### INTENSITY AND FREQUENCY

Although phantom pain is present in 60% to 80% of amputees, the number of patients with severe pain is substantially smaller and in the range of 5% to 15%. In a prospective study of lower limb amputees, the mean intensity of pain 6 months after amputation was 22 (range, 3 to 82) on a visual analog scale (VAS, 0 to 100).11 Similar results were found in another prospective study.10 The pain is usually intermittent and only a few patients are in constant pain. Episodes of pain attacks are most often reported to occur daily or at daily or weekly intervals.7,12,15

### LOCALIZATION AND CHARACTER

Phantom pain is primarily localized to the distal parts of the missing limb. In upper limb amputees, pain is normally felt in the fingers and palm of the hand, and in lower limb amputees, it is generally experienced in the toes, foot, or ankle.5,11,16,17 Phantom pain is often described as shooting, pricking, and burning. Other terms used are stabbing, pricking, pins and needles, tingling, throbbing, cramping, and crushing. Some patients have vivid descriptions, such as “a hammer is slammed at my calf” and “ants are crawling around inside my foot.”11

### FACTORS AFFECTING PHANTOM LIMP PAIN

#### PREAMPUTATION PAIN

Some retrospective studies have pointed to preamputation pain as a risk factor for phantom pain.2,18,19 Houghton and colleagues found a significant relationship between preamputation pain and phantom pain in the first 2 years after amputation in vascular amputees, but in traumatic amputees, only phantom pain immediately after the amputation was related to preamputation pain.2 The relationship between preamputation pain and phantom pain...
has also been confirmed by prospective studies. In a prospective study by Nikolajsen and associates, a relationship between preamputation pain and phantom pain was found 1 week and 3 months after the amputation. However, phantom pain never developed in some patients with severe preamputation pain, whereas severe phantom pain developed in others with only modest preoperative pain. Another question is to what extent the pain experienced before amputation may “survive” as phantom pain. In a retrospective study by Katz and Melzack, 68 amputees were questioned about preamputation pain and phantom pain from 20 days to 46 years after amputation. Fifty-seven percent of those who had experienced preamputation pain claimed that their phantom pain was a replicate of the pain that they had before the amputation. The number of patients with similar descriptions of preamputation pain and phantom pain was, however, much lower in two prospective studies. In the study by Nikolajsen and associates, the character and localization of pain were recorded before and at specific time intervals after the amputation. Although 42% of patients claimed that their phantom pain was a replicate of the pain that they experienced before the amputation, the degree of similarity between preamputation and postamputation descriptions of pain was not higher in patients who claimed similarity than in those who claimed no similarity between phantom pain and preamputation pain. Thus, retrospective memories about pain should be judged carefully. It is likely that the pain experienced preoperatively may resemble the phantom pain in some patients, but this is not the case in the vast majority of patients.

**PSYCHOLOGICAL FACTORS**

Amputation of a limb is a traumatic experience, and many amputees exhibit a range of psychological symptoms such as depression, anxiety, grief, and self-pity. In a survey of 914 amputees, depressive symptoms were shown to be a significant predictor of the intensity of phantom pain. As in other chronic pain conditions, coping strategies influence the experience of pain. Passive coping strategies, especially catastrophizing, are associated with phantom limb pain. Other psychosocial factors, such as social support, also play an important role in the adjustment to phantom pain.

**OTHER FACTORS**

Phantom pain may be modulated by several other internal and external factors such as attention, distress, coughing, urination, and manipulation of the stump. It is unclear whether the use of a functionally active prosthesis, as opposed to a cosmetic prosthesis, reduces phantom pain. Both experimental and clinical studies have shown that there is a significant genetic contribution to the development of chronic pain, including neuropathic pain after nerve injury.

It has been claimed that phantom pain may be provoked by spinal anesthesia in lower limb amputees. However, Tessler and Kleiman prospectively investigated 23 spinal anesthetics in 17 patients with previous lower limb amputations and found that phantom pain developed in only 1 patient but resolved in 10 minutes.

</table>

PHANTOM SENSATIONS

Phantom sensations are more frequent than phantom pain and are experienced by nearly all amputees (see Table 26.1 for details). Phantom sensations do not usually pose a major clinical problem; however, more than 30% of amputees may find these sensations moderately to severely bothersome. The two phenomena are strongly correlated. In a study by Kooijman and associates, phantom pain was present in 36 of 37 upper limb amputees with phantom sensations but in only 1 of 17 without phantom sensations. Similar to phantom pain, nonpainful sensations usually appear within the first days after amputation. Immediately after amputation, the phantom limb often resembles the preamputation limb in shape, length, and volume. Over time, however, the phantom fades, with sensation of the distal parts of the limb disappearing. For example, upper limb amputees may feel their hand and fingers, and lower limb amputees may feel their foot and toes. Telescoping (shrinkage of the phantom) is reported to occur in about a third of patients. The phantom gradually approaches the amputation stump and eventually becomes attached to it (Fig. 26.1).

STUMP PAIN

Stump pain is common in the early postamputation period. In a prospective study that included 54 lower limb amputees, all patients experienced some stump pain in the first week after amputation, with a median intensity of 15.5 (range, 0 to 61) on a 0 to 100 VAS. Stump pain can, however, persist beyond the stage of postsurgical healing. The prevalence of chronic stump pain varies in the literature, but severe pain is probably seen in only 5% to 10% of cases (see Table 26.1 for details).

Stump pain may be described as pressing, throbbing, burning, squeezing, or stabbing. Some patients have spontaneous movements of the stump ranging from slight, hardly visible jerks to severe contractions. Careful sensory examination of the amputation stump may reveal areas with sensory abnormalities such as hypoesthesia, hyperalgesia, or allodynia.

Similar results have also been found in more recent studies.

MECHANISMS OF PHANTOM PAIN

The mechanisms underlying phantom limb pain are not completely understood. However, it is now clear that nerve injury is followed by a number of morphologic, physiologic, and chemical changes in both the peripheral and central nervous system and that all these changes are likely to play
a role in the induction and maintenance of phantom limb pain. The first events are likely to occur in the periphery, which subsequently generates a cascade of events that sweep more centrally until cortical brain structures are finally recruited. The involvement of cortical structures may be responsible for the complex and vivid characteristics of certain phantom phenomena. The following three sections present a brief overview of peripheral, spinal, and supraspinal mechanisms.

**PERIPHERAL MECHANISMS**

Both experimental and clinical studies confirm that mechanisms in the periphery (i.e., in the stump or in dorsal root ganglion [DRG] cells) play a role in the phantom limb concept. Following a nerve cut, the formation of neuromas is seen universally. Such neuromas show abnormal spontaneous and evoked activity after mechanical or chemical stimulation. The ectopic and increased spontaneous and evoked activity from the periphery is assumed to be the result of an increased and also de novo expression of sodium channels.

Percussion of the stump or of the identified stump neuromas induces stump and phantom pain. In a classic microneurographic study of two amputees, Nyström and Hagbarth showed that tapping of neuromas was associated with increased activity in afferent C fibers and increased phantom pain sensation. However, in a more recent study showed that there is an inverse correlation between phantom pain intensity and pressure pain threshold of the stump early after amputation. Injection of local anesthetic into the stump may reduce or abolish the phantom pain and tap-evoked pain temporarily.

It has been claimed that surgical removal of a neuroma abolishes phantom pain. For example, Sehirlioglu and colleagues described a woman who suffered from phantom limb pain following lower limb amputation at the age of 5 years. At the age of 65 years, the pain gradually disappeared, parallel to the evolution of cauda equina compression because of an intraspinal tumor. The phantom limb pain gradually reappeared after surgical removal of the tumor.

A very large number of experimental studies support the importance of spinal factors. After nerve injury there is an increase in the general excitability of spinal cord neurons, where C fibers and Aδ afferents gain access to secondary pain-signaling neurons. Sensitization of dorsal horn neurons is mediated by release of glutamate and neuropeptides. This sensitization may manifest itself in several ways, including reduced flexion reflex thresholds in response to noxious mechanical and thermal stimulation in the limb contralateral as well as ipsilateral to the injury, increased persistent neuronal discharges with prolonged pain after stimulation (wind-up phenomena), and expansion of peripheral receptive fields.

Some amputees show abnormal sensitivity to pressure and to repetitive stimulation of the stump with a von Frey filament. The pharmacology of spinal sensitization involves increased activity in N-methyl-D-aspartate (NMDA) receptor-operated systems, and many aspects of the central sensitization can be reduced by NMDA receptor antagonists. In human amputees, stump or phantom pain evoked by repetitive stimulation of the stump can be reduced by the NMDA antagonist ketamine.

**SUPRASPINAL MECHANISMS**

Amputation produces a cascade of events in the periphery and in the spinal cord. It is reasonable to assume that these changes will eventually sweep more centrally and alter neuronal activity in cortical and subcortical structures. Also, the phantom limb concept with its complex perceptual qualities and its modification by various internal stimuli (e.g., attention, distraction, or stress) shows the phantom image to be a product of the brain.

Animal studies have demonstrated functional plasticity of the primary somatosensory cortex after amputation. After dorsal rhizotomy, a lowered threshold to evoked activity in the thalamus and cortex can be demonstrated, and adult monkeys display cortical reorganization in which the mouth and chin invade cortices corresponding to the representation of the arm and digits that have lost their normal afferent input.

Studies in humans using different cerebral imaging techniques have also documented cortical reorganization after
amputation. In a series of studies, Flor’s group has shown a correlation between phantom pain and the amount of reorganization in the somatosensory cortex. Birbaumer and associates studied the effect of regional anesthesia on cortical reorganization in upper limb amputees and found that brachial plexus blockade abolished pain and reorganization in three of six amputees. Huse and coworkers showed in a small group of amputees that cortical reorganization and pain were reduced during treatment with morphine. In contrast to cases of traumatic amputation, in a group of four patients with congenital absence of a limb without a phantom, Reilly and Sirigu demonstrated that the motor cortex does not contain a representation of the missing limb in this patient group.

Changes have also been observed at subcortical levels. Using neuronal recording and stimulation techniques, it was shown that thalamic neurons, which do not normally respond to stimulation, begin to respond and show enlarged somatotopic maps in amputees. In addition to functional plasticity, structural alterations also follow amputation. Draganski and colleagues demonstrated a decrease in the gray matter of the thalamus in 28 amputees. The decrease was correlated with the time span after amputation and explained as a structural correlate of the loss of afferent input.

The idea of using perioperative analgesic interventions to prevent the development of phantom limb pain was prompted by the observations that (1) phantom pain is in some cases a replicate of the pain experienced before the amputation and (2) pain before the amputation increases the risk for postamputation phantom pain. These observations led to the theory that preamputation pain creates an imprint in memorizing structures of the central nervous system and that such an imprint could be responsible for persistent pain after amputation.

**Epidural Interventions**

Bach and associates carried out the first study on prevention of phantom pain: 25 patients were randomized to receive either epidural bupivacaine and morphine for pain relief for 72 hours before the amputation (11 patients) or conventional analgesics (14 patients). All patients underwent spinal or epidural analgesia for the amputation, and both groups received conventional analgesics to treat postoperative pain. Blinding was not described. After 6 months the incidence of phantom pain was lower in patients who had received the preoperative epidural blockade.

Jahangiri and coworkers examined the effect of perioperative epidural infusion of diamorphine, bupivacaine, and clonidine on postamputation stump and phantom pain. Thirteen patients received the epidural treatment 5 to 48 hours preoperatively and for at least 3 days postoperatively. A control group of 11 patients received opioid analgesia on demand. All patients underwent general anesthesia for the amputation. The incidence of severe phantom pain was lower in the epidural group 7 days, 6 months, and 1 year after amputation. The study was not randomized or blinded.

Nikolajsen’s group carried out a randomized, double-blind, placebo-controlled study in which 60 patients scheduled for lower limb amputation were randomly assigned to one of two groups: a blockade group that received epidural bupivacaine and morphine before and during the operation (29 patients) and a control group that received epidural saline by the same regimen and oral or intramuscular morphine preoperatively (31 patients). Both groups underwent general anesthesia for the amputation, and all patients received epidural analgesics for postoperative pain management. Patients were interviewed about preamputation pain on the day before the amputation and about stump and phantom pain after 1 week and 3, 6, and 12 months. The median duration of the preoperative epidural blockade (blockade group) was 18 hours. After 1 week, 51.9% in the blockade group and 55.6% in the control group reported phantom pain. Subsequently, the figures (blockade/control) were 82.4%/50% at 3 months, 81.3%/55% at 6 months, and 75%/68.8% at 12 months (difference not significant). The intensity of stump and phantom pain and consumption of opioids were also similar in the two groups at all four postoperative interviews.

In a retrospective review of 150 amputees, no difference was found in the incidence of phantom pain 24 months after the amputation in those who had received epidural, spinal, or general anesthesia for the amputation.

In a recent study, Karanikolas and colleagues described 65 patients undergoing lower limb amputation who were assigned to five treatment groups in a prospective randomized trial: (1) preoperative and postoperative epidural analgesia and epidural anesthesia for surgery; (2) preoperative intravenous patient-controlled analgesia (PCA), postoperative epidural analgesia, and epidural anesthesia for surgery; (3) preoperative and postoperative intravenous PCA and epidural anesthesia for surgery; (4) preoperative and postoperative intravenous PCA and general anesthesia for surgery; and (5) controls—conventional analgesia and general anesthesia. Epidural analgesia or intravenous PCA was initiated 48 hours preoperatively and continued for 48 hours postoperatively. At the 6-month follow-up, the prevalence of phantom limb pain was significantly lower in groups 1 (7.7%), 3 (30.7%), and 4 (23%) than in group 5 (75%), thus showing that perioperative management may affect the phantom pain outcome.

**Peripheral Regional Anesthesia**

The effect of perineural or intraneural blockade on phantom pain was examined in a few studies. Fisher and Meller introduced a catheter into the transected nerve sheath at the time of amputation and infused bupivacaine for 72 hours in 11 patients. Phantom pain did not develop in any patients during a 12-month follow-up. Two retrospective studies have found negative and positive effects, respectively, of a similar treatment. Pinzur and associates prospectively randomized 21 patients to receive a continuous postoperative infusion of either bupivacaine or saline at the transected end of the sciatic or posterior tibial nerve but failed to find any difference between the two groups with regard to the incidence of phantom pain after 3 and 6 months.

Lambert and associates compared two techniques of regional analgesia: 30 patients were randomized to treatment via an intraoperatively placed perineural catheter for
intraoperative and postoperative administration of bupivacaine or epidural bupivacaine and diamorphine started 24 hours before the amputation and continued for 3 days postoperatively. All patients underwent general anesthesia for the amputation. The preoperative, perioperative, and postoperative epidural pain treatment was not superior to the intraoperative and postoperative perineural pain treatment in preventing phantom pain since the incidence of phantom pain was similar in the two groups after 3 days and 6 and 12 months.79

In a recent study, interesting results have been reported following a prolonged infusion of local anesthetics via a perineural catheter. Seventy-one patients received a perineural infusion of 0.5% ropivacaine for a median period of 30 days (range, 4 to 83 days) after the amputation. The infusion of ropivacaine was discontinued at regular intervals but restarted if the intensity of phantom pain exceeded 1 on a 5-point verbal scale. The incidence of severe to intolerable phantom pain was only 3% after 12 months.80

**SYSTEMIC INTERVENTIONS**

A few studies have examined the effect of medical interventions in the perioperative and postoperative period. In an observational open study with historical controls, Dertwinkel and colleagues suggested that intravenous ketamine infused intraoperatively and for 72 hours after amputation could reduce phantom pain.81 A randomized, double-blind trial including 43 patients found no effect of a similar treatment.82

In another double-blind study, 19 patients with acute traumatic amputation of the upper extremity were randomized to either oral memantine, 20 to 30 mg daily, or placebo for 4 weeks after amputation. All patients received continuous postoperative brachial plexus analgesia. Memantine treatment reduced phantom pain after 4 weeks and 6 months, but not after 12 months.83

Nikolajsen and associates randomized 46 lower limb amputees to either oral gabapentin or placebo for the first 30 days after amputation. The first dose of 300 mg gabapentin or placebo was given on the first postoperative day, and the dosage was gradually increased until a maximum of 2400 mg/day was reached. The intensity, frequency, and duration of phantom pain attacks were recorded daily in the first 30 days and after 3 and 6 months. The intensity of stump pain was also recorded and sensory testing of the stump was performed. The two treatment groups were similar in almost all outcome parameters. Thus, early and prolonged treatment with gabapentin did not seem to reduce the incidence of phantom pain.84

In conclusion, perioperative interventions, such as epidurals, other nerve blocks, and systemic treatments, are effective in the treatment of immediate postoperative stump pain. However, it is evident that more well-designed controlled trials are necessary to further evaluate the potential for different perioperative treatment regimens to reduce chronic phantom pain (for a review of studies on the prevention of phantom pain see Ypsilantis and Tang85).

**TREATMENT**

Treatment of chronic pain after amputation, in particular, treatment of phantom pain, represents a major challenge to the clinician. There is not much evidence from randomized trials to guide clinicians in treatment, and most studies dealing with phantom pain suffer from major methodologic limitations: samples are small, randomization and blinding are either absent or inappropriate, controls are often lacking, and follow-up periods are short. Halbert and colleagues performed a systematic literature search (Medline 1966 to 1999) to determine the optimal management of phantom pain. The authors identified 186 articles, but after exclusion of letters, reviews, descriptive trials without intervention, case reports, and trials with major methodologic errors, only 12 articles were left for review.86 The most recent Cochrane systematic review on pharmacologic management of phantom limb pain87 resulted in just 13 eligible studies with a total of 255 amputees. The authors’ conclusion was that data from the studies included were not sufficient to support any particular medication for established phantom limb pain. Table 26.2 shows selected studies on the treatment of phantom pain.

**MEDICAL TREATMENT**

**TRICYCLIC ANTIDEPRESSANTS**

At least two studies have examined the effect of tricyclic antidepressants on phantom pain. In one study, 39 patients were randomized to receive either amitriptyline or active placebo during a 6-week trial period. The dosage of amitriptyline was increased until the patient reached the maximum tolerated dose of 125 mg/day. However, the study showed no effect of amitriptyline on pain intensity or secondary outcome measures such as satisfaction with life.88 In the other study, 49 traumatic amputees were randomized to receive amitriptyline (mean dose of 55 mg/day), tramadol (mean dose of 448 mg/day), or placebo for 1 month. The administration of tramadol and placebo was blinded; amitriptyline was given nonblinded as an open comparison. Nonresponders (less than 10-mm pain relief on a VAS from baseline to day 3) were switched to the alternative active treatment, that is, tramadol to amitriptyline treatment and vice versa. Placebo nonresponders were switched to tramadol or amitriptyline. Both tramadol and amitriptyline had almost abolished stump and phantom pain at the end of the treatment period.89

**GABAPENTIN AND PREGABALIN**

The effect of gabapentin on established phantom limb pain has been examined in two studies. Bone’s group examined the effect of gabapentin in a double-blind crossover study that included 19 patients with phantom pain. The dose of gabapentin was titrated in increments of 300 mg to the maximum dosage of 2400 mg/day. After 6 weeks of treatment, gabapentin was better than placebo in reducing phantom pain.90 Smith and associates administered gabapentin or placebo for 6 weeks to 24 amputees in a double-blind, crossover fashion with a maximum dose of 3600 mg/day. Gabapentin did not decrease the intensity of pain significantly, but the participants rated the decrease in pain as more meaningful during the treatment period with gabapentin.91 Thus far, the effect of pregabalin on phantom pain has not been examined in controlled trials.

**OPIOIDS**

Failure to provide efficient pain relief should not be accepted until opioids have been tried. In a placebo-controlled, crossover study that included 12 patients, a significant reduction in phantom pain was found during a 4-week treatment phase with oral morphine. In another randomized, double-blind, active placebo-controlled, crossover study, 31 amputees received a 40-minute infusion of lidocaine, morphine, or diphenhydramine. When compared with placebo, morphine reduced both stump and phantom pain, whereas lidocaine reduced only stump pain. The same group examined the effect of oral treatment with morphine, mexiletine, or placebo in 60 amputees during an 8-week treatment period. Postamputation pain was significantly reduced during treatment only with morphine.
NMDA RECEPTOR ANTAGONISTS

The effect of NMDA receptor antagonists has been examined in different studies. In a double-blind, placebo-controlled, crossover trial, intravenous ketamine reduced pain, hyperalgesia, and wind-up-like pain in 11 amputees with stump and phantom pain.\(^{37}\) Eichenberger and colleagues studied the effect of a 1-hour infusion of ketamine alone, a combination of ketamine and calcitonin, calcitonin alone, and placebo in 20 amputees with phantom pain. Ketamine alone significantly reduced phantom pain. Its combination with calcitonin provided no additional effect, and calcitonin alone had no effect on pain.\(^ {94}\) Four other trials have examined the effect of memantine, an NMDA receptor antagonist available for oral use. In all studies, memantine was administered in a blinded, placebo-controlled, crossover fashion to patients with established stump and phantom pain. Memantine at doses of 20 or 30 mg/day failed to have any effect on spontaneous pain, allodynia, and hyperalgesia.\(^ {95-98}\)

OTHER DRUGS

Calcitonin significantly reduced phantom pain when used intravenously in the early postoperative phase in one study.\(^ {99}\) However, a more recent study found no effect of such a treatment.\(^ {94}\) A large number of other treatments, such as dextromethorphan, topical application of capsaicin, intrathecal opioids, various anesthetic blocks, injections of botulinum toxin, and topiramate, have been claimed to be effective in relieving phantom pain, but none of them have proved to be effective in well-controlled trials with a sufficient number of patients. In a recent controlled trial of botulinum toxin versus lidocaine/methylprednisolone injections, neither of the treatments reduced the intensity of phantom limb pain at up to 6 months’ follow-up.\(^ {100}\) In another recent study with a crossover design, phantom pain was attenuated by injection of bupivacaine into the contralateral painful muscle areas under study.\(^ {101}\) Sympathetic blocks may also reduce phantom pain, but only for a limited time after the injection.\(^ {49}\)

NONMEDICAL TREATMENT

A recent survey of treatments used for phantom pain revealed that after pharmacologic treatment, physical therapy was the treatment modality most often used.\(^ {102}\) Physical therapy involving massage, manipulation, and passive movements may prevent trophic changes and vascular congestion in the stump. Other treatments, such as transcutaneous electrical nerve stimulation (TENS), acupuncture, biofeedback, and hypnosis, may in some cases have a beneficial effect on stump and phantom pain. A recent Cochrane systematic review failed to find any controlled study on the effectiveness of TENS for the treatment of phantom pain and stump pain. It has been suggested that mirror therapy can reduce phantom pain.\(^ {104,105}\) In a larger clinical trial of 80 amputees, however, Brodie and associates failed to find any significant effect of mirror treatment.\(^ {106}\) Flor’s group demonstrated that sensory-discriminative training involving the application of stimuli to the stump reduced pain in five upper limb amputees.\(^ {107}\) The advantage of most of the aforementioned methods is the absence of side effects and complications and the fact that the treatment can easily be repeated. However, most studies are mainly observational.

SURGICAL AND OTHER INVASIVE TREATMENTS

Surgery on amputation neuromas and more extensive amputations previously played important roles in the treatment of stump and phantom pain. Today, stump revision is performed only in cases of obvious stump pathology; in properly healed stumps there is almost never any indication for proximal extension of the amputation because of pain. In a recent prospective study of patients with neuropathic pain, including phantom pain, pain was relieved in only two of six patients following surgical neuroma removal.\(^ {46}\) The results of other invasive techniques such as dorsal root entry zone lesions, sympathectomy, and cordotomy have generally been unfavorable, and most of them have been abandoned. Surgery may produce short-term pain relief, but the pain often reappears. Spinal cord stimulation and deep brain stimulation may be used for the treatment of phantom limb pain.\(^ {108,109}\) Because the methods are invasive and associated with considerable cost, they should be used only for carefully selected patients. Until more clinical data become available, guidelines in analogy with the pharmacologic regimens used for other neuropathic pain conditions are probably the best approximation, especially for the treatment of stump pain.\(^ {110}\) A combination of medical and nonmedical treatment may be advantageous, and in general, treatment should be noninvasive. Surgery on the peripheral or central nervous system is always associated with further deafferentation and therefore an increased risk for persistent pain.

Central post-stroke pain (CPSP) syndrome is uncommon after stroke and occurs in only about 8% of patients. However, because of the common occurrence of stroke, CPSP is a major central neuropathic pain. The pain originates from the stroke lesion itself, which induces neuroplastic changes that result in disordered central nervous system (CNS) processing within the distributed sensory network. The first note of CPSP is attributed to Adolf Wallenberg in 1895 when he described a case of lateral medullary stroke, or Wallenberg’s syndrome. His case involved a 38-year-old man who suffered “vertigo without loss of consciousness.” Wallenberg reported that the man “developed pain and hyperesthesia of the left side of his face and body, hyperesthesiae of the right half of the face, and loss of pain and temperature sensitivity in the right extremities and right half of the torso.” In 1906, Dejerine and Roussy described a case of intractable pain following a thalamic stroke, which was then named the thalamic syndrome. Symptoms included persistent hemianesthesia, mild hemiataxia, severe persistent often intolerable pain unresponsive to treatment, and choreoathetoid movements, all found on the hemiplegic side of the body. In 1911, Head and Holmes, by using controlled stimuli in patients with spontaneous pain following stroke, determined that cortical lesions could not cause such pain without involvement of the thalamus.

Davison and Schick published 11 clinical-pathologic cases of spontaneous pain in 1935 that were associated with lesions in the thalamus, spinal cord, peripheral nerves, and cerebral cortex. It became clear from this review and other case studies that spontaneous pain may follow various lesions in the CNS. Riddoch wrote a summary of these findings and defined central pain as being spontaneous and associated with an over-reaction to stimulation as a result of lesions within the CNS. In 1969, Cassinari and Pagni determined that CPSP can result from a lesion anywhere along the spinothalamic and thalamocortical pathways and that involvement of these pathways is necessary for the development of CPSP. However, it must be recognized that pain does not always result from these lesions. Currently, it is recognized that cortical, subcortical, thalamic, and lateral brainstem strokes can all cause CPSP, in addition to sensory changes and impaired motor control and weakness, but pain is not always a necessary outcome.

Pain from any cause is common after stroke and occurs at an incidence of 14% to 43% in the acute and subacute stages of recovery. Among the many causes of post-stroke pain, CPSP is a less common etiology. More frequently, pain after stroke is a result of musculoskeletal processes, including hemiplegic shoulder pain, arthritis, myofascial disorders, and tendonitis. For this reason, the diagnosis of CPSP cannot be made without eliminating other possible causes of localized pain. In addition to the musculoskeletal causes, others include gout, deep vein thrombosis, complex regional pain syndrome, and painful spasms. Painful diabetic neuropathy is another form of neuropathic pain that can be seen in patients with stroke because of the close association between diabetes and cerebrovascular disease, but this pain is peripheral rather than central. Pain occurs in diabetic neuropathy with damage to Aδ and C fibers. Diabetic neuropathy is often accompanied by bilateral pain, whereas CPSP is almost always unilateral, and both conditions may occur simultaneously in patients with stroke. Although these two forms of neuropathic pain may respond to similar treatment, because of subtle differences in response to therapy, a careful diagnosis is critical.

In clinical practice, therefore, CPSP is a diagnosis of exclusion. The incidence of CPSP in patients with stroke is 8% in general and 9% after thalamic hemorrhage, but there is only a 5% incidence of moderate to severe pain. Onset of CPSP in the first days following the stroke is rare, but 63% of patients will have pain within the first month after stroke onset and nearly all the rest within a year.

Typically, a patient with CPSP will complain of severe pain on the side of the body contralateral to the lesioned hemisphere associated with sensory changes in the painful region. In the case of a lateral medullary stroke, the pain can be located in areas of sensory loss, which include the ipsilateral face and contralateral body. The pain associated with CPSP can be spontaneous or evoked. Spontaneous pain in some cases is episodic, whereas in others it may be continuous. Spontaneous pain is most commonly described as burning (47% to 59%) or aching (30% to 41%), often deep within the painful body area. Less commonly, a patient may complain of lacerating pain (7% to 26%) or pricking pain (6% to 30%). When pain is evoked, it can be caused by a nociceptive source that induces pain out of proportion to the stimulus (hyperpathia). Bovie and colleagues found that 59% of patients with CPSP had hyperalgesia in the painful region on pinprick testing, 37% had hypalgesia, and only
4% had a normal pinprick sensation. Patients with stroke lesions in the thalamus are more likely to report that pinprick sensation is hyperalgesic.

Pain can also be evoked by non-nociceptive sources (allodynia), but the actual clinical response to different nonpainful stimuli can vary. Most patients will have some allodynia on examination, but as many as a third will have none. Of those with allodynia, the majority will experience pain with limb movement (70%), although some find that movement relieves the pain (19%). Thermal and tactile stimulation can evoke pain or reduce it as well. Nearly half of patients will have pain with cold stimuli (48%), but a few find that cold reduces their discomfort (7%). A warm stimulus was found to increase pain in 22% and reduce it in another 30%. Frequently, patients will find that emotions increase pain (19%), and 37% achieve relief of pain with rest.

Just over half (52%) of patients with CPSP have no hemiplegia, and only 37% have moderate hemiplegia. Severe hemiplegia is less commonly associated (11%). On the other hand, ataxia is present in 62%, but choreoathetosis is found in only about 4%.

Establishing a definitive diagnosis of CPSP is difficult and requires a thorough clinical assessment, elimination of other causes of the pain, and cranial imaging to confirm the presence of an appropriate brain lesion. Klit and associates recommended that definitive criteria for CPSP require that the patient have a history of stroke with an associated lesion on imaging and that the pain have a plausible anatomic distribution both by history and physical examination. Before confirming the diagnosis of CPSP, other possible causes of the pain must be excluded (Box 27.1).

### PATHOPHYSIOLOGY

In lecture II of a series of lectures published in 1906 under the title “The Integrative Action of the Nervous System,” C.S. Sherrington introduced the division of sensory systems into an exteroceptive pathway and an interoceptive pathway. The exteroceptive pathway begins with receptors in the skin and muscle that transmit stimuli external to the body. This pathway can transmit both nociceptive and non-nociceptive stimuli, with nociceptive stimuli traveling along the spinothalamocortical tracts. Fibers in this conventional pathway ascend along the lateral spinothalamic tract through the thalamus to the motor cortex (M1) in the precentral gyrus.

The interoceptive pathway, in contrast, responds to signals originating within the body, such as the viscera, and travels along a distinct pathway called the lamina I spinothalamic cortical tract (Fig. 27.1). This pathway manages afferent signals that transmit information about the physiologic condition of the entire body and thereby modulates homeostasis, visceral pain, and thermoregulatory activity. Fibers along this tract ascend to the thalamus, which then provides a rich supply of afferent input to the insular cortex. The lamina I system also has input to the periaqueductal gray and parabrachial nucleus, which send signals to the anterior cingulate cortex via the thalamus. This input influences the emotional state of the individual. The insular cortex modulates this by providing inhibitory feedback to the periaqueductal gray and parabrachial nucleus (see Fig. 27.1). Lesions along either the exteroceptive or interoceptive pathway can result in reduced or altered sensation.

The pathophysiology of CPSP has not been clarified but probably results from maladaptive neuroplastic changes within the CNS that result in aberrant sensory perception. CPSP can be considered a kind of “deafferentation phenomenon” because lesions are located within the spinothalamic cortical pathway and probably resulting in maladaptive alterations in synaptic facilitation and inhibition. Less likely would be a type of “release phenomenon” in which lesions of thelemniscal pathway carrying nonpainful sensation leave

**Box 27.1** Diagnostic Criteria for Central Post-stroke Pain Syndrome

- Exclusion of other probable causes of the pain
- Pain with a distinct neuroanatomically plausible distribution
- A history suggestive of stroke
- Indication of a distinct neuroanatomic distribution by clinical examination
- Indication of a relevant vascular lesion by imaging

---

**Figure 27.1** The lamina I spinothalamocortical sensory (interoceptive) pathway, which has a role in modulating thermoregulatory activity, homeostasis, and visceral pain. Afferent signals reach the anterior cingulate gyrus via brainstem nuclei (periaqueductal gray and parabrachial nucleus) and the medial dorsal thalamus. The anterior cingulate gyrus along with the rest of the limbic system regulates the emotional state of the individual. Afferent information also reaches the insular cortex through the ventromedial thalamus, which in part functions as a negative feedback to the brainstem nuclei. Disruption of these connections plays an important role in central pain. (From Harvey RL. Central poststroke pain syndrome. Top Stroke Rehabil. 2010;17:163-172.)
the pain pathways and unbalanced pain signals are transmitted to the cortical centers.21 Because lemniscal injury is neither critical nor necessary for the development of CPSP, this later theory lacks much scientific support.15,16 Theories on the cause of CPSP are dependent on several concepts: first is that injury to the spinothalamocortical tracts is necessary; second, that the pain is a result of late neuroplastic changes within CNS; and third, that pain perception is linked closely to the emotional state of the individual and the behavioral drive that signals a homeostatic imbalance.20 For example, disruption of the negative feedback loop to the midbrain homeostatic structures (see Fig. 27.1) might lead to unopposed afferent input to the anterior cingulate gyrus. Activity in the cingulate gyrus is associated with emotional distress. The current theories for CPSP follow.

Central disinhibition: This theory suggests that CPSP is a result of a reduction in inhibitory neural activity at the cortical or thalamic level. In addition, pain may derive from reduced γ-aminobutyric acid (GABA) concentrations within the spinal cord or cerebral levels.

Central excitation: This theory proposes that pain is due to abnormal burst activity within the lateral and medial thalamic nuclei.

Thermosensory inhibition: In this theory, CPSP is proposed to be due to loss of descending inhibitory control from the interoceptive cortical structures, including the dorsal posterior insula on brainstem homeostatic sites such as the periaqueductal gray and parabrachial nucleus, which in turn will result in unabated thermoregulatory drive to the medial thalamus and the anterior cingulate cortex (see Fig. 27.1).

Abnormal central modulation: This theory suggests that there is a loss of central non-noxious temperature fibers along the lamina I spinothalamocortical pathway above the motor decussation. Loss of fibers in this tract would disrupt the capability of the CNS to modulate temperature perception, which could cause symptoms of allodynia.

Loss of aminergic modulation: If there is a general reduction in adrenergic and serotonergic modulation within the CNS, the function of the afferent pathways may be altered and result in greater perception of pain.

Alteration of the N-methyl-d-aspartate (NMDA)-glutamate system: Thalamocortical excitability might be enhanced by increased glutaminergic NMDA stimulation and result in changes consistent with long-term potentiation that enhance the perception of pain.

These different proposed mechanisms may all be involved in the development of CPSP, or different mechanisms may be involved. For example, some of the theories listed were formulated by considering the pharmacology of medications that have shown efficacy in treating CPSP, including their inhibitory, excitatory, or modulating effects on CNS activity. It is important to note that because there are a number of medications with different pharmacologic mechanisms and no single medication is completely effective, it is likely that CPSP has multiple physiologic causes associated with neuropharmacologic changes at multiple locations. In any one patient, multiple pain-inducing mechanisms may also be at play. This not only complicates our understanding of the etiology of CPSP but also complicates management as well.

Use of medication for the treatment of CPSP is part of the overall comprehensive approach to pain management, which also includes physical conditioning, modification of functional task performance, supportive counseling, and behavior modification. Thus, pharmacology is not used in isolation, especially since the clinical response to treatment with medications is literally “fifty-fifty.” That is, at best only about half the patients will derive any benefit from the medications prescribed, and those who do will have only about 50% relief of their symptoms. Medications useful in managing CPSP fall into five categories: membrane stabilizers, aminergic agents, glutamate antagonists, GABA agonists, and N-type calcium channel blockers (Box 27.2). When medications are used, it is recommended that one class be tried at a time and if one class fails, a medication from a different class be used for the next trial.

**PHARMACOLOGIC MANAGEMENT**

Anticonvulsants and antiarrhythmic agents provide a neural membrane-stabilizing effect that may have a tempering effect on CPSP. Carbamazepine was tested by Leijon and Bovie (along with amitriptyline and placebo) in a double-blind, three-phase, placebo-controlled crossover trial. Each of the three drugs was administered in a randomized manner over a period of 4 weeks separated by a 1-week washout in patients with CPSP.24 Carbamazepine had a modest, but not statistically significant, effect in reducing pain scores in 36% of patients with CPSP versus a 7% reduction during the placebo phase. Side effects of carbamazepine included vertigo, tiredness, and gait disturbance. Phenytoin has not been well studied for CPSP, but in a small study in which eight subjects had central pain associated with thalamic injury, three had improved pain scores and three others had worse pain. Intravenous lidocaine has the capacity to reduce pain associated with stroke, as demonstrated in a randomized, double-blind, crossover trial of lidocaine, 5 mg/kg administered over a 30-minute period; 62.5% of patients with central pain from spinal cord injury or stroke experienced a reduction in spontaneous pain and brush-induced or mechanical allodynia for 45 minutes following drug infusion.25 When placebo was given, only 37.5% of subjects had any reduction in spontaneous pain, and

**Box 27.2 Pharmacologic Management of Central Post-stroke Pain Syndrome**

| Membrane stabilizers: carbamazepine, intravenous lidocaine |
| Aminergic agents: amitriptyline, fluoxetine, duloxetine (a study showed a trend toward improved pain scores21)|
| Antiglutaminergic agents: ketamine, lamotrigine (a study showed a reduction in pain scores but no clear effect on evoked pain22) |
| γ-Aminobutyric acid agonists: oral baclofen may be efficacious |**N-type calcium channel blockers:** pregabalin, possibly gabapentin |
evoked pain was not affected. In another small case series, Edmonson and colleagues used intravenous boluses of lidocaine, 50 to 100 mg given over a 2-minute period. The four patients with CPSP reported reduced pain within 12 hours of drug administration. Lightheadedness is common during and after lidocaine infusion. Mexiletine is an oral antiarrhythmic similar to lidocaine but was not well tolerated in a clinical trial. Oral doses of mexiletine of between 400 and 800 mg daily improved pain in 30% to 88% of patients, but many stopped taking the medication because of side effects, including nausea, dyspepsia, chest pain, and tiredness. Thus, antiarrhythmic agents may have some efficacy in relieving CPSP, but the currently available drugs are impractical for clinical use. Presently, of the membrane-stabilizing agents, carbamazepine has the best, albeit limited efficacy.

**AMINERGIC AGENTS**

The aminergic agents include antidepressant medications that modify norepinephrine and serotonin centrally. Leigon and Bovie studied amitriptyline, a tricyclic antidepressant, in the placebo-controlled crossover trial mentioned in the last section. Given at a maximum dose of 75 mg daily, amitriptyline resulted in a reduction in pain scores in 67% of patients versus 7% during the placebo phase (P < 0.05) and outperformed carbamazepine in comparison. Patients experienced only mild side effects, including tiredness and dry mouth. An open-label trial of the serotonin-specific reuptake inhibitor fluvoxamine (25 to 125 mg) given over a period of 2 to 4 weeks resulted in 31 subjects experiencing a mean pain reduction of 22% on a visual analog scale (P < 0.01). Chronic stroke patients did not fare as well as those who were within 1 year of stroke onset. Duloxetine, a mixed serotonin and norepinephrine reuptake inhibitor, has also been studied in a randomized placebo-controlled trial lasting 8 weeks. At doses of 60 to 120 mg daily in patients with either stroke- or spinal cord–related pain, there was a trend toward improved pain scores on a visual analog scale, but a significant reduction in brush (P = 0.035) and cold (P < 0.001) allodynia. The pain disability index was not different between groups, but patients taking duloxetine had significant improvement in the bodily pain domain of the 36-item Short-Form Health Survey (SF-36). Duloxetine was associated with more somnolence. In all these studies on aminergic agents, the reduction in pain was independent of any effects on depression. Presently, amitriptyline is recommended as the drug of first choice from the adrenergic class for treatment of CPSP.

**GABA AGONISTS**

Thiopental is a potent GABA_A agonist in the barbiturate class. Yamamoto and colleagues showed a statistically significant reduction in pain in 56% of patients with CPSP. In another trial of intravenous propofol (a GABA_A agonist), pain was reduced in more than 70% of subjects with CPSP and in patients with other forms of central pain, although it was ineffective for peripheral neuropathic pain. Baclofen is a GABA_B agonist and was studied for treatment of CPSP in a case series by Tiara and others. A bolus of intrathecal baclofen was given to five subjects, and some pain reduction was achieved in four of them. Another trial of oral baclofen given to patients who responded to an intrathecal infusion was not effective. Long-term use of intrathecal baclofen via an implanted pump has not been studied. Intrathecal midazolam has been shown to cause a transient reduction in central pain in one patient with spinal cord injury, but it has not been similarly tested in subjects with CPSP. The GABA agonists have limited use for CPSP, but oral baclofen may be efficacious in some cases.

**N-TYPE CALCIUM CHANNEL BLOCKERS**

Gabapentin and pregabalin, drugs that are structural analogs of GABA, are commonly used to treat central pain. They have a unique mechanism of action, however, most likely associated with impairment of transmembrane trafficking of voltage gated N-type calcium channels by binding to the δ subunit of the channel protein. Vranken and colleagues studied 40 subjects with central pain, 12 of whom had strokes. Subjects were randomized to either pregabalin, 150 to 600 mg daily, or placebo. Those receiving pregabalin had a mean reduction in visual analog score by 2.5 points with no corresponding reduction after placebo. Pregabalin was also associated with improved SF-36 pain scores, but there was no reduction in pain-related disability. Gabapentin has yet to be studied for CPSP, but one study did demonstrate a significant reduction in brush allodynia and pinprick hyperalgesia, but no change in spontaneous pain, after experimental intradermal injection of the irritant capsaicin. Pregabalin and gabapentin are agents worthy of trial from this class.
but they are clinically often limited by side effects in patients with post-stroke pain.

**NONPHARMACOLOGIC APPROACHES**

**TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION**

In a single small study assessing the efficacy of transcutaneous electrical nerve stimulation (TENS) for CPSP, 15 subjects with CPSP underwent TENS treatment consisting of high- and low-frequency stimulation applied to either the side of body, ipsilateral or contralateral to the pain. The results of this study were mixed in that four subjects (27%) experienced clinically important pain relief by an average of 42%, five experienced a transient increase in pain, and the remaining six had no change in their pain characteristics.

**DEEP BRAIN STIMULATION**

Several clinical trials and case studies have described the use of deep brain stimulation (DBS) for CPSP; however, these reports present conflicting information on efficacy. Owen and others implanted deep electrodes in 15 patients into both the ventroposterolateral (VPL) thalamus and the periventricular gray (PVG) regions with an externalized stimulator. Following trial stimulation, a fully implanted system was placed if the subject responded to the use of one or both electrodes. Seventy percent of the patients with either cortical or subcortical stroke responded positively to DBS with a reduction in visual analog score by 42% to 54%. In contrast, Rasche and colleagues studied the use of DBS in patients with various causes of central pain, including some with CPSP. These patients also received implants in both the VPL thalamus and PVG region. Among the 11 stroke survivors implanted, only 2 (18%) had any relief, and many of the nonresponders had an increase in pain. Current evidence suggests that placement of the electrode in the PVG region might be preferred because stimulation in this area has been shown to reduce low-frequency field potentials in the thalamus in association with pain relief. A recent case study reported a patient with a right temporoparietal lesion who had significant pain relief after DBS of the PVG region. This patient’s pain relief was also associated with normalization of sensory testing, including resolution of allodynia and improved sensory discrimination. Although PVG implantation seems to show better efficacy than VPL implantation in the CPSP literature, implantation within the centromedian thalamic nuclei, also involved in the motivational- affective components of pain, may be another option worth exploring further in clinical trials.

**MOTOR CORTEX STIMULATION**

Motor cortex stimulation (MCS) involves the surgical implantation of a surface electrode usually over the dura covering the precentral gyrus, contralateral to the area of pain. The electrode is connected to a pacemaker-like pulse generator implanted subcutaneously over the chest wall. Direct implantation of the electrode in the subdural space over the M1 cortex or within the central sulcus has been tried as well. Selection of the precentral gyrus rather than the postcentral gyrus was determined by the early work of Tsubokawa and others, who found better pain relief with MCS than with stimulation of the primary sensory cortex. Using the epidural approach, they achieved a 67% to 73% response rate to MCS, defined as at least a 50% reduction in visual analog scale score. Acceptable pain relief lasted beyond a year in many patients following implantation, although some experienced recurrence of pain after a few months. In another study, MCS achieved a mean 83% reduction in visual analog score in the 32 subjects who reported reduced pain, 11 of whom had pain following stroke. Kata-yama and associates achieved greater than a 60% reduction in pain for at least 2 years in nearly half of patients with CPSP in whom an MCS device had been implanted. In a recent review of the efficacy of MCS for chronic pain, Fontaine and associates noted that among all causes, 54% of patients will have a good response to MCS, with the best responders being those with CPSP and trigeminal neuralgia. MCS implantation is not without complications, including infection (5.7%), hardware failure (5.1%), and postoperative seizures (12%), but there have not been any cases of chronic epilepsy.

Canvero and Bonicalzi described several clinical factors that predict success with MCS after implantation of the device. Patients with CPSP have the best outcomes with MCS if they have intact or nearly intact motor function. A normal thermal sensory threshold in the painful body region is also a predictor of clinically relevant pain relief. Pain relief following presurgical intravenous infusion of ketamine or barbiturate predicts a better response to MCS than if pain relief is achieved with an intravenous infusion of morphine. A positive response to intravenous infusion of propofol can also be used to identify candidates for MCS. Pain relief following repetitive transcranial magnetic stimulation (rTMS) can have predictive value for success with MCS. Given the invasive nature of epidural cortical stimulators, it has been recommended that these clinical variables be used for patient selection before electrode implantation.

An alternative to epidural implantation might be noninvasive cortical stimulation. rTMS uses a magnetic coil to provide electromagnetic pulses over the cranial surface that induce local currents in the underlying cortex and, as noted, can predict outcomes with MCS. When used as a treatment modality for central pain, both low- and high-frequency rTMS has shown some efficacy in reducing pain, at least transiently. Providing several sessions of rTMS can result in longer-lasting pain relief. As with MCS, rTMS is targeted to the motor cortex contralateral to the pain, which provides better pain reduction than does stimulation of the SI cortex, supplementary motor area, or premotor area. Individuals with lesions in the thalamic region show a better response to rTMS than do subjects with brainstem strokes. A critical limitation of rTMS is that the pain relief is at best transient and lasts just a few hours. Additional clinical trials using various rTMS stimulation parameters and TMS combined with pharmacology...
Transcranial direct current stimulation (tDCCS) uses a low-voltage (1 mA) direct current between two electrodes, one over the motor cortex and the other over the contralateral orbit. No clinical trials using tDCCS have been published for the treatment of CPSP, but this modality has shown efficacy in patients with fibromyalgia and central pain after spinal cord injury. Future studies using tDCCS with anodal stimulation over the motor cortex, contralateral to the side of pain, may demonstrate utility, and it could prove to be more clinically practical than rTMS because tDCCS could potentially be used at home with proper patient education.

It is presently unclear how stimulation of the motor cortex reduces pain in patients with CPSP. Tsubokawa and colleagues suggested that central pain is a result of aberrant plastic changes in the inhibitory receptive fields of the sensory cortex such that non-noxious input can stimulate nociceptive neurons centrally. Thus they have proposed that MCS blocks these aberrant connections either through orthodromic stimulation via motor neuron pathways to the SI cortex or through antidromic stimulation of sensory fibers that project from the SI cortex. Garcia-Larrea and others were not able to support this concept with positron emission tomography (PET). In their study, regional blood flow during MCS was increased primarily in the VL thalamus, a thalamic region described earlier that has rich connections with the M1 cortex and postcentral regions. The PET findings demonstrated no increased regional blood flow in M1 or SI during stimulation of the motor cortex. Similarly, Goto and colleagues used diffusion tensor imaging to evaluate white matter fiber tract integrity in patients with CPSP and found that patients with intact thalamocortical tracts had a better response with rTMS targeted to the motor cortex than did subjects lacking integrity of these fibers. PET scanning also demonstrates increases in regional blood flow within other structures in association with MCS, including structures such as the medial thalamus, anterior cingulate gyrus, upper brainstem, and contralateral insular cortex. These structures make up portions of the lamina I spinothalamocortical (interoceptive) pathway, which has a significant role in pain processing as discussed previously (see Fig. 27.1). It seems plausible, then, that MCS might reduce CPSP via orthodromic and antidromic stimulation of the thalamus via the thalamocortical pathways, which may have a neuromodulating effect on pain-processing structures, including the anterior cingulate, brainstem structures, and insular cortex. Some have proposed that MCS works via GABA mediation because patients who respond to an intravenous propofol infusion (GABA A agonist) also respond well to MCS. It is also possible that MCS modulates pain through descending cortical spinal pathways that connect to dorsal horn structures.

MCS is currently available only for off-label use in the United States for the treatment of central pain, but growing evidence of potential long-term efficacy that is superior to pharmacologic management might bring it to the forefront of clinical practice, at least as one option among many of the current choices available.

Spinal Cord Injury Pain

R. Norman Harden | Amy J. Kirsling | Katrina M. Thomas | Robert P. Yezierski

The chronic pain associated with injury or disease of the central nervous system (CNS) represents a long-standing puzzle, presents a significant challenge to scientific and health care communities, and is consequently a significant barrier to optimal rehabilitation and quality of life in these patients. The mystery of how a lesion in systems that mediate pain perception can actually produce pain continues to baffle those searching for an underlying mechanism. The evidence that we have clearly points to a complicated and heterogeneous pathophysiology and, as in all chronic disease, involvement of psychosocial components. Because therapy for pain from spinal cord injury (SCI) is challenging, it is clear that a more comprehensive understanding of the mechanisms of disease (treatment targets) is crucial. This chapter focuses on clinical identification of the mechanisms and subsets of this condition, its pathobiology, and the current (rather weak) evidence base for treatments.1,2

PREVALENCE AND INCIDENCE

Pain is a frequent consequence of paraplegia and tetraplegia following both complete and incomplete spinal cord lesions.1 The development of pain after SCI was first described over 100 years ago, and currently more than 600,000 individuals in the United States live with SCI, with approximately 11,000 new such injuries occurring per year.1,3,4 Historically, the loss of sensory, motor, bowel, bladder, and sexual function was viewed as the most significant consequences of SCI. However, the onset and presence of pain directly relate to the ability of patients to regain optimal levels of function and quality of life, and unmanaged pain may be a principal cause of the failure of optimal rehabilitation.4,5 An early study reported that 37% of SCI patients with cervical or high thoracic lesions would trade relief of pain for any chance at regaining motor function.6 In one survey, 11% of respondents reported that pain rather than loss of motor function prevented them from working.1,7 In another study, 37% of patients experiencing SCI pain rated the pain as “very difficult to deal with” (rating it from 7 to 10 on a scale from 0 to 10).5 These and many other studies lend support to the pervasive and negative impact of pain on function and quality of life following SCI.1

Historical prevalence analyses of any type of pain after SCI have found it to range from 34% to 96% (approximate mean of 67%) in studies published between 1947 and 1991. More recent studies using more comprehensive pain assessment strategies indicate that the overall prevalence of all types of SCI pain ranges from 70% to 80%.3,8,9

CLASSIFICATION/TAXONOMY

Clinical observations suggest that the variety of pain syndromes associated with SCI together with the lack of a unified taxonomy has been the principal impediment to not only accurate epidemiologic studies but also effective clinical research.4,10-12 The International Spinal Cord Injury Pain classification was proposed after review by major SCI and pain organizations and validation using vignettes. In this system, the type of SCI pain is classified as nociceptive (visceral, musculoskeletal, or other) or neuropathic (resulting from a disease or lesion of the somatosensory nervous system). Neuropathic pain following SCI is further classified as neuropathic pain directly related to the SCI (at-level or below-level pain, where level refers to the neurologic level of injury) or other neuropathic pain (indirectly related or unrelated to the SCI).1,13,14 The SCI Pain Task Force of the International Association for the Study of Pain has proposed a similar taxonomy, which represents a further step toward a mechanism-based classification. This taxonomy is divided into three tiers. In the first tier, pain is divided into nociceptive pain (i.e., pain attributable to non-neurogenic tissue damage) and neuropathic pain (i.e., pain attributable to damage to peripheral or central nervous tissue, or both).15,16

The most straightforward and logical classification scheme for clinical assessment simply categorizes pain below the lesion (true “central pain” phenomena), pain at the level of the lesion (most like radiculopathic/neuropathic), and pain above the lesion (often called “musculoskeletal” in the literature). Another important source or cause of pain in clinical diagnosis is pain evoked in a viscus (“visceral pain”). In one study of the incidence and prevalence of different types of pain in a cohort of 100 patients, musculoskeletal pain (above the lesion, 59%) was the most common type, followed by at-level (41%) and below-level (34%) neuropathic pain. Visceral pain (5%) was the least common.1,17 The mean time until onset of any type of SCI pain was 1.6 years. The shortest onset times were recorded for at-level pain (1.2 years) and pain above the level of injury (“musculoskeletal,” 1.3 years). Below-level neuropathic pain (1.8 years) and visceral pain (4.2 years) developed later.17 The delayed onset of pain can potentially cause some confusion for patients who believe that the onset of sensations corresponds to neurologic recovery and thus may present a minor clinical difficulty for physicians who are aware of the reality that these sensations may represent the development of a pathologic condition that complicates the day-to-day management of patients.1

Among all types of SCI pain, below-level pain (central pain) is the most common (25% to 52%) and could be the most difficult to treat.6,11,17-20 Below-level pain is described as the “most severe or excruciating” of all SCI pain reported.17,18
Often accompanying below-level pain is autonomic dysreflexia, which is a potentially life-threatening condition triggered by sensory input below the lesion (spasticity, sympathetic nervous system afferent input). Symptoms associated with autonomic dysreflexia include increased or decreased blood pressure and pulse, headache, and a risk for cerebral hemorrhage, cardiovascular collapse, and seizures.

At-level pain is also common (12% to 42%) and “severe” and can likewise be quite difficult to treat. Pain at the level of the lesion may result not only from damage to peripheral nerves near the site of entry into the cord but also from damage to central neural elements and tracts; thus, the pain mechanisms associated with this type of pain are probably various and complicated. 

Above-level pain generators are common (60%) and heterogeneous, such as those of “ergonomic” pathology secondary to overuse of the shoulders and arms causing myofascial pain in the shoulder joints from wheelchair use, or “crutch palsy” as a result of mechanical compression of nerves from orthotics. Above-level pain may also be due to mechanics such as secondary changes following fractures and fixation. Above-level pain is important to identify because it is often the easiest to treat effectively.

Visceral pain is usually manifested as dull or cramping abdominal sensations that may be associated with nausea and autonomic reactions. The pain may be related to bowel, bladder, or kidney dysfunction or distention but may also represent a neuropathic type of pain. It is not known whether there is a central component responsible for visceral pain, but damage to central afferent terminals is known to have peripheral consequences. Because SCI patients may not have the typical signs of abdominal illness, a high index of clinical suspicion should be maintained, which requires careful examination whenever any new pain or changes in existing pain occur. Increases in spasticity, pain at any location, or an autonomic reaction may be the only indication of abdominal organ dysfunction. Autonomic dysfunction may complicate the management of SCI patients with a lesion above the splanchnic outflow (sixth thoracic level). At-level and below-level allodynia, hyperalgesia (evoked pain), and spontaneous pain historically represent the primary targets of both basic and clinical research.

### PATHOLOGY AND MECHANISMS

SCI pain is related to the nature of the lesion, damage to neurologic structures, secondary pathophysiologic changes in surviving tissue (neural and non-neural tissue), and associated psychosocial syndromes. Because pain is a significant consequence of SCI, it is crucial to understand the mechanisms involved to target therapy more efficiently. Experimental models reveal crucial insights related to the potential mechanisms responsible for pain following SCI. These models and methods try to explain a complicated series of anatomic and functional changes seen in spinal and supraspinal locations. There are many similarities between the cellular and chemical events that occur after SCI and those that follow peripheral nerve injury. Furthermore, neuropathic lesions are easier to study (both with animal models and clinically), and there is considerably more evidence in the treatment of neuropathies.

Thus, because of the absence of much useful evidence on the treatment of SCI pain, we must often extrapolate mechanisms and therapy from the more extensive peripheral neuropathy literature.

Traumatic or ischemic damage to the spinal cord triggers a dynamic cascade of molecular, biochemical, anatomic (“plasticity”), and cellular reactions. These events in turn produce physiologic changes at both the spinal and supraspinal levels that contribute to the onset of dysesthetic sensations, prominently pain. With evolution of the concept of the “central injury cascade” and its role in initiation and maintenance of SCI pain, there has been good progress in determining certain characteristics of each step involved. Injury to the spinal cord ultimately results in abnormal sensory processing in most cases. Contributing to this are changes in the level of neuronal excitability (the “irritable focus”), denervation supersensitivity (and loss of diffuse noxious inhibitory controls), inactivation or activation of cellular signaling pathways, and glial-neuronal interactions. Cord injuries obviously cause structural damage but can also lead to reorganization of the spinal and supraspinal circuits that integrate process and transmit sensory information. There are also changes in the supraspinal centers and their chemical mediators that maintain the balance between inhibition and excitation. Primary and secondary events also ultimately result in afferent dysesthesias and efferent modulation, which result in pathologic changes in the initiation, perception, and maintenance of injury-induced pain. There is an expectation that the completeness (as in surviving tracts) or level of injury should correlate with the onset and type of pain. However, despite a hypothetical correlation between incomplete as well as thoracolumbar lesions and a higher incidence of pain, studies have not identified any other consistent predictors. One very significant problem in understanding and studying pain in SCI is the vagaries of the clinical designations of “completeness.” The American Spinal Injury Association (ASIA) system, though superficially useful in physiatric practice, is not helpful in determining the actual physiologic status of cord structures. Thus, clinically “complete” lesions by ASIA criteria are rarely physiologically anatomically complete in the sense that there are often surviving tracts (afferent and efferent) and frequently intact and disinhibited sympathetic chains. Reliance on the ASIA system for research categorization is a dead end. Research cannot progress, particularly treatment research, without a surviving tract and functional status subset analysis by formal psychophysical and biometric measurements.

Central pain can be characterized as spontaneous or evoked, persistent or intermittent, and localized or diffuse. A significant number of patients report pain sensations such as “burning,” “shooting,” “Radiating,” “ice-like,” “squeezing,” and “stabbing.” There may be allodynia, hyperalgesia, and “numb” areas. The pain can summate with repeated stimuli (wind-up) and linger with prolonged aftereffects. Pain may be evoked or worsen with many peripheral sensory stimuli such as touch, vibration, and cold. It may arise from visceral or somatic structures or be evoked by infections, sudden noises, jarring movements, and distention of visceral structures, as well as by various affective conditions. Evoked pain can be dramatic and typically persists long after the stimulation ceases (afterdischarge). All these
features are consistent with so-called central sensitization/ augmentation of cerebral sensory processing. Spontaneous pain varies greatly in character and is aggravated by stress and emotion, especially anxiety. It can be provoked or exacerbated by auditory, visual, olfactory, and visceral stimuli. Thus, when evaluating pain, it is critical to assess intensity, sensory signs and symptoms, physical and emotional triggers, mood, sociologic situations, and the quality of life of patients.

Multiple hypotheses have been advanced to explain central pain, including the loss of spinal inhibitory mechanisms, the presence of pattern generators (irritable focus) within the injured cord, sensitization of supraspinal relay nuclei, synaptic plasticity (rewiring), activation of spinal and supraspinal microglia and astrocytes, changes in cellular signaling pathways at spinal and supraspinal sites, involvement of irritative or excitatory generators of the spinothalamic and lemniscal pathways, and loss of thermosensory inhibitory control over pain pathways (one type of diffuse noxious inhibitory control). There is also a possible contribution from altered gene expression.

Another challenge in researching abnormal sensations following SCI is the development of experimental models of injury that are consistent with the pathologic pain characteristics seen in humans. A number of models have been developed, including mechanical trauma, isolated lesions, complete transection, chemical lesions, and ischemic injury. The events that follow SCI are dynamic, progress rostrally and caudally from the core of the lesion, and affect spinal, subcortical, and cortical structures. Since there is a broad spectrum of pathophysiologic changes initiated by SCI, it is a challenge to identify which events have a causal relationship with the onset of pain and which are merely secondary consequences of the injury process in the evolution of pain. In human SCI, a variety of critical methods are available for studying and quantifying psychophysical function. Examples of these methods include thermal quantitative sensory testing (QST); small fibers, lateral spinothalamic tracts), vibration QST (large fibers, dorsal columns), and sympathetic skin response.

Evidence of dysesthesia or pain responses at the level of spinal lesions has been provided by animal models of excitotoxicity, ischemia, and contusion injury. The excitotoxic model simulates the elevation in excitatory amino acids that occurs after injury. The most common experimental model is the weight drop or contusion model, and it is believed to be the most clinically relevant but is difficult to use in studies of sensory function because of hind limb paresis or paralysis interfering with behavioral responses. Although the contusion model has many characteristics in common with the human injury, it has been challenged as an inappropriate model for study of the altered sensation following injury. An alternative approach involves selected spinal lesions (such as cord hemisection) alone or combined with other interventions. These various experimental models produce distinct pathologic or behavioral changes (or both) that appear to be relevant to human SCI, create opportunities to study mechanisms, and may prove useful in drug screening.

Critical events in the aftermath of experimental SCI include a transient elevation in excitatory amino acids and the production of a variety of potentially toxic mediators such as endogenous opioids (dynorphin), prostaglandins, cytokines, nitric oxide, and reactive oxygen compounds. Other consequences of SCI include upregulation of mRNA for tumor necrosis factor-α and dynorphin and activation of transcription and nuclear factors. Activation of the NF-κB family of transcription factors is significant since it has a role in inducing more than 150 genes involved in inflammatory, proliferative, membrane excitatory, and cell death responses.

Within the first 15 minutes after SCI, cell membranes start to break down and the phospholipase, arachidonic acid, and eicosanoid cascades are activated. Reactive oxygen species are destructive by-products of these injury cascades. There are significant increases in intracellular calcium. Calcium is directly involved in multiple intracellular signaling pathways (including pain sensitization). One hour after SCI, DNA microarray analysis has identified changes in the mRNA levels of 165 genes involved in regulating transcription factors, inflammatory processes, cell survival, and membrane excitability. Within hours of injury, ion shifts result in cellular swelling and local edema, expansion of the extracellular space, loss of integrity of the blood–spinal cord barrier, and sustained depolarization in damaged cells. This collection of cellular and molecular events can have a profound impact on the functional state of spinal neurons and ultimately promote the onset of chronic pain. Since there are many possible contributing factors and processes, it is not likely that events occur in a uniform, orderly, or sequential manner.

Descending influences may be involved in the at-level pain phenomena, such as pathways emanating from the rostral ventromedial (RVM) medulla. The abnormal firing of sensory neurons reaches RVM neurons and completes a spinobulbospinal feedback loop that increases the hyperexcitability of neurons in the spinal cord. Central sensitization and synaptic plasticity in the CNS are thought to contribute to acute and potentially persistent pain, although most research in this regard has been done on peripheral neuropathic pain. Central sensitization is thought to involve changes in the excitability of spinal neurons and eventually in the development of spinal and potentially supraspinal pain generators and amplifiers.

Despite evidence supporting the hypothesis that cellular or axonal damage predisposes an individual to both at-level and below-level pain, it may be clinically important to distinguish between these regionally distinct categories of pain. It is interesting to point out that SCI pain may be reported in a progressive sequence from at-level to below-level pain, thus implying that the two clinical entities interact. This suggests the possibility that the abnormal neural activity (spinal or supraspinal) associated with at-level pain predisposes an individual to the development of below-level pain (SCI-type central pain). Importantly, the hypothetical influence of abnormal activity in gray matter nuclei may also influence the development of below-level pain after specific white matter damage.

Following complete spinal transection, pain is reported below the injury with common descriptions such as “uncomfortable sensations,” “tightness,” or “burning.” Severe pain may also follow hemisection. One of the most illustrative conditions that give rise to central pain is syringomyelia. More than half of patients with delayed-onset central pain...
after a spinal injury have syringomyelia, and it appears that
the pathophysiologic changes in spinal tissue surrounding
the syrinx itself are responsible for the pain.\textsuperscript{92} Damage to
Lissauer’s tract by root avulsion can also cause very intense
and difficult-to-treat pain syndromes.\textsuperscript{1,93}

Pathologic damage to the central cord is particularly
prominent following vertebral dislocation, an injury that
compresses the spinal cord and destroys gray matter, typi-
cally with variable white matter involvement. In contrast,
surgical interruption or compression of long spinal path-
ways usually involves only portions of the gray matter either
directly or by disruption of the blood supply to injured
segments.\textsuperscript{94} The gray matter damage resulting from these
types of lesions more often results in pain. However, when
central damage to the cord is minimized by making super-
ficial lesions in one anterolateral column, prolonged con-
tralateral hypoalgesia is produced without chronic pain,
alldynia, or hyperalgesia.\textsuperscript{4,65,95}

One of the challenges in studying below-level pain is find-
ing a behavioral measure that effectively engages the neu-
ronal substrates thought to be involved in producing this type
of pain. It is generally agreed that below-level pain has spinal
as well as supraspinal (including thalamic and cortical) com-
ponents. Therefore, to effectively evaluate below-level pain,
it is necessary to use a behavioral measure that engages both
these components. At present, behavioral measures that use
operant tasks as the basis for behavioral responses are the
only outcome measures that meet these criteria. For this
reason, to effectively study below-level pain one must use
an operant behavioral task. Unlike reflex responses, these
tasks require cortical processing, an important component
required for below-level pain. One difficulty in studying pain
conditions in SCI is selection of suitable behavioral mea-
sures. For example, if the assumption is that to experience
below-level pain the cortex must be engaged, the behavioral
measures selected to be used in evaluating this type of pain
must produce cortical activation. An example paradigm to
test this would be through operant testing that requires cor-
tical processing of afferent input, decision making based on
environmental cues, and adapting behavior in response to
nociceptive stimuli.\textsuperscript{96} An example of an error in this regard
would be to consider segmental reflex responses below the
lesion as relevant in evaluating below-level pain.\textsuperscript{33}

Gray matter damage appears to be an important factor in
the development of below-level pain. A recent clinical study
in patients with and without below-level pain showed that a
common pathologic feature in patients with below-level pain
was the involvement of lesions that included a central core
of spinal gray matter.\textsuperscript{1,97} Although reduced temperature and
pain sensations have been used to support the involvement of
damaged spinothalamic connections in the development of
central pain, recent evidence has shown that neuronal
hyperexcitability is also important in the development of
below-level pain. Furthermore, loss of spinothalamic func-
tion did not appear to predict this type of pain.\textsuperscript{98} This work
complements previous magnetic resonance imaging find-
ings showing that patients with below-level pain have larger
gray matter lesions than do patients without pain.\textsuperscript{97} Addi-
tional evidence supporting this conclusion comes from studi-
es showing that anterolateral cord lesions result in evoked
pain caudal to the spinal injury only when gray matter is
involved and the fact that spontaneous pain behavior can be
elicited with spinal lesions restricted to the gray matter.\textsuperscript{57,99}
Below-level pain may therefore be expressed when portions
of supraspinal sensory processing targets are deprived of
input from the classic pain pathways and then indirectly
activated by other sources of alternative input from a dys-
functional neuronal core (i.e., pain-generating mechanism)
rostral to the site of injury.\textsuperscript{57,95}

Although the condition of pain after SCI is believed to
originate from abnormal activity in the spinal cord, there is
also support for the involvement of supraspinal structures,
such as the diencephalon, that receive abnormal input from
the injured cord. The contribution of this input, together
with the effects of deafferentation (secondary to the death
of spinal projection neurons), sprouting of undamaged
fibers, and functional unmasking of nonfunctional local
circuits, could contribute to the development of focal gen-
erators or amplifiers of abnormal discharges at supraspinal
sites.\textsuperscript{100,101} Two reports describing elevated blood flow in
thalamic nuclei (possibly reflecting changes in metabolic
demand and the functional state of thalamic neurons) lend
support to thalamic involvement in supraspinal responses to
SCI.\textsuperscript{102,103} Complementing these observations are descrip-
tions of changes in the concentration of metabolites (deter-
mined with in vivo magnetic resonance spectroscopy) in the
ventral posterolateral nucleus of patients with and without
SCI pain and reports of dysrhythmic thalamic activity in
hyperreflexic rats following SCI.\textsuperscript{29,104} Changes in the excit-
ability of thalamic neurons represent a potential source of
abnormal activity, as well as a site for amplification of incom-
ing information from the spinal cord. Thus, below-level
neuropathic pain may be expressed when portions of supra-
spinal targets are deprived of input from the spinothalamic
and other spinal pathways and are activated by abnormal
(spontaneous or evoked) activity from levels of the spinal
cord above the level of injury.\textsuperscript{4}

One factor that remains unclear in the mechanism of
below-level pain is the precise role of spinal influences
(i.e., abnormal activity near the site of the lesion—the pen-
umbral region) in the maintenance of this type of pain. The
transient relief of below-level pain in humans following the
application of local anesthetic to the proximal stump of a
spinal lesion or removal of segments of cord (cordectomy)
rostral to the site of injury suggests that the presence of a spi-
nal generator plays a significant role in maintaining chronic
below-level pain. Thus, the supraspinal changes secondary
to deafferentation and the emergence of a spinal generator
of abnormal activity are two significant events that poten-
tially contribute to the development and maintenance of
below-level pain.\textsuperscript{4,42}

Although the majority of SCI pain research has focused on
spinal mechanisms of enhanced sensitivity, the potential role
of descending (supraspinal) modulation (both facilitatory
and inhibitory) should not be ignored. Given that neuroki-
nin-1 receptor (NKIR)-expressing lamina I neurons repres-
ts the spinal effector of a bulbospinal projection system
involving µ receptor–expressing neurons in the RVM medulla,
one can speculate that this feedback system contributes to
the condition of SCI pain, similar to the mechanism proposed
following peripheral nerve and tissue damage.\textsuperscript{32,84,105-108}
The fact that RVM neurons undergo significant functional
changes following spinal injury suggests that this region con-
tributes to a central pain–generating mechanism following
spinal injury. Accordingly, experiments targeting lamina I NK1-expressing neurons with the neurotoxin saporin conjugated to substance P showed that elimination of these neurons significantly reduced the onset and severity of injury-induced at-level spontaneous pain behavior.

A critical factor in the initial onset of at-level behavioral changes in response to mechanical and thermal stimuli is believed to be loss of inhibitory tone within the injured cord. Loss of spinal inhibition enhances the recruitment of surrounding neurons and spread of abnormal at-level sensations, including pain. The second condition involves emergence of a “pattern-generating mechanism” (spinal and supraspinal). This hypothesis led to the conclusion that not all postinjury pain is due to noxious input; some may be due to changes in the firing patterns, including burst activity and long afterdischarges, of neuronal pools adjacent to a site of injury. Results consistent with a “pattern-generating” mechanism include (1) the existence of focal regions of hyperactivity in the spinal cord region surrounding the site of injury (penumbral region) and thalamus of spine-injured patients, (2) the effectiveness of cordectomy and local anesthetics in alleviating pain when delivered to the injured cord, and (3) sensitization and prolonged afterdischarges of spinal sensory neurons following SCI injury.

Patients with central pain can be studied with neurometabolic techniques such as single-photon emission computed tomography (SPECT), positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS), which together with pharmacologic dissection can be helpful in classifying metabolic techniques such as single-photon emission computed tomography (SPECT), positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS), which together with pharmacologic dissection can be helpful in classifying.

At present, because a proven long-term effective treatment of central pain is not available, the strategy for treatment is to consider multiple treatment modalities by extrapolating from similar diseases, especially neuropathy, to systematically determine the best approach for an individual patient. There are varieties of treatment modalities. The realistic goal of treatment of SCI pain is to reduce the intensity of the pain to a tolerable level with interventions that have acceptable risk and cost. In brief, tricyclic antidepressants, gabapentin, and pregabalin are considered first-line treatments (see Table 28.1). Mixed serotonin-noradrenaline (and dopamine) reuptake inhibitors may be considered when tricyclic antidepressants are not tolerated. Opioids, including tramadol, are considered second-line treatments. In refractory cases, implantation treatment of central pain may be considered, but the risk and cost of these unproven

**TREATMENT**

At present, because a proven long-term effective treatment of central pain is not available, the strategy for treatment is to consider multiple treatment modalities by extrapolating from similar diseases, especially neuropathy, to systematically determine the best approach for an individual patient. There are varieties of treatment modalities.
Gabapentin and pregabalin had strong evidence of alleviating chronic hypersensitivity in spinally injured most clinical scenarios. The anticonvulsants lamotrigine controlled trials), and these drugs should be considered in effectiveness in treating SCI pain (five good randomized studies have shown reduced pain behavior and excit -

These very general and hypothetical pharmacotherapy guidelines are not supported by evidence (because there are no randomized controlled trials of note or drugs approved by the Food and Drug Administration for pain from spinal cord injury); rather, they are often extrapolated from related diseases for which the evidence base is somewhat better, such as neuropathy (e.g., see Harden30). These general guidelines do not supplant the education and experience of a skilled physician after careful analysis of the individual case.

**CHAPTER 28 — SPINAL CORD INJURY PAIN**

In animal models, spontaneous pain represented by excessive grooming behavior and the spatial threshold hypothesis were investigated by using three drugs that target different aspects of secondary injury: agmatine (N-methyl-d-aspartate [NMDA] receptor antagonist, nitric oxide synthase inhibitor), interleukin-10 (IL-10, anti-inflammatory), and cyclosporine (immunosuppressant). Despite their different mechanisms of action, in excitotoxic, ischemic, or traumatic models of CNS injury, each drug has demonstrated neuroprotective effects by suppressing abnormal neuronal activity and reducing the spread of injury-induced tissue damage. When compared with saline, agmatine, IL-10, and cyclosporine delayed the onset of excessive grooming, reduced grooming severity and the grooming area, and decreased the area of neuronal loss in the spinal cord. Treating the excessive grooming behavior after onset with the same drugs still reduced the grooming area, grooming severity, and neuronal loss in the spinal cord when compared with saline treatment. There is evidence that these medications attenuate ischemic damage, prevent the development of segmental hypersensitivity, and reduce chronic pain from SCI in humans. Basic science suggests that NMDA receptors and other excitatory amino acid receptors contribute to allodynia and hyperalgesia, thereby implying that drugs that manipulate these conditions may have clinical value. There is currently no NMDA receptor antagonist that is logistically pragmatic for human use. It is reasonable to consider memantine, dextromethorphan, or a trial of low-dose ketamine, but these agents should be considered “experimental” and presented to the patient as such until there is evidence.1

Sex, strain, and gonadal hormones also exert significant influences on the onset and progression of spontaneous pain behavior following SCI. Severe pain behavior develops in animals treated with estradiol, whereas those treated with progesterone have a delayed onset and attenuated
severity and progression of such behavior.\textsuperscript{162} The fact that sex, strain, and hormonal effects influence the temporal profile of pain behavior and, more importantly, the longitudinal spread of neuronal damage following injury suggests an additional level of complexity of the endogenous neuroprotective and neurodegenerative mechanisms in the CNS. Consistent with these observations are other reports in which age, sex, and strain factors were found to contribute to differences in the prevalence and severity of pain following SCI.\textsuperscript{20,163,164} Unraveling the key components of the complex variables associated with SCI may help researchers identify critical therapeutic targets and develop novel strategies for controlling spinal injury and its clinical consequences.\textsuperscript{33}

As the results of the aforementioned studies suggest, there is a critical distance of neuronal loss along the longitudinal axis of the cord that when exceeded, leads to the expression of pain-related behavior.\textsuperscript{155,162} Neuroprotective interventions that limit the spread of neuronal loss result in the prevention or delayed onset of this behavior. These studies thus support a neuroprotective hypothesis of SCI pain and point to the possibility that neuroprotective strategies targeting selected components of the spinal injury cascade may be useful in the prevention or treatment of pain conditions associated with SCI.\textsuperscript{1} Until evidence is available, practical approaches in the clinic may be simple nutraceutical interventions such as vitamin C and bioflavonoids, which certainly meet the risk-benefit analysis.

The concept of a pain-generating mechanism after SCI is bolstered by the existence of hyperactivity, sensitization, and prolonged afterdischarges in spinal sensory neurons following SCI.\textsuperscript{22,131,132,139,165} which has led to empirical pharmacologic approaches to the treatment of this condition. For example, lidocaine and ketamine, which reduce the transmission of cell membrane excitability and glutamate activation, have been shown to be effective in reducing SCI pain. Subarachnoid lidocaine, a potent nonselective sodium channel blocker, relieved SCI pain.\textsuperscript{15,22,116} In a double-blind crossover trial, the effect of intravenous lidocaine on different components of neuropathic pain was studied in 16 patients with post-stroke pain (\(n = 6\)) or SCI pain (\(n = 10\)). The results showed a short-term benefit in spontaneous pain and in mechanical allodynia and hyperalgesia, but not in thermal allodynia or hyperalgesia.\textsuperscript{22,131}

Baclofen and propofol are effective in increasing pain modulation or inhibition.\textsuperscript{33,158,166-168} Intrathecal baclofen has been shown to reduce the musculoskeletal pain associated with spasticity, but its impact on neuropathic or central pain per se is questionable.\textsuperscript{142} Propofol, a \(\gamma\)-aminobutyric acid (GABA) A receptor agonist, has shown some benefit in preliminary studies.\textsuperscript{15,166} Cannabinoids also showed conflicting evidence in improving spasticity-related pain.\textsuperscript{142}

Anecdotal interventional treatment strategies for different types of SCI pain include surgery, intrathecal pharmacology, and axial and deep brain stimulation; however, there is no definitive evidence at this time, and none of these strategies can currently survive a risk-benefit or cost-benefit analysis. There is very little literature that addresses non-drug-related therapies for SCI pain, but there is an abundance of evidence for general rehabilitation of victims of SCI.\textsuperscript{2} A study of transcranial electrostimulation treatment demonstrated that pain decreased in the treatment group by 51\% in comparison to sham-treated subjects. Interestingly, an elevation in salivary cortisol levels in this trial was associated with pain relief in the stimulation phase.\textsuperscript{140,169,170}

A characteristic of SCI pain that has been consistently documented is its detrimental impact across multiple quality-of-life domains, including life satisfaction, mood, reintegration, and physical health. Despite the multiple non–drug-related treatment strategies used to manage different aspects of the biopsychosocial disease that is SCI, there are currently no proven treatments.\textsuperscript{22,23,171} In the absence of evidence, the risk-benefit analysis suggests that rehabilitation-based interdisciplinary treatments should always be included in the empirical management of SCI pain.

**CONCLUSION**

The pain associated with spinal injury does not have a simple or single mechanism. It is more probable that in any given case several components of the central injury cascade contribute to the development and maintenance of different pain states or phenotypes.\textsuperscript{27} Continued research directed toward understanding specific components of the spinal injury cascade, as well as the neuroplastic changes initiated in the brain and spinal cord, may provide a better understanding of the spinal and supraspinal mechanism or mechanisms responsible for this condition and soon lead to the development of more effective therapeutic approaches. Currently, an approach that includes the best available data for drug therapy, complemented by humanitarian empirical trials informed by evidence from related diseases and, most importantly, a thoughtful interdisciplinary approach to non–drug-associated therapy, is the most likely to lead to effective pain management and optimal functional rehabilitation.\textsuperscript{1,22,142}

**KEY POINTS**

- Pain above the level of the lesion is often mechanical or musculoskeletal and postural. Mechanisms include myofascial pain (e.g., overuse of the shoulder with a wheelchair), nerve compression (e.g., “crutch palsy”), and seating and position problems.
- Pain at the level of the lesion is usually some mixture of proximal peripheral nerve injury (neuropathic, radiculopathic) and central pain (such as damage to the nerve entry zone, Rexed laminae I and II), as well as damage to long tracts causing ectopic generators to arise in the afferent pain pathways and dysfunction of descending inhibitory pathways.
- Pain below the level of the lesion is “true central pain” and is also probably due to ectopic generators, loss of inhibition, demodulation, and central sensitization.
- It is critical to determine as much as possible about the mechanism and location of the pain generators (history, physical examination, psychophysical testing, and imaging) because these are the therapeutic targets.
- All chronic pain is biopsychosocial, and it is critical to embrace the psychosocial dysfunction in SCI pain since these features are often easier to treat effectively than the biomedical targets.
KEY POINTS—cont’d

• Because there is very little evidence to guide the treatment of SCI pain, it is critical to understand its mechanisms since this leads logically to treatment decisions that are often based on data extrapolated from related conditions (e.g., if the putative mechanisms are predominately consistent with neuropathic pain, selection from the pallet of proven antineuropathic medications is logical as early empirical choices).

• Non-drug-related therapies from rehabilitation medicine, which meet the test of risk versus benefit, should be considered.

Chronic widespread pain presents challenges to patients, clinicians, and researchers in both diagnosing and treating its complex manifestations. As with many pain disorders, clinicians identified a grouping of symptoms, and the scientific community has attempted to develop sensitive and specific diagnostic criteria. This process has evolved recently to reflect an improved understanding of the disease process and the challenge of accurately diagnosing fibromyalgia (FM) in the clinical setting. Moreover, the complex pathophysiology obscures both the etiology and treatment options for this centrally mediated disease. Myofascial pain syndrome (MPS) is frequently found under the same umbrella as FM. They have separately struggled for recognition in the medical arena despite being fairly common in every contemporary society and exacting a moderately severe toll on the patients who suffer from them.

Explanations for this situation are varied but may relate to obscure belief systems on the part of physicians regarding the nature of the conditions themselves. Similarly, FM and MPS are painful and impair the ability of the affected person to function normally. Both are assessed subjectively, with some semi-objective clinical signs. Both can be associated with patient behavior that makes clinicians worry that something is being missed. Neither has a specific laboratory test that unequivocally defines the condition, like many of the disease states along the spectrum of central sensitization. Both seek simple instruments that are robust to change, with clinical improvement. Until relatively recently, neither had medications approved by the U.S. Food and Drug Administration (FDA) specifically indicated for treatment of its symptoms. Both FM and MPS cause mild to moderate dysfunction in the majority of patients, but with new understanding of the pathophysiology and improved diagnostic criteria, there have been changes in the field in the last several years.

Nevertheless, these conditions are easily distinguished from each other on the basis of medical history, physical examination, and even some laboratory findings. Therefore, it is even possible to identify patients who have both conditions at the same time. This chapter attempts to summarize the current status of these disorders with respect to their clinical features, epidemiology, pathogenesis, and management.

**MYOFASCIAL PAIN SYNDROME**

**DIAGNOSTIC CRITERIA**

The combined work of Kellgren, Travell, and Simons has influenced the development of proposed criteria for the diagnosis of MPS1-4 (Box 29.1). It is described as a painful regional syndrome characterized by the presence of an active trigger point (TrP) in a skeletal muscle. The implications of an active TrP are that the examiner should expect to find spot tenderness with deep palpation over the TrP. Stimulation of these TrPs should result in concordant pain. Moreover, there should be concomitant referral of pain to a zone of reference within the affected muscle. A latent TrP has been defined as one for which there is no passive experience of spontaneous pain but pain is still inducible by manipulating the TrP. Manipulation of the TrP is generally achieved by digital pressure, a flick across the muscle, or penetration by a needle. This stimulation typically induces a “twitch” response, which can be felt as a palpable taut band that restricts normal excursion of the affected muscle.

The problem for investigators trying to validate diagnostic criteria for MPS has been that experienced clinicians have not been able to demonstrate a high level of agreement when applying the Simons and Travell criteria to serially blinded patients versus disease controls or healthy controls.5-8 Moreover, even experienced clinicians need to standardize their examination techniques and approach for proper interpretation of the findings. When this was done immediately before performing blinded examinations, the results were much more reproducible.5 The most reproducible clinical features from among the Simons and Travell3 criteria were finding a tender spot (the TrP) in the proximal or distal third of an affected skeletal muscle, referral of pain to a zone of reference, and reproduction of the patient’s usual pain. Much poorer reliability was associated with eliciting local tenderness, palpating a taut band, and documenting the local twitch response.

A telling series of two tables has been provided by Simons and colleagues.1 The first table summarizes the inter-rater reliability (κ values) from four clinical studies for various critical examination procedures used in diagnosing MPS. The second compares the relative difficulty of performing or interpreting these test procedures versus the relative importance of these tests in diagnosing MPS confidently. The tests considered more important in making the diagnosis are also the ones most difficult to perform or interpret.

Part of the problem may have been that there are so many muscles in the body that have the potential to be affected by MPS; examination techniques need to be adapted for each muscle. Clinicians who are skilled in diagnosing MPS must have an adequate knowledge of neuromuscular anatomy and function, plus a high level of manual dexterity and trained sensory discrimination in their hands. In addition, these skills must account for the common distortions in ideal anatomy by patients’ neglect of their physical conditioning and the development of overlying layers of adipose tissue. If every MPS patient had the “ideal body” with well-defined
musculature, the anatomic challenge might be less onerous. Some muscles are particularly difficult to evaluate because they are under other muscles (e.g., piriformis deep to the gluteal muscles of the buttocks). The muscles in the lower extremities seem to be more problematic in this regard than those in the trunk and upper extremities.

A study design patterned after that used to develop the 1990 American College of Rheumatology (ACR) research classification criteria for FM has been proposed to validate diagnostic criteria for MPS involving muscles of the upper part of the torso. Application of this protocol by teams of experts (a Delphi and a blinded examiner) at two centers in different countries confirmed the historically observed outcome that there was poor agreement (κ = 0.21 to 0.35) on the diagnosis between pairs of examiners based on the standard examination approaches. Primarily, this discrepancy resulted from examination of the healthy controls by the blinded examiner when a very high proportion exhibited a taut band, an area of tenderness, a local twitch response, a jump sign, and even referral of pain. Moreover, the most specific discriminators of patients with MPS from healthy controls were painfully restricted range of motion, muscle strength limited by pain, the skin rolling test, and the pressure pain threshold according to algometry. A second component of the study involved the use of validated questionnaire instruments that examined subjective pain, dysfunctional sleep, physical function, anxiety, and depression. Significantly, the questionnaire instruments were more consistently effective in distinguishing individuals with MPS from healthy controls than were the examination measures. Of particular interest were the findings of sleep dysfunction, anxiety, and depression in MPS patients, all of which challenge the long-standing notion that myofascial pain is primarily a "peripheral" pain disorder. Further analysis of these data will probably result in recommendation of a combined diagnostic profile for MPS that involves elements from the medical history, validated questionnaire instruments, and musculoskeletal examination.

Although there are certainly critics of the Simons and Travell clinical criteria for the diagnosis of MPS, it is generally agreed by physicians treating patients with MPS involving muscles of the and Travell clinical criteria for the diagnosis of MPS, it is generally agreed by physicians treating patients with

### PREVALENCE ESTIMATES

The prevalence of MPS in the general population is uncertain. This information is difficult to obtain because there are as yet no validated diagnostic criteria for the condition. Thus, it has not been possible to confidently seek out the disorder on a large scale with screening survey instruments.

In a study designed to document the prevalence of MPS in a general internal medicine practice, Skootsky and coworkers screened 201 patients and more thoroughly evaluated 172 who visited an academic health care center for various reasons; 54 patients whose symptoms included musculoskeletal pain were retained for additional testing. Patients with pain conditions clearly unrelated to MPS were eliminated. The remaining patients underwent a detailed TP examination guided by body pain diagrams that had been completed by the patients. When a muscle was found to contain a TP, it was digitally compressed for 5 to 20 seconds to see whether that maneuver would intensify the pain. The diagnosis of MPS was made when the patient exhibited regional pain intensified by digital pressure and the referral pattern corresponded with established referral maps. Sixteen patients (30% of 54, 8% of 201) in this academic general internal medicine practice satisfied criteria for the diagnosis of MPS. As shown in Figure 29.1, this would be slightly higher than the reported prevalence of FM (about 6%) in an academic internal medicine practice.

A national survey of 1663 American Pain Society members resulted in 403 completed surveys being returned. The participants responded to questions about the legitimacy of MPS as a unique condition, whether they considered it to be distinct from FM, and which signs or symptoms were important for its diagnosis. Of the respondents, 88% indicated that MPS is a legitimate diagnosis and 81% believed that it is distinct from FM. When examined by specialty, the perception of legitimacy ranged from 50% to 100%, with osteopaths and orthopedic surgeons (poorly sampled at only 0.5% and 1.2% of the respondents, respectively) reporting the lowest legitimacy (50% to 60%) and anesthesiologists and physiatrists, who accounted for 67% of the respondents, indicating higher than 90% legitimacy for MPS. The latter groups were generally (83%) convinced that MPS is distinct from FM. When asked about which findings were essential in making the diagnosis of MPS, the respondents showed strong support for regional pain, the presence of TPs, normal findings on neurologic examination, and pain that decreases with local injection. The respondents considered irrelevant or placed much less importance on finding palpable nodules, a local twitch response, and decreased range of muscle motion.

As advocates of the MPS construct strive for uniformity in their approach to diagnosis, there is also value in striving for uniform and logical terminology. If the essence of the condition is conceptualized, it is the TP. Many authors have referred to this construct as a “myofascial TP,” as though that maneuver would intensify the pain. The diagnosis of MPS was made when the patient exhibited regional pain intensified by digital pressure and the referral pattern corresponded with established referral maps. Sixteen patients (30% of 54, 8% of 201) in this academic general internal medicine practice satisfied criteria for the diagnosis of MPS. As shown in Figure 29.1, this would be slightly higher than the reported prevalence of FM (about 6%) in an academic internal medicine practice.
RELATED SYNDROMES

MPS taxonomy encompasses target areas of dysfunction as well. Specifically, two areas of the body that deserve special attention are the muscles of mastication and the muscles of the pelvis.

Dentists typically diagnose and manage temporomandibular joint disorder, now considered part of the spectrum of temporomandibular disorders; it is also referred to by some as myofascial pain dysfunction (MPD) syndrome. Fricton’s classic study of MPD identified 164 patients with this condition from among 296 with pain in the head and neck. In the patients with MPD, there was tenderness in at least one muscle of mastication, referral of the pain to an expected zone of reference, and frequent comorbid conditions such as postural or emotive factors. In most cases (66%) the symptoms emerged gradually, but in others there was a history of antecedent dental work or a motor vehicle accident.

The muscles of the pelvis can contribute to pain that can be confused with low back pain or with female organ pathology that can be manifested as urethral pain, vulvodynia, or dyspareunia. Pelvic area muscles with MPS (e.g., piriformis, iliopsoas, obturator internus) can refer pain to pelvic structures and cause dysfunction, or they can compress nerves (sciatic nerve, pudendal nerve), which then results in the symptoms.

PROPOSED PATHOGENESIS

Even though many theories on the etiology of MPSs have been proposed, researchers have not yet developed a definitive pathway. Briefly, it has been suggested that predisposing factors, such as body asymmetry and poor posture, can conspire with mechanical stressors, radiculopathy, nutritional inadequacies, endocrine dysfunction, or anger or other psychological factors to initiate the symptoms of MPS.

Exploration of the TrP via needle electromyography in a rabbit model of MPS and in symptomatic humans has led to the finding of spontaneous electrical activity (SEA). In a controlled research study, an electromyographer found this SEA phenomenon significantly more often when probing with an electromyographic needle in the location of a human TrP site than in the location of a control site. When researchers demonstrated that local infusion of phenolamine eliminated this SEA phenomenon and the pain, it was speculated that the TrP had the characteristic adrenergic dependency of the muscle spindle. Others have argued that the TrP is anatomically located at a neuromuscular junction. Thus, the evidence seems to support a spinal reflex that could involve the spindle and neuromuscular junction within the muscle, the spinal cord, and the radicular nerves that connect the muscle to the cord.

The most dramatic demonstration of objective abnormalities in MPS has come from microanalysis of interstitial fluid samples obtained from human skeletal muscle TrPs. The concentrations of proteins, bradykinin, calcitonin gene–related peptide, substance P (SP), tumor necrosis factor-α, interleukin-1β (IL-1β), serotonin, and norepinephrine were found to be significantly higher in this fluid. Local ischemia is suggested by a lower than normal pH in the region of the TrP (P < 0.01).

MANAGEMENT APPROACHES

The trend of therapeutic recommendations for MPSs favors the use of a systematic, comprehensive, multidisciplinary approach to treatment. It has been emphasized that important components of such a program should include the services of an experienced provider who has made an accurate diagnosis, has identified predisposing and perpetuating factors, and makes strategic use of both physical modalities and medications of proven efficacy. These recommendations appear to be surprisingly confident interventions for a condition whose very diagnosis is plagued by uncertainty.
A simple physical intervention that is often at least temporarily effective involves repeatedly applying a cold spray over the TrP in line with the involved muscle fibers, followed by gentle massage of the TrP and stretching of the affected muscle.\textsuperscript{1,3} Observing dramatic therapeutic success with this procedure had the effect of generating belief in the MPS concept on a broader scale. It is also potentially educational for patients as a technique to abort progression of future attacks at an early stage by applying their own local stretch and massage. On the other hand, it is acknowledged that this approach is more readily applied to a superficial muscle, such as the trapezius fibers around the neck, than to a more deeply positioned muscle, such as the piriformis or iliopsoas muscles of the pelvis.

The skills of an experienced physical therapist can be used to teach better posture, body mechanics, and relaxation techniques and to provide TrP massage, postisometric relaxation, reciprocal inhibition, and other manual modalities.\textsuperscript{1,3}

A more invasive approach to therapy is local injection or dry needling of the TrP.\textsuperscript{1,3,29} Even though the pain of MPS in a given muscle can be eliminated by local anesthesia of the relevant sensory and motor nerves, this approach provides only temporary relief. The more lasting approach is referred to as TrP injection. After the symptomatic (active) TrP has been identified, small amounts of local anesthetic can be injected into the muscle via short jabs of the needle into the location of the TrP.

It is believed that local anesthetic offers no long-term benefit but does make the procedure less uncomfortable. Many practitioners argue in favor of dry needling because the overall results are similar and the patient is not placed at risk of being sensitized to an adverse reaction from the anesthetic.\textsuperscript{31} The effectiveness of the needling procedure is explained by local structural damage to the TrP as a result of repeated passes of the needle. It is less clear whether scar tissue formation in the area represents an impediment to recurrence or a nidus favoring it. Typically, several local needling applications over a period of weeks or months are needed to achieve a cure. The required course is recognized to be substantially longer when MPS is complicated by the comorbidity of FM.\textsuperscript{6} Some have found additional usefulness in the injection of botulinum toxin,\textsuperscript{32} but others have failed to demonstrate a significant effect in controlled clinical trials.\textsuperscript{33}

Therefore, it seems likely that MPS is a legitimate clinical construct that has not been fully elucidated, partly because MPS is challenging to diagnose but more importantly because diagnostic criteria have not yet been validated. This is not likely to change until experts in the field feel the need for validated criteria and put their collective efforts to the task so that the results will be more universally accepted. Until this is accomplished, MPS will remain in a form of clinical and scientific limbo. Once validated diagnostic criteria are developed, the next steps would be possible—to conduct epidemiologic, pathologic, and therapeutic studies. The outcomes of such studies would substantially advance the field, both scientifically and in the arena of public opinion.

### FIBROMYALGIA

#### DIAGNOSTIC CRITERIA

The ACR developed research criteria for the classification of FM syndrome based on the results of a multicenter research study in 1990 (Table 29.1). The scientific community quickly accepted these criteria with a broad application for epidemiologic, biologic, and therapeutic studies. The ACR research classification required only two components for diagnosis: a history of widespread pain (i.e., located in all four quadrants of the body and axial) for at least 3 months and allodynia in response to digital pressure (defined as pain with 4 kg of pressure) at 11 or more of the 18 anatomically defined tender points (Table 29.2). The research diagnostic criteria demonstrated moderate sensitivity (88.4%) and specificity (81.1%) for FM against control patients. The study design included pain-free individuals and patients with other painful conditions as the control groups.

The tender points in FM are conceptually and anatomically different from the TrPs that define MPS. FM tender points are symmetrically distributed throughout the body, whereas TrPs have a more random distribution. In contrast to MPS, these tender points are not limited to muscular locations but also include other soft tissue structures and do not refer or radiate pain to other locations. The ACR’s research criteria unknowingly created several problems. Researchers developed these criteria to standardize research identification of FM. The research classification identified 18 anatomically defined tender points (see Table 29.2) where patients with FM have allodynia in response to digital pressure. Unfortunately, clinicians appropriated these criteria for clinical diagnosis. Many providers did not follow the intent or structure of the criteria, which made the diagnosis of FM even more complicated.

Primary care physicians diagnose the majority of cases of FM rather than subspecialists. Consequently, many physicians either rigidly (and inappropriately) applied the research criteria or simply rejected their face validity. Accordingly, few providers consistently identified and applied 4 kg of pressure to all 18 designated areas. They used symptom-based diagnostic criteria that focused on fatigue, cognitive impairment, and somatic symptoms, which were excluded in the original research criteria. Moreover, an additional problem with the criteria is that patients with improved symptoms and examination findings no longer met the classification.

Twenty years after the initial research classification was developed, the FM research community recognized the growing need for clinical diagnostic criteria that reflect the spectrum of FM and practical components of clinical diagnosis. The objective was to develop a screening tool with wide applicability that could be used to diagnose and assess the severity of the FM symptoms. Researchers evaluated patients in whom FM was previously diagnosed by using the widespread pain index (WPI) and categorical scales. The new criteria used these categorical scales to assess patients’ cognitive symptoms, unrefreshing sleep, fatigue, and other somatic symptoms. The ACR used these categorical scales to develop a severity scale. Finally, they combined the severity scale with the WPI to stratify disease severity in patients with FM (Box 29.2).

**PREVALENCE ESTIMATES**

FM has been found in all ethnic groups studied to date; it is not limited to affluent or industrialized nations. With prevalence estimates ranging from 2% to almost 12% in the general population, it must be viewed as a common medical condition. Its prevalence increases with age, most dramatically in women, with a peak in the fifth to seventh decade (7.4% to 10%). Middle-aged women are four to seven times more likely to be affected than men of similar age. This was another unintended consequence of the 1990 ACR criteria—by using the same tenderness threshold in men and women even though we now understand that women are substantially more tender than men, these criteria overestimate the prevalence of FM in men. By contrast, the sex distribution of childhood FM is almost equal (probably

<tr>
<td>3= Great deal of symptoms</td>
<td></td>
</tr>
</tbody>
</table>

The SS scale score is the sum of the severity of the symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.

*Somatic symptoms that might be considered are muscle pain, irritable bowel syndrome, fatigue or tiredness, difficulty thinking or remembering, muscle weakness, headache, pain or cramps in the abdomen, numbness or tingling, dizziness, insomnia, depression, constipation, pain in the upper part of the abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud’s phenomenon, hives or welts, ringing in the ears, vomiting, heartburn, oral ulcers, loss of or change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulty, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.
because girls do not appear to be more tender than boys until after puberty), and many children outgrow their symptoms. About 15% of patients seen in rheumatology clinics are classified as having FM, whereas the prevalence of FM is about 6% in other practice settings. In 1997, the annual direct cost of care for the average FM patient in the United States was estimated to be more than $2000. Multiplied by the 6 million U.S. patients with FM, this figure predicts an annual direct cost of more than $12 billion.

In a study designed to examine the prevalence of FM in a midwestern community, Wolfe and associates found that about 60% of the general population in their study did not currently have pain. About 30% of the general population had acute or regional pain (the latter would include MPS), and about 10% had chronic widespread pain (the category for FM). Follow-up examination revealed that about 2% of the general population (all within the 10% in the chronic widespread pain subgroup) met criteria for the classification of FM, but the patients who reported having regional pain were not examined to confirm the presence of MPS (Fig. 29.1A). In 2008, the National Arthritis Data Workgroup used these data with the population census data to extrapolate an estimated 5 million Americans with FM. The ability to accurately generalize the estimated 2% prevalence of FM in Wichita, Kansas, to the broader U.S. and international populations is uncertain. FM poses a diagnostic challenge, as well as a management flow quandary, for many providers. The proposed clinical flow would stratify these patients for improved management (Box 29.3).

Little is known about the incidence of FM, but risk factors for its development may include physical trauma, a febrile illness, or a family history of FM; these factors may not be mutually exclusive. A narrowed cervical canal may be an important risk factor for the development of chronic pain following a whiplash injury.

### Clinical Features

The clinical manifestations of FM are usually more complex than body pain alone. Associated symptoms (comorbidities) often require further investigation and specific management. For example, patients describe disordered sleep, fatigue, cognitive dysfunction, dizziness, headaches, psychological distress, depression, anxiety, chest pains, dysesthesia in the hands, cold intolerance, restless legs, and irritable bowel or irritable bladder syndrome. These comorbid symptoms clearly contribute to the suffering experienced by patients with FM. As a result, dysfunctional behavioral patterns and disability develop in affected individuals.

### Cognitive Dysfunction

People with FM frequently complain of diminished cognitive function. This ranges from difficulty concentrating when reading a book to short-term memory deficits. Research has suggested that FM patients perform poorly on a range of cognitive tasks and exhibit premature cognitive aging, with the main evidence of abnormality being derived from distraction or multitasking experiments.

### Affective Distress

Before FM was better understood as a condition of central sensitization, patients with this condition were often suspected of having a psychiatric disorder. Indeed, the frequencies of depression and anxiety in patients with FM were each found to be about 40% at the time of diagnosis of FM, but that left 60% who were not actively depressed or anxious. Depression also occurs with rheumatoid arthritis (20% to 30%), cancer, and other chronic conditions (14% to 33%). In these settings the psychological comorbidities are believed to result from the pain and physical limitations imposed by the disease. The same could be true for FM.

---

**Box 29.3 Proposed Plan for Screening and Comprehensive Care of Patients with Fibromyalgia**

**Phase 1: Pain Screening and Primary Care**

Phase 1 involves a simple screening questionnaire that the receptionist for a primary care health professional (primary care physician [PCP], chiropractor, nurse practitioner, physician assistant, general practitioner, general internist) would give to every patient entering the waiting room until all the primary care professional’s regular patients had been assessed (see Fig. 29.2). Thereafter, it may be given only to new patients. When the PCP reviews the form of a patient with pain (question 1 answered “yes”), a decision about the symptom’s distribution would be made (localized pain, regional pain, widespread pain). A second decision would be whether to initiate care for the patient’s symptoms or refer the patient for further care of this problem.

**Phase 2: Comorbidity Screening and Secondary Care**

Based on findings on the screening material, a patient identified as having widespread pain would be examined by the PCP or referral physician to make the diagnosis (fibromyalgia [FM] if it applies). The next stage would be screening for comorbid conditions by a well-informed and willing PCP or consultant (rheumatologist, neurologist, pain specialist, internist, physiatrist). The patient would begin an exercise program and counseling with a professional specifically trained to provide advanced care for FM. Problems found in counseling (e.g., marital, financial, psychiatric) would spin off to an experienced specialist (e.g., counselor, psychologist, psychiatrist, disability advisor, financial counselor).

**Phase 3: Comorbidity Screening and Tertiary Care**

Based on second-line screening for comorbid conditions, care would begin for the additional diagnoses. This phase may involve referral to tertiary subspecialty care (e.g., cardiologist, gastroenterologist, neurologist, neurosurgeon, physical therapist, psychiatrist, physiatrist, obstetrician-gynecologist, urologist). This care would be integrated with follow-up by the primary care resource.

**Phase 4: Long-Term Primary Care and Follow-up Assessment**

The primary or secondary health care professional would continue to monitor the patient over time and assess the status of care for pain and comorbid conditions. There would be monitoring for side effects to medications and for new problems intruding on the continuity of the FM that might or might not be related to it. In this phase it is important to note that every new symptom in a patient with FM is a component of the FM. Health care providers will need to know what is and is not expected with FM.
Sexual abuse in childhood is no longer a viable hypothesis for the primary cause of FM.41

INSOMNIA
Most FM patients experience chronic insomnia. Some have difficulty falling asleep (initial insomnia), but most awaken feeling distressingly alert after only a few hours of sleep (mid-insomnia) and are then unable to sleep soundly again until it is almost morning (terminal insomnia). People with FM typically awaken in the morning feeling painfully stiff, cognitively sluggish, and unrefreshed by their sleep. It is surprising that these chronically sleep-deprived individuals have difficulty napping during the day.

STIFFNESS
The morning stiffness experienced by most FM patients is remarkable because it lasts so long and is so severe. The typical stiffness of osteoarthritis usually lasts 5 to 15 minutes, whereas that of patients with inflammatory rheumatoid arthritis is 30 minutes to 2 hours. By comparison, the stiffness of FM patients typically lasts 45 minutes to 4 hours. The best clinical correlate with morning stiffness in FM is pain, so patients may not be clearly distinguishing these seemingly different symptoms.

FATIGUE
Approximately 80% of patients with FM complain of fatigue. Consequently, a large proportion of individuals who meet the criteria for FM also meet the criteria for chronic fatigue syndrome. The differential diagnosis of fatigue is difficult because it must include various sleep disorders, chronic infections, autoimmune disorders, psychiatric comorbidities, and neoplasia. Fatigue may also result from residual levels of sedating medication, such as tricyclic antidepressant drugs or other sedatives often used to treat the insomnia associated with FM.

Figure 29.2 Screening questionnaire for chronic widespread pain as seen in fibromyalgia syndrome (FM). The findings supportive of FM would be chronic pain from question 1, the relative severity of the pain from question 3, and widespread pain from question 4. Each question could also be applied to other categories of soft tissue pain, and patients with localized or regional musculoskeletal pain, if present, would be identified by the body pain diagram. APT, average pain threshold; TPI, tender point index.
IRRITABLE BOWEL SYNDROME AND DYSPESPIA

Irritable bowel syndrome (IBS) and benign dyspepsia are common gastrointestinal conditions that occur in 30% to 50% of patients with FM. A feature common in both FM and IBS may be central sensitization. These conditions may be synergistic with respect to patients’ perception of their illness and have a modulating effect on the clinical outcome. A common differential diagnosis is lactose intolerance, which can cause intermittent cramping, diarrhea, and flatulence. A simple litmus test of feces will often show acidic pH when lactose intolerance is the cause of the diarrhea.

INTERSTITIAL CYSTITIS, PAINFUL BLADDER SYNDROME, AND FEMALE URETHRAL SYNDROME

Roughly 60% of FM patients experience urinary urgency and nocturia on a regular basis, and there is a high rate of bidirectional comorbidity between interstitial cystitis/painful bladder syndrome and FM. Up to 12% of FM patients also fulfill the diagnostic criteria for female urethral syndrome, which is defined as the presence of urinary frequency, dysuria, suprapubic discomfort, and urethral pain despite sterile urine. Many patients report having been treated with antibiotics frequently for culture-negative urinary tract infections. Intensive investigations often fail to disclose a specific cause. Eliminating certain dietary substances such as caffeine or alcohol from the patient’s diet can sometimes be helpful. Self-report questionnaire instruments have been developed to facilitate screening for this condition in FM patients (see Fig. 29-1).

RELATED SYNDROMES

Conversely, FM can develop in patients with other chronic diseases during the course of their symptoms. For want of better terminology, in the setting of another painful condition or inflammatory disorder, the FM condition has been referred to as secondary FM. This terminology is not intended to imply that the FM is caused by the other condition, but the terminology is entrenched and serves a purpose. Secondary FM may not be clinically distinguishable from primary FM, but increasingly, there are laboratory findings that can be used to distinguish these FM subgroups.

As examples of secondary FM, almost 30% of patients with rheumatoid arthritis, 40% of patients with systemic lupus erythematosus, and 50% of those with Sjögren’s syndrome have concomitant FM. Patients with a rheumatic disease and FM seem to experience articular pain disproportionate to their synovitis. This must be considered when treating the rheumatic condition because increasing the dosage of antirheumatic medications in the absence of active inflammation may have little effect on the pain amplified by FM. The best results are obtained by treating each condition separately.

Patients with a rheumatic disease and concomitant FM should be warned that a transient increase in FM symptoms may occur with each decrease in glucocorticoid dosage (steroid withdrawal FM), so the usual FM therapy may need to be increased transiently. This is a surprising phenomenon because glucocorticoid is not helpful in treating primary FM. To avoid interference with a steroid taper by emergent FM, it is best to decrease the dosage of the glucocorticoid used to treat the rheumatic disease in graduated steps at about 2-week intervals. The rate of the taper depends on the current dosage.

Infectious and inflammatory conditions that seem to be associated with FM include hepatitis C, tuberculosis, syphilis, and Lyme disease. The prevalence of overlap may depend on the prevalence of the infectious disease in the community. An academic practice in a Lyme-endemic area evaluated 788 patients with apparent infection for a mean of 2.5 years. Of those with Lyme disease, 20% met the criteria for FM. The symptoms of FM developed 1 to 4 months after infection, often in association with Lyme arthritis. The signs of Lyme disease generally resolved with antibiotic therapy, but the FM symptoms often persisted. The largest subgroup of the 788 patients did not have Lyme disease, but they did meet the criteria for FM or chronic fatigue syndrome.

PATHOGENESIS

Patients with FM have a constellation of symptoms, but the most common is pain. Before the advent of research techniques such as quantitative sensory testing and functional neuroimaging, many believed that FM and chronic widespread pain had primarily a psychosocial origin with little “organic” basis. However, patients with FM demonstrate reliably augmented sensory processing that was initially thought to be confined to the sensation of pain (i.e., hyperalgesia or allodynia) but is now known to include hypersensitivity to other sensory stimuli such as auditory stimulation. Functional magnetic resonance imaging (MRI) studies have corroborated this finding of hyperalgesia or allodynia in that multiple studies have now shown that FM patients display increased neuronal activation in comparison to controls when the same low-intensity stimulus is applied to both groups. These imaging studies also provide a theoretical basis for globally augmented sensory processing in FM since the area of the brain that most consistently exhibits increased activity in FM and most other chronic pain states is the insula, a region involved in polysensory integration. Even though multiple mechanisms to assess alterations in pain perception are used, the pressure pain threshold (rather than heat or electrical stimuli) response has the closest relationship with the clinical features of FM and other chronic pain states.

Patients with FM have also been found to have altered levels of biomarkers associated with pain, specifically glutamate and SP. Harris and colleagues’ recent work using proton spectroscopy to evaluate insular glutamate elevations in patients with FM demonstrated higher mean levels than in controls. Although such techniques do not allow simple patient testing, the findings support the distinct biologic identity of FM. Endogenous opioid levels are elevated relative to controls, thereby providing a potential mechanism for the lack of responsiveness to opioid therapy in patients with FM. Objectively, this has been demonstrated through positron emission tomography (PET)-derived μ-receptor occupancy.

Abnormalities in neurochemical mediators of central nervous system (CNS) nociceptive function are clearly present in ways consistent with the patterns of symptoms. The role of neurochemicals as neurotransmitters and modulators of the nociceptive process has been studied extensively in animals. It is believed that these agents participate in
descending inhibition of nociception. This line of reasoning has led to the measurement of neurotransmitter levels in biologic fluids obtained from FM patients. Several major classes of biochemical participants in the nociceptive process are the biogenic amines (e.g., serotonin, norepinephrine, dopamine), excitatory amino acids (e.g., glutamic acid, glutamine, aspartic acid, asparagine, glycine, arginine), neurokinins (e.g., SP, calcitonin gene–related protein, arginine vasopressin, neuropeptide Y), nerve growth factor (NGF), and probably nitric oxide. The biogenic amines are generally considered to be antinociceptive, whereas the excitatory amino acids, SP, NGF, and perhaps even nitric oxide would more likely be pronociceptive.

Moldofsky and Walsh were the first to suggest that serotonin (5-hydroxytryptamine [5-HT]) might be involved in the pathogenesis of FM, both in failing to attenuate persistent pain and in failing to correct the chronic deficiency in slow-wave sleep. They found a clinical correlate between FM pain and the plasma concentration of tryptophan. They found a clinical correlate between FM pain and the plasma concentration of tryptophan.

Moreover, the serum and cerebrospinal fluid (CSF) of FM patients were found to exhibit low concentrations of tryptophan. Early findings of a low serum concentration of 5-HT have been supported by other investigators. Levels of 5-HT have not yet been reported in the CSF of FM patients, but levels of its immediate precursor, 5-hydroxytryptophan (5-HTP), and its metabolic product, 5-hydroxyindole acetic acid (5-HIAA), have been studied. In FM, both were found to have lower than normal CSF concentrations relative to the CSF of healthy normal controls. In addition, 5-HIAA was measured in 24-hour urine samples of patients with FM and compared with the results from healthy normal controls. Even the numbers of active FM tender points correlated with the concentration of 5-HT in FM sera.

The role of α-adrenergic agonists such as norepinephrine in the antinociception system of FM patients may be similar to that of 5-HT, but a number of unique features of this biogenic amine have attracted attention. The concentration of 3-methoxy-4-hydroxyphenyl-glycol (MHPG), the inactive metabolite of norepinephrine, is significantly lower than normal in CSF. The concentration of homovanillic acid, the inactive metabolite of dopamine, was found to be significantly lower than normal in FM CSF. This finding, which would imply low CNS levels of dopamine in FM, was complemented by a study of the role of dopamine receptors in the function of the hypothalamus and pituitary in FM.

The neuropeptide SP is an 11–amino acid peptide that has several important roles in the process of nociception. Activated, small, thinly myelinated Aδ- and C-fiber afferent neurons respond to noxious peripheral stimuli by releasing SP into laminae I and V (Aδ) and lamina II (C fiber) of the spinal cord dorsal horn. With random interstitial diffusion, SP or its C-terminal peptide fragment makes contact with its neurokinin-1 (NK1) effector receptor. The mechanism of action of SP in the dorsal horn of the spinal cord is not entirely clear, but it appears to not be a signal transporter, as is glutamic acid. Rather, SP apparently facilitates nociception by arming or alerting spinal cord neurons to incoming nociceptive signals from the periphery.

Vaeroy and associates, working in Norway, were the first to recognize that the concentration of SP was elevated (average threefold increase) in the CSF of FM patients in comparison to healthy controls. Their findings have now been reproduced in three other clinical studies. The biologic relevance of SP in CSF to the pain of primary FM is still uncertain. An important question is whether an elevated CSF SP level is unique to FM. An earlier report indicated that CSF SP concentrations are lower than normal in various chronic painful conditions. For example, CSF SP levels were found to be lower than normal in patients with diabetic neuropathy and chronic low back pain.

The elevated CSF SP level in FM has prompted much speculation about the cause. NGF was known to stimulate the production of SP in small, afferent, unmyelinated neurons. It was therefore an exciting development to have found elevated levels of NGF in the CSF of primary FM patients, but not in those with FM and an associated painful inflammatory condition (secondary FM). This suggests that there may be different mechanisms for the elevated SP level in primary FM and in FM associated with inflammatory diseases.

Another approach to understanding the cause of FM has been through genetic studies. About a third of FM patients have reported that another family member, usually a female, has a similar, chronic pain condition or has already been given the diagnosis of FM. Published studies have documented familial patterns. Some have predicted an autosomal dominant mode of inheritance for FM, and evidence for this has increased. In a study by Yunus and coworkers, a linkage of FM with the histocompatibility locus was examined by the sibship method. A complete genome scan of families with two or more FM-affected members has been undertaken by using samples of DNA from a large number of multicase FM families for comparison of clinical and laboratory genotypic features. Meanwhile, several candidate genes have been proposed to directly explain the specific metabolic abnormalities that have been consistently observed in FM. A study of 80 multicase FM families has already examined markers spanning the genomic regions for the following: the serotonin transporter (HTTLPR, three regional markers) on chromosome 17, the serotonin receptor 2A (HTR2A, three regional markers) on chromosome 13, and the histocompatibility locus antigen (HLA, two regional markers) region on chromosome 6. No evidence for linkage was found in the HTTLPR region. Families with an older age of onset were linked to the HLA region (logarithm of the odds [LOD] = 3.02, P = 0.00057), thus suggesting an immune-mediated pathogenesis. In the HTR2A region, the results indicated a moderately strong linkage to families with a younger age of onset, less severe pain, lower levels of depression, and absence of IBS (LOD = 5.56, P = 0.000057). The HTR2A genome is polymorphically imprinted, so the issue of parent of origin will need to be considered in future studies. Bioinformatics mining and further sequencing of genes in the HTR2A region will help identify specific polymorphisms for further clinical association testing.

Another appealing gene candidate as a causative factor in FM would be the enzyme catechol-O-methyltransferase (COMT), which physiologically inactivates catecholamines such as dopamine, norepinephrine, and endorphins, as well as catecholamine-containing drugs. Polymorphism (actually dimorphism) in the gene encodes for variations in COMT...
enzyme activity. The COMT gene exists in two forms, L and H, which make copies differing by a single amino acid (either methionine or valine) at the variable site. This small variation has a large effect on the activity of COMT. Subjects with the LL phenotype, who have two copies of the methionine version, make threefold to fourfold less COMT than do those with the HH variant, which contains valine at the variable site. The significance of COMT polymorphism (LL, LH, or HH) in FM was assessed by Gursoy and colleagues. Seventy-three patients with FM and 61 demographically matched healthy controls were included in the study. Although no significant difference was found between LL and LH separately, the LL and LH genotypes together were more highly represented in FM syndrome than in the healthy normal control groups (P = 0.024). In addition, the prevalence of HH genotypes in FM was significantly lower than that in the control groups (P = 0.04).

The much higher prevalence of FM in women has led to speculation regarding gender-specific causes. For example, in an epidemiologic study of a midwestern community, the curves representing pain thresholds (sensitivity to a pressure stimulus) in men and women consistently showed lower values for women. Because the examination component of the ACR criteria for FM involves the response to a fixed pressure stimulus of 4 kg, it is not surprising that these criteria have identified more women than men with multiple sclerosis. Understanding of the mechanisms responsible for this gender-related difference in pain thresholds is incomplete. Measurements of female hormones have not been very fruitful. One possible explanation is that men normally synthesize substantially more 5-HT in their brains than women do.

Many symptoms of FM resemble those observed in patients with hormone deficiencies. This observation has led to the study of neuroendocrine function in FM. Subsets of patients with FM exhibit functional abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis, sympatheticadrenal (autonomic nervous) system, hypothalamic-pituitary-thyroid axis, hypothalamic-pituitary-gonadal axis, or hypothalamic-pituitary–growth hormone axis. In FM patients, the HPA axis exhibits an exaggerated adrenocorticotrophic hormone (ACTH) response to insulin-induced hypoglycemia or stressful exercise. Despite this dramatic rise in serum ACTH level in FM, the level of cortisol did not rise commensurately. Mediators that regulate the HPA axis include corticotropin-releasing factor, serotonin, norepinephrine, SP, and IL-6.

Growth hormone was identified as a target because of its production during delta-wave sleep (stages 3 and 4, non-rapid eye movement sleep), which many FM patients fail to achieve normally. An alternative means of monitoring growth hormone production has been to measure the plasma levels of insulin-like growth factor type I (IGF-I, previously known as somatomedin C), which has a long half-life. An age-adjusted deficiency of IGF-I has been documented in FM. In addition, administration of human growth hormone to FM patients was effective in reducing the severity of FM symptoms.

The reasons why these endocrinopathies would be associated with a chronic pain syndrome are not entirely clear. It may be that CNS abnormalities in the availability of biogenic amines such as serotonin, norepinephrine, and/or dopamine are responsible for the abnormal regulation of the neuroendocrine system. These systems interact and are interdependent, so in susceptible individuals a partial failure of one system may lead to subtle malfunctions in others.

Moreover, immune function abnormalities have been identified as early as the 1980s. This foundation has been expanded to additional markers. An early epidemiologic search for serum antinuclear antibodies disclosed that almost a third of FM patients exhibit low titers of these autoantibodies, but more recent reports have reduced this figure to 14% or to as low as 8.8% in FM versus 8.9% in patients with osteoarthritis. There have been intermittent reports of lymphocyte immune abnormalities in people with FM, but the outcomes of these studies were variable and hard to interpret in light of the clinical picture. More recently, two studies have critically evaluated the possible role of cytokines in patients with FM. Serum IL-8 and IL-6 levels from in vitro–stimulated peripheral blood mononuclear cell cultures were significantly higher in the FM sample. The serum IL-8 level was most dramatically elevated in FM patients who were also depressed, but it also correlated with pain intensity and the duration of FM symptoms. Its production in vitro is stimulated by SP, which may help explain the elevated levels of both these cytokines, even in different fluid compartments, in FM patients. It is therefore of interest that IL-6 has been successfully administered to people with FM and found to substantially modulate the severity of FM-related symptoms.

In summary, the pathogenesis of FM was shaped by the recognition of allodynia as a manifestation of abnormal central nociceptive processing. This has redirected the collective view of FM. This revised perspective pointed research on this condition in a new direction, specifically toward the study of central sensitization. Some abnormalities found in FM, namely, the low 5-HT and elevated SP levels, are logically consistent with a pain amplification syndrome. The extent to which these mechanisms are unique to FM will be critical in determining the direction of future research.

**MANAGEMENT APPROACHES**

The objectives of FM treatment are to reduce pain, improve sleep, restore physical function, maintain social interaction, and re-establish emotional balance. A reasonable community objective might be to reduce the need for expensive health care resources. To achieve these goals, patients will need a combination of social support, education, physical modalities, and medication.

**ADEPT**

It is reasonable to view treatment approaches in categories, and sometimes an acronym can help the physician remember them. For that purpose, a six-step outline of therapy has been developed: ADEPT living stands for attitude, diagnosis, education, physical modalities, treatment with medication, and living.

**ATTITUDE**

Attitude refers to the preparation, or frame of mind, that each participant brings to the therapeutic interaction. Clinicians must be prepared to accept FM as a real condition that exerts a tremendous impact on the patient’s life. From
the patient’s perspective, it will be important to realize that FM is just one of hundreds of conditions of concern to the health care provider. Additionally, the initial symptoms for different medical conditions can be very similar; therapy for FM is still experimental, and the physician’s time with each patient is necessarily limited. The attitudes of family members, employers, policy makers, and politicians all have an important impact on the patient’s condition.

DIAGNOSIS

The correct diagnosis should be made not only to identify FM but also to disclose any comorbid medical conditions. If the patient has concomitant hypothyroidism, diabetes mellitus, or renal insufficiency, the approach to management will also need to accommodate these other conditions. For example, when rheumatoid arthritis and FM are evident in the same patient, treatment is more successful when both conditions are treated as though the other were not present.

EDUCATION

Education is crucial to the management of FM. Understanding is power when it comes to maintaining a proper attitude, adapting to limitations, and taking an active role in the therapeutic program. Several studies have examined the effects of cognitive-behavioral therapy (CBT) on outcome in FM and demonstrated positive effects on pain scores, pain coping, pain behavior, depression, and physical functioning. Such gains are often maintained for several months after completion of the therapy, and periodic booster sessions may prolong the benefits. Some clinicians, regarded as providing an environment for learning discontent, have viewed support groups negatively. On the other hand, joining a resource-oriented support group can help FM patients come to terms with a complicated illness.

PHYSICAL MODALITIES

A variety of physical modalities have been proposed as interventions for FM and can logically be segregated into two categories—those that patients can accomplish for themselves and those that require active participation by a trained therapist. At home, patients can pace their usual activities by setting a clock to time the necessary work activity and then balance the work time with an equal period of rest. Progressive exercise, heat applied as a shower or bath, and Jacobson relaxation techniques can all be used as self-directed therapies with minimal cost.

Aerobic exercise was among the first nonpharmacologic strategies advocated for FM patients, with convincing evidence of benefit. Its goals are to maintain function for programs alone. However, one should be aware that high levels of exertion can temporarily worsen the pain and result in fear of movement (kinesophobia), especially in this patient population. When the diagnosis of FM is first made, the patient is usually deconditioned and has already learned to fear the pain induced by exercise. When prescribing exercise for FM patients, the clinician should begin with low-intensity exercise, such as walking in place in a swimming pool, and minimize eccentric muscle contractions. Continuation of the exercise program will be facilitated by a gradual reduction in pain. Other physical therapies, including yoga, Pilates, and tai chi, have been found to be effective in reducing the pain associated with FM. However, other alternative and complementary methods, including Reiki, provided no benefit.

Most patients report benefit from heat in the form of dry or moist heat. Many find that a hot bath or shower can be more effective than analgesic medication for headache, body pain, and stiffness. The application of heat can relax muscles, facilitate exercise, and improve the sense of well-being. Cold application is preferred by some. Light massage that gradually progresses to deep sedative palpation of large body surfaces can reduce muscle tension, but its influence on body pain usually lasts only 1 or 2 days.

TREATMENTS

Cognitive-Behavioral Therapies

Numerous psychological therapies have been found to be beneficial for relief of pain in those suffering from chronic widespread pain, including FM. In a recent randomized controlled trial (RCT) it was found that telephone-based CBT was beneficial in health care–related quality outcomes. In this study 442 patients with chronic widespread pain were randomized to receive 6 months of telephone CBT, graded exercise, combined intervention, or treatment as usual. Patients receiving CBT with or without exercise did better than those undergoing standard medical treatment. Those who combined CBT with exercise improved to the greatest degree. These improvements in quality of life were long lasting and the interventions were cost-effective by using telephone instead of face-to-face CBT. Attention modification has also been very successful in altering the perception of pain in patients with chronic widespread pain. Attention bias refers to the phenomenon whereby patients identify with information that reinforces their focus on their painful condition. The goal of attention modification is to interrupt this negative and self-reinforcing cognitive cycle. In a recent RCT, the Attentional Modification Paradigm (AMP), in which patients completed two 15-minute AMP sessions per week for 4 weeks, was used to facilitate such changes in attentional pain biases. Those in the AMP program reported statistically significant and substantial reductions in several individual difference variables relative to those in the control condition, and a greater proportion experienced clinically significant reductions in pain.

Pharmacotherapies

Recent developments regarding FM therapy relate to new medications being developed and tested specifically for this condition. Three medications are currently approved by the FDA for the treatment of pain related to FM—the amine reuptake inhibitors duloxetine and milnacipran and the membrane stabilizer pregabalin—although many medications are used with varying success in off-label fashion. The theoretical background relating these agents to FM has been based on various biochemical or physiologic abnormalities.
found in FM and known to be important contributors to the pathogenesis of pain. One approach to the therapeutic goals of pharmaceutical therapy would be to say that FM has three main domains (or symptoms) that represent targets for therapeutic intervention, such as pain, insomnia, and depression, but others could be substituted as well.

Nonsteroidal Anti-Inflammatory Drugs

It seems logical that analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) should be an important component of a multimodal treatment program for a painful condition such as FM, but NSAIDs have not been shown to be effective as monotherapy for this condition. Perhaps the more important role of such agents is to contribute synergy with other medications because it is very likely that some of the central sensitization seen in conditions such as FM is probably being driven by peripheral nociceptive input. For example, there is evidence that acetaminophen slightly enhances the benefit achieved from tramadol therapy—hence the development of tramadol-acetaminophen tablets.

Local Anesthetics

Lidocaine infusions have not generally been found to provide supplemental benefit in addition to oral amitriptyline intake on pain outcomes. However, a recent study of 68 FM patients with MPS and 56 FM patients with regional joint pain showed that peripheral TrP injections and hydroelectrolytes ameliorated FM pain and increased pain thresholds at sites distant from the therapeutic interventions, thus providing further evidence that painful peripheral stimuli contribute to the perpetuation of central augmentation.

Opioids

Although opioids are prescribed for the treatment of FM, clinical experience and empirical evidence indicate that they are not effective in ameliorating this condition. Thus, the risk for tolerance, opioid-induced hyperalgesia, addiction, and prescription drug diversion is not justified by the insignificant therapeutic benefit. When patients are taking an opioid, it is recommended that proactive treatment be undertaken to manage the anticipated side effects, such as constipation and pruritus. The aim of opioids in severe cases and those refractory to all conservative medical and psychological therapies should not be merely pain relief but rather clear improvement in physical function. If improvement in function is not achieved, these agents must be discontinued and not restarted. A therapeutic trial with a defined end point and defined target dose must be discussed with the patient in advance of starting opioid-based therapy. If the physician and patient engage in opioid therapy, a clear behavioral contract needs to be signed by both parties.

Serotonin

In vivo synthesis of 5-HT can be augmented by the administration of 5-HTP, which benefits from one-way kinetics in conversion to 5-HT. It is effective in the treatment of FM at a dosage of 100 mg three times daily and is available over the counter in the United States. Tropisetron is a 5-HT₃ antagonist that has been subjected to controlled study in Europe for the treatment of FM. A responder group that exhibits a rapid and steady decrease in pain intensity has been distinguished from a nonresponder group that showed almost no response. There seems to be a bell-shaped dose-response curve; the best effects are seen in patients receiving 5 mg tropisetron (39% responder rate), but that effect is lost at higher dosages. Treatment with tropisetron is well tolerated, limited mainly by gastrointestinal side effects. A randomized, double-blind, placebo-controlled trial of dolasetron, an intravenously administered 5-HT₃ receptor antagonist, found that patients with FM experience significant pain relief at 3 months of therapy, but this benefit was not long lasting. Recent work has suggested that the drug cyclobenzaprine, which was shown to be effective for FM several decades ago, might work in part by blocking 5-HT₂A receptors.

Amine Reuptake Inhibitors

Tricyclic antidepressant drugs are effective at a low dose (10 to 150 mg) and improve sleep and enhance the effects of analgesics. The largest experience is available for amitriptyline in very low doses (10 to 25 mg) given at night to improve sleep. A combination of fluoxetine and amitriptyline was found to be more effective than either agent alone. However, in another study neither amitriptyline nor nortriptyline had any greater benefit than placebo did. Selective serotonin reuptake inhibitor (SSRI) drugs were developed for the treatment of depression; however, in the usual antidepressant dosages these agents are effective as monotherapy for depression, and in very high dosages (fluoxetine, 80 mg/day), for relief of FM pain. This analgesic effect may be non-serotonin selective at these high doses. The analgesic effects of the tricyclic drugs, not apparent with normal dosages of SSRIs, have suggested that the small contribution from inhibition of the norepinephrine transporter might be critical to their pain-relieving effect. In the tricyclic class there is a large—up to 900-fold—difference between norepinephrine reuptake inhibition activity and that of serotonin.

Another class of amine reuptake inhibitors includes the selective serotonin-norepinephrine reuptake inhibitors (SSNRI), which have been developed to achieve better balance between inhibition of the reuptake of serotonin and norepinephrine. One class (exemplified by duloxetine) exhibits almost equivalent activity serotonin-norepinephrine reuptake inhibitor [SNRI] whereas the other class (norepinephrine selective reuptake inhibitor [NSRI] exemplified by milnacipran) exhibits potent inhibition of norepinephrine reuptake. Duloxetine has antidepressant activity, which may be an important reason for choosing it to treat FM patients who are depressed (about 40% of FM patients are depressed). In dosages of 60 to 120 mg once daily in the morning, duloxetine can be effective in controlling FM body pain, regardless of whether the patient is depressed. It is well tolerated by most FM patients. Nausea, dry mouth, constipation, diarrhea, and anorexia are reported more frequently with active drug than with placebo. The adverse effects can be lessened by starting the drug at a low dosage (50 mg in the morning) and gradually increasing it as tolerated, such as increasing the morning dosage by 30 mg every week. The most common target dose is 60 mg in the evening; however some have noted efficacy at higher doses.

Tramadol is a medication with mixed action. It inhibits reuptake of serotonin and norepinephrine in combination with weak μ-opioid agonism. It reduces the impact of pain on FM patients. As monotherapy, it significantly reduces
the severity of the pain experienced but is not helpful for insomnia or depression. In combination with acetaminophen, substantial synergy has been noted. Nausea and dizziness can be limiting at first in about 20% of patients, but initiating therapy with just one tablet at bedtime for 1 to 2 weeks can reduce the frequency of this adverse effect and allow a progressive increase in dosage by about one tablet every 4 days to full therapeutic levels. A typical maintenance dosage for FM is 300 to 400 mg/day in three to four divided doses, concomitant with acetaminophen at 2 to 3 g/day in divided doses. Milnacipran, an SSNRI with threefold greater selectivity of norepinephrine over serotonin, has been shown to be effective and durable in reducing the pain of FM in two RCTs and the pooled analysis of these studies. Benefit has been shown for a 1-year period with few adverse events; the most common have been nausea, headache, and constipation.

**Substance P**

Because the SP level is markedly elevated in the spinal fluid of FM patients, it has been thought to be involved in the pathogenesis of FM. Discovery and characterization of the SP receptor (NK1 receptor) gave rise to the development of NK1 receptor blockade drugs to provide new treatment options. Unfortunately, the potent NK1 antagonists that were developed failed to exhibit much analgesic efficacy in FM or other chronic pain conditions.

**N-Methyl-d-Aspartate Agonists**

The pain amplification of central sensitization can be inhibited or attenuated by N-methyl-d-aspartate (NMDA) receptor antagonists. Two NMDA receptor antagonists, ketamine and dextromethorphan, have been studied in patients with FM and were both found to exhibit beneficial effects on spontaneous pain and allodynia. In the case of ketamine, about 50% of FM patients benefited in an open trial. The concept of FM subgroups was advanced by these findings because ketamine clearly identified responsive and unresponsive subjects from among otherwise comparable FM patients. The usefulness of ketamine as a therapeutic agent for FM has been limited by the fear of adverse effects, such as psychological disturbances (e.g., feelings of unreality, altered body image perception, modulation of hearing and vision), dizziness, anxiety, aggression, and nausea. Furthermore, a more recent trial that examined the long-term analgesic benefit of intravenous ketamine infusions found no benefit on discontinuation of ketamine or 8 weeks following the discontinuation and therefore the benefit of intravenous ketamine infusion may be restricted to its predictive value for dextromethorphan or oral ketamine therapy.

**α5β Ligands**

Some drugs initially developed as anticonvulsants have the potential to raise the threshold for pain fiber depolarization, as they do for central neurons to reduce seizure activity. Pregabalin and gabapentin are ligands for the α5β subunit of voltage-gated calcium channels. These compounds have been found to have antihyperalgesic/antiallodynic, anxiolytic, and anticonvulsant activity in animal models. They reduce the release of several neurochemicals, including glutamate, norepinephrine, and SP. Pregabalin was found to be effective in reducing the severity of body pain, improving quality of sleep, and reducing fatigue in FM patients. Pregabalin is available in the United States but is scheduled as a controlled substance because of its mild anti-anxiolytic activity. In therapeutic dosages (300 to 600 mg/day in two or three divided doses), it is well tolerated. Adverse effects can include dose-related dizziness and somnolence, which resolve despite continuous therapy with the drug. This observation suggests that it is helpful to start at a low dosage and increase it gradually (perhaps weekly) to help the patient adapt. One approach is to start with 100 to 150 mg at bedtime and increase the nighttime dosage weekly to 300 to 450 mg before adding a smaller morning dosage to achieve 450 to 600 mg/day. Weight gain (5 to 10 lb) and peripheral edema occur in 6% to 12% of patients, without any evidence of an effect on the heart or kidneys. Gabapentin has similarly been shown to be effective in FM patients.

Sodium oxybate, a metabolite of γ-aminobutyric acid (GABA), exhibits sedative-hypnotic activity. It influences both presynaptic and postsynaptic GABA receptors. This scheduled drug is already approved by the FDA for the treatment of narcolepsy with cataplexy and excessive daytime sleepiness. It is beneficial in managing the insomnia of FM, but it is also effective in reducing the pain of FM. In a small, randomized, placebo-controlled clinical trial of FM patients, oxybate was shown to significantly increase total sleep time, enhance slow-wave sleep, reduce alpha intrusion into slow-wave sleep, decrease nighttime awakenings, reduce daytime fatigue, and increase the production of growth hormone. It was also observed to decrease the severity of the perceived pain significantly and reduce the tender point index. A more recent study has supported these findings. In therapeutic dosages (3 to 6 g/day in two divided doses at night), oxybate was well tolerated, as illustrated by the high rate of study completion. Nausea (15%) and dizziness (7%) were the most common oxybate dose-related adverse events but generally resolved with continued therapy. In a more recent RCT, it was found to reduced pain, fatigue, and sleep disturbance and improve functionality in patients with FM. The strong efficacy of this compound in FM, coupled with recent work showing that GABA levels are low in the insula of individuals with FM, has rekindled interest in the use of GABA agonists for FM and other chronic pain states, although safety issues will probably preclude γ-hydroxybutyrate from being the compound that is used with any frequency.

**Strategic Polypharmacy and Newer Therapeutic Agents**

The use of specific combinations of the newer therapeutic agents, or strategic polypharmacy, has been proposed for the management of FM. It should be pointed out, however, that there are no published data on the consequences of combining drugs that are effective as monotherapy. The critical principles of this concept for FM are that complementary medications should be from different drug classes, have different mechanisms of action, and not be synergistic for any serious adverse effect. For an FM patient whose two most prominent symptoms are pain and depression, the use of duloxetine would be appropriate, and it might be chosen as first-line monotherapy. Duloxetine or milnacipran can be used to treat pain in an FM patient even if depression is
not present because these drugs and other classes of anti-depressants subsequently shown to have analgesic properties (e.g., tricyclics) have generally been found to be equally effective for pain regardless of whether depression is present.109 In an FM patient with pain and insomnia, the use of pregabalin or a tricyclic would be logical. Obviously, either of these drugs could be used to treat the pain even if insomnia was not present. In an FM patient with three prominent symptoms (e.g., pain, insomnia, depression), the use of either pregabalin or a low-dose tricyclic in combination with duloxetine would be appropriate and safe. Because there is little published research experience with such a regimen, it must be considered clinically experimental, tailored to the individual patient, and carefully monitored for safety. Despite the lack of good data to support this, most clinicians and researchers experienced in the treatment of FM believe that it is important to use combinations of drug and non-drug therapies to achieve the best overall improvements.

PROCEDURAL INTERVENTIONS

Surgical interventions for FM pain are not indicated or recommended, and the search for a surgical panacea has resulted in unnecessary or potentially harmful surgical care of patients with chronic widespread pain, including FM. Other noninvasive procedures have been examined for efficacy in the population with chronic widespread pain. Transcranial magnetic stimulation (TMS) of the prefrontal cortex can cause changes in acute pain perception and alleviation of depression.125,130 In a recent RCT, the authors recruited 20 patients with FM and randomized them to receive 4000 pulses at 10-Hz TMS (n = 10) or sham TMS (n = 10) treatment for 10 sessions over a 2-week period along with their standard medications, which were fixed and stable for at least 4 weeks before starting the sessions. Patients who received active TMS had a mean 29% (statistically significant) reduction in pain symptoms in comparison to their baseline pain. Sham TMS participants had a 4% change in daily pain from their baseline pain. At 2 weeks after treatment, there was significant improvement in depression symptoms in the active group in comparison to baseline.131 TMS was well tolerated, with few side effects; however, this treatment is rarely covered by insurance and can therefore place a substantial financial burden on the patient.

OTHER COMORBID CONDITIONS

Management of other specific symptomatic domains in FM deserves separate attention.

DYSFUNCTIONAL SLEEP

Since the original description of dysfunctional sleep in people with FM, it has been clear that this symptom should be a focus of therapy. Nonetheless, management of insomnia in patients with FM remains nonspecific and empirical. The sedating tricyclic biogenic amine reuptake drugs, such as amitriptyline and cyclobenzaprine, have been the most commonly prescribed medications for FM insomnia. They are not ideal for this role because they cause a number of adverse effects and are subject to tachyphylaxis, but a 1-month holiday from all biogenic amine reuptake inhibitors can restore effectiveness.132 Because SSRIs, SNRIs, and NSRIs are sometimes so stimulatory that they can interfere with sleep, they should be taken in the morning. Even though the use of benzodiazepines is not generally recommended for FM since these drugs impair slow-wave sleep, newer hypnotic drugs, such as zopiclone and zolpidem, improve sleep in FM—albeit without correcting the disturbed sleep pattern seen on the electrophysiological and without any measurable influence on FM pain.133 Rebound (withdrawal insomnia) with zolpidem is problematic but can be avoided if patients use the drug no more than three times weekly (alternate days). Two medications used more recently in the FM setting—pregabalin and oxynate—will probably meet the needs for this indication because they are effective for both pain and sleep disturbances.124,134,135 In addition, both actually correct the non–rapid eye movement sleep pattern abnormalities seen with FM.

FATIGUE AND DAYTIME TIREDNESS

Fatigue in FM is probably the direct result of chronic insomnia. In addition, a small subpopulation of FM patients are sufficiently depressed to make the usual activities of daily life seem overwhelming. Overlap of FM with medical conditions such as sleep apnea, hypothyroidism, diabetes, chronic infection, or anemia can also drain energy, so they should be included in the differential diagnosis. Mild exercise can reduce fatigue in patients with FM. Pharmacologic therapy for fatigue in FM will increasingly rely on the improved life that can be achieved with medication therapy. It seems unwise to treat the daytime fatigue of FM with stimulants such as caffeine or ephedrine derivatives because the exhausted brain will eventually require restorative rest.

DYSAUTONOMIA

Orthostatic hypotension may respond to liberal intake of water, increased dietary salt, the use of compressive stockings, or a combination of these measures, but occasionally, the addition of a mineralocorticoid will be required.136 Patients may benefit from avoiding the effects of caffeine and nicotine. Mild cardiac rhythm dysautonomia may be viewed more as a marker of FM than as a comorbid condition requiring intervention.

IRRITABLE BOWEL SYNDROME

Treatment of IBS in FM patients relies on general measures that include dietary adaptations such as avoiding caffeine, alcohol, fat, or specific foods that can be identified as worsening the symptoms. Depending on the predominant form of IBS (constipation predominant, diarrhea predominant, or a combination of constipation and diarrhea) experienced by the patient, somewhat selective symptomatic medications can be used. Pain can be treated with antispasmodic agents and tricyclics. For the diarrhea-predominant form, classic antidiarrheal agents such as loperamide and diphenoxylate can be used. In refractory cases, cholestyramine or antibiotics can be considered. Alosetron (Lotronex) is indicated for severe cases of diarrhea-predominant IBS, but there is a black box warning regarding the use of this potent 5-HT₃ receptor antagonist. It can cause ischemic colitis and serious complications of constipation, such as hospitalization, blood transfusion, surgery, and death. Distribution of this drug is restricted to prescription by physicians who have been specifically trained in its use. For the constipation-predominant form of IBS, a diet high in fiber and osmotic laxatives such...
as lactulose, psyllium (Metamucil), and sorbitol or magnesium preparations can be helpful. Sometimes four prunes per day will facilitate a more normal stool consistency. Tegaserod maleate (Zelnorm) had been used for this purpose for some time, but it has been withdrawn from the market because of liver toxicity.

INTERSTITIAL CYSTITIS, PAINFUL BLADDER, AND FEMALE URETHRAL SYNDROME

Treatment of irritable bladder or urethral syndrome in patients with FM includes general measures and medication. It is important to maintain high fluid intake, avoid foods that irritate the bladder (fruits, fruit juices, coffee), and perform pelvic floor exercises regularly. Medications that can be helpful include antispasmodics, muscle relaxants, urinary anesthetics, and tricyclic agents. Interstitial cystitis may or may not be related to the FM.

ACKNOWLEDGMENT

Portions of this chapter were transcribed or modified from the chapter “Myofascial Pain Syndrome and Fibromyalgia Syndrome” by I. Jon Russell in the fourth edition of Raj’s Practical Management of Pain.

SUMMARY

Despite our evolving understanding of the disease process and increased therapeutic options, patients with chronic widespread pain continue to present a diagnostic and management challenge. The disparate range of symptoms found in patients with chronic widespread pain and the multitude of associated comorbid conditions in the patient population contribute to the diagnostic difficulties in an increasingly overburdened health care system. Moreover, the most successful treatment modalities require significant personal changes in behavior and lifestyle by patients, which creates a substantial barrier to implementation. Even FM’s diagnostic criteria are controversial, with researchers and clinicians working to develop a working definition to help identify these patients. The most recent collaboration resulted in the development of preliminary diagnostic criteria that address symptom severity (see Box 29.2).

The clinical manifestations of FM include cognitive dysfunction, affective distress, insomnia, stiffness, musculoskeletal pain, and fatigue. These nonspecific symptoms have contributed to both the diagnostic and therapeutic challenge of managing FM. Associated comorbid conditions include chronic fatigue syndrome, IBS, interstitial cystitis, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren’s syndrome. This diverse clinical picture complicates both the diagnostic specification and the burden of individual patient suffering.

The evolution of the pathogenesis of FM is being clarified through molecular studies, sensory testing, and other testing modalities, including functional MRI and PET. Abnormalities in neurochemical biomarkers are being recognized as being associated with FM. Immunologic changes are also being identified through work with interleukins and cytokines. Genetic markers (COMT gene) and gender may also play a role in the development of these chronic widespread pain syndromes. The composite result of these novel investigative approaches is an emerging spectrum of identifiable biochemical and functional changes that contribute to chronic widespread pain.

Treatment modalities are aligning into a multidisciplinary paradigm that includes multiple recent drug developments, cognitive-behavioral modalities, physical therapy, and exercise programs. Recent changes in FDA-approved pharmacotherapies include the use of pregabalin, as well as the amine reuptake inhibitors duloxetine and milnacipran. Implementation of therapeutic agents is frequently tailored to the patient’s individual symptoms and comorbid conditions (e.g., osteoarthritis vs. insomnia). Ultimately, the most successful treatment outcomes result from multimodal therapy that relies heavily on patient involvement and investment (physical therapy, exercise regimens, CBT).

KEY POINTS

- The objectives of treatment of fibromyalgia (FM) are to reduce pain, improve sleep, restore physical function, maintain social interaction, and reestablish emotional balance. To achieve these goals, patients will need a combination of social support, education, physical modalities, and medication.
- Patients with FM demonstrate reliably augmented sensory processing, which was initially thought to be confined to the sensation of pain (i.e., hyperalgesia, allodynia) but is now known to include hypersensitivity to other sensory stimuli.
- Patients with FM have also been found to have altered levels of biomarkers associated with pain, specifically, glutamate and substance P.
- Three medications are currently approved by the Food and Drug Administration for the treatment of pain related to FM: the amine reuptake inhibitors duloxetine and milnacipran and the membrane stabilizer pregabalin.
- Myofascial pain syndrome is defined as a painful regional syndrome characterized by the presence of an active trigger point in a skeletal muscle.

INTRODUCTION

Headache is a problem that has plagued humans since the beginning of recorded time. It is one of the most common medical complaints and accounts for more than 18 million outpatient visits per year in the United States. More than 1% of physician’s office visits and emergency department visits are primarily for headache.1,2 In 1988, the International Headache Society (IHS) published a formal classification system for the diagnosis of headache disorders,3 which has since been updated and improved (International Classification of Headache Disorders, second edition [ICHD-2]).4 The IHS classification system (Box 30.1) continues to divide headache into primary and secondary disorders. In a primary headache disorder, headache itself is the illness and no other etiology is diagnosed. In a secondary headache disorder, headache is attributed to an identifiable structural or metabolic abnormality.

INSTRUMENTS AND SCALES IN HEADACHE

Headaches can severely interfere with daily functioning and productivity.5,6 Research has demonstrated that improvement in symptoms and quality of life (QOL) are not perfectly correlated: symptoms may improve, but function may not.7 Consequently, it is important to embrace instruments that measure QOL. Instruments that assess migraine disability can improve headache care by facilitating physician-patient communication and guiding treatment decisions. Various headache scales are in use. The scales can be divided into two main groups: scales that measure the impact of a single migraine attack (with or without therapy) over a 24-hour period and scales that measure the impact of migraine over a span of weeks or months. The first group of scales has been used in randomized, placebo-controlled trials; they are highly sensitive to acute treatment effects.8 The second group of scales has been chosen to compare results in randomized trials.9

Scales that measure the impact of an acute attack include (1) QOL (Migraine-Specific Quality-of-Life Questionnaire [MQoLQ] and Quality of Life Questionnaire [MSQ Version 2.1]) and (2) headache impact and disability (Headache Needs Assessment [HANA] Survey). Scales that measure long-term impact are (1) QOL (Migraine-Specific Quality-of-Life [MSQOL] Scale), (2) headache impact (Headache Impact Test [HIT], Headache Impact Questionnaire [HimQ], and Henry Ford Hospital Disability Inventory [HDI]), and (3) migraine disability (Migraine Disability Assessment [MIDAS]).

SCALES THAT ASSESS QUALITY OF LIFE

QOL is influenced by environmental, economic, social health-related, spiritual, and political factors. The fundamental domains of instruments that measure QOL include physical, psychological, and social areas. Both generic and disease-specific measures have been used to measure QOL. The most commonly used generic scales are the Medical Outcomes Study (MOS) instrument, which includes the 20-Item Short-Form Health Survey (SF-20),10 the SF-36, and the SF-12.11 Other generic QOL scales used in headache studies include the Sickness Impact Profile,12 the Nottingham Health Profile,13 and the Psychological General Well Being Index.14 The specific QOL scales for migraine fall into two broadly defined categories: those that measure QOL in a single migraine attack (MQoLQ and MSQ Version 2.1) and those that measure the QOL over a period of weeks or months (MSQOL).

MIGRAINE-SPECIFIC QUALITY-OF-LIFE QUESTIONNAIRE

The MQoLQ is a questionnaire that assesses the short-term decrements in QOL associated with acute migraine headache attacks.15 This questionnaire evaluates QOL impairment in the 24-hour period following the onset of a migraine headache. The questionnaire is self-administered and is completed quickly and easily. The MQoLQ consists of 15 items with five domains: (1) work functioning, (2) social functioning, (3) energy/vitality, (4) migraine headache symptoms, and (5) feelings and concerns. There are three items within each domain. The response option for each of the items is on a 7-point scale, with 1 indicating maximum impairment of QOL and 7 indicating no impairment. Each domain has a maximum score of 21 and a minimum score of 3. The scores were compared between migraine-free and migraine periods. The construct validity of the questionnaire was established by showing that there are significant relationships between subjects’ 24-hour MQoLQ scores and other indices of clinical migraine headache such as headache severity, limitation of activity, number of associated migraine symptoms, global change in migraine symptoms, and migraine duration.15 The ability of the MQoLQ to capture within-subject change in QOL was evaluated by comparing QOL scores during a “migraine-free” period with MQoLQ scores 24 hours after migraine onset.8 The MQoLQ should be applicable to all adults suffering from episodic migraine headache. It was designed primarily for use in clinical trials to assess migraine management and to be responsive to subject changes in QOL in the 24 hours following the onset of a migraine headache. The MQoLQ
assesses subjective well-being and daily ability to function, in addition to measuring the typical associated symptoms of migraine, such as nausea, photophobia/phonophobia, and head pain. The 24-hour MQoLQ should not be used to measure global QOL between headache episodes.

QUALITY-OF-LIFE QUESTIONNAIRE (MSQ VERSION 2.1)

The MSQ is a disease-specific QOL instrument with three hypothesized scales; it has been developed, tested, and revised. The MSQ (version 2.1) was structured similar to older versions of the MSQ (versions 1.0 and 2.0). The revised 14-item MSQ (version 2.1) consists of 7 items in the role-restrictive dimension that measure the degree to which performance of normal activities is limited by migraines, 4 items in the role-preventive dimension that measure the degree to which performance of normal activities is interrupted by migraines, and 3 items in the emotional function dimension that measure the emotional effects of migraine. The MSQ dimensions had low to modest correlations with the two component scores of the SF-36 and were modestly to moderately correlated with migraine symptoms. The validation was structured in three separate analyses applied to 267 subjects. The MSQ provides clinicians, researchers, and those who fund health care a measurement tool to assess health-related QOL. The questionnaire was designed to be completed quickly and easily in a self-administered form. This study suggested that the mean MSQ (version 2.1) scores 6 to 12 points higher (indicating better QOL).

SCALE THATS ASSESS HEADACHE IMPACT AND DISABILITY

Headache impairs physical, social, and emotional functioning, but a diagnosis cannot always be made despite the availability of helpful tools. One reason for this is poor patient-physician communication. If the impact that headaches are having on a person’s life can be communicated adequately to the physician, the likelihood of appropriate management will increase. Impact and disability instruments are scored differently and have different interpretations. Generally, the impact is scaled in a positive direction, with higher scores reflecting better QOL (i.e., lower impact). For disability measures, higher scores reflect greater limitation of activity (i.e., higher impact). Measurement of headache-related disability, together with assessments of pain intensity, headache frequency, tiredness, alterations in mood, and cognition, can be used to assess the impact of migraine on sufferers’ lives and on society. The tools currently used for assessing
headache impact are the HIT and HIT-6, HimQ, HANA Survey, and HDI or Henry Ford Hospital Questionnaire. These scales, when used properly, can improve communication between patients and physicians, assess migraine severity, and act as outcome measures to monitor treatment efficacy. Impact tools are also used, along with other clinical assessments, to produce an individualized treatment plan.20 Disability measures assess impairment in role functioning (i.e., reduced ability to function in defined roles, such as paid work).5 The disability instruments used are the HDI and the MIDAS.

HEADACHE IMPACT TEST
The HIT is a tool that measures headache’s impact on a person’s ability to function on the job, at home, and in social situations. The HIT was developed by the psychometricians who developed the SF-36 health assessment. HIT was designed for greater accessibility (on the Internet at www.headachetest.com and www.amlhealthy.com and as a paper-based form known as HIT-6). HIT-6 is a practical test that consists of six questions. A patient can complete the test in less than 2 minutes. HIT-6 assesses disability over a 4-week period. The range of scores is 36 to 78. Higher scores signify greater impact of disability. A score of 60 or higher indicates a severe impact (the headache stops family, work, school, or social activities), a score between 56 and 59 indicates a substantial impact, a score between 50 and 55 signifies some impact, and a score below 49 denotes no impact.21 The availability of this test on the Internet, with feedback provided, makes it a useful tool to help headache sufferers understand the burden of their migraines and seek appropriate management.

HEADACHE IMPACT QUESTIONNAIRE
The HimQ measures pain and limitations in activity over a 3-month period. This instrument was the precursor to the MIDAS instrument (see disability scales). The HimQ score is derived from four frequency-based questions (i.e., number of headaches, missed days of work, missed days of chores, or missed days of non–work-related activity) and four summary measures of the average experience across headaches (i.e., average pain intensity and average reduced effectiveness when having a headache at work, during household chores, and in non–work-related activity).22,23 This scale was validated after assessing the pain and limitations in activity in a population-based sample of 132 migraine headache sufferers enrolled in a 90-day daily-diary study who completed the HimQ at the end of the study. Previous studies of the validity of retrospective pain and disability reporting were mixed.22,24-31 Study participants completed the HimQ in person and then completed daily diaries for 90 days. The HimQ was developed to identify headache sufferers who have the greatest need for medical care. Self-administered questionnaires can adequately capture information to rate pain severity.

HEADACHE NEEDS ASSESSMENT SURVEY
The HANA questionnaire was designed to assess two dimensions (frequency and bothersomeness) of migraine’s impact.32 Seven issues related to living with migraine were used as ratings of frequency and bothersomeness. Validation studies were performed in a Web-based survey, a clinical trial responsiveness population, and a retest reliability population. Headache characteristics (e.g., frequency, severity, and treatment), demographic information, and the HDI were used for external validation. The HANA can be used in medical practice groups (e.g., headache centers, managed care groups) as a screening tool to detect potential problems. Scores from the scale are compared before and after treatment to determine the headache’s impact. Primary care physicians could use the HANA to screen patients with migraine for further evaluation. Once identified, those with severe migraine may be candidates for further evaluation and immediate treatment. The HANA has several advantages in that it can (1) select who should be treated, (2) increase productivity by adequately treating headaches, and (3) identify the need for aggressive treatment without the usual slow advancement through stepped-care algorithms. This brief, self-applied questionnaire may be a useful screening tool to evaluate migraine’s impact. The two-dimensional approach to patient-reported QOL allows individuals to weight the impact of both frequency and bothersomeness of chronic migraine (CM) on multiple aspects of daily life.

HENRY FORD HOSPITAL DISABILITY INVENTORY
The HDI is useful in assessing the impact of headache and its treatment on daily living.33-36 It is a paper-and-pencil instrument that probes the functional and emotional effects of headache on everyday life. The HDI is a 25-item headache disability inventory, with each item requiring a “yes” (4 points), “sometimes” (2 points), or “no” (0 points) response. Thus, a maximum score of 100 points reflects severe self-perceived headache disability. The scale is easy to complete and simple to score and interpret. The HDI has high internal consistency, reliability, and good content validity; the long-term (2 month) test-retest stability of the HDI was robust.35,34 The test-retest reliability for the beta-HDI was acceptable for the total score and functional and emotional subscale scores.35 Scales of this nature help investigators understand headache’s impact on everyday life. Thus, the HDI can be used to (1) assess the impact of headache on the patient’s daily living, (2) monitor the effect of therapeutic intervention, and (3) plan for a global approach to coping with headache with the patient’s involvement.

MIGRAINE DISABILITY ASSESSMENT QUESTIONNAIRE
The MIDAS questionnaire (Fig. 30.1) was developed to measure headache-related disability and improve doctor-patient communication about the functional consequences of migraine. The questionnaire was based on five disability questions that focus on lost time in three domains: school-work or work for pay; household work or chores; and family, social, and leisure activities.37 This scale can be used by physicians, nurses, pharmacists, and alternative practitioners. It is easy to complete and takes only a few minutes. The MIDAS questionnaire has demonstrated reliability,38 as reported in two separate population-based studies, one in the United States and one in the United Kingdom, and validity by using
a 3-month daily-diary study as the “gold standard.”\textsuperscript{39} Scores on the MIDAS are highly correlated with physician judgments about the severity of illness and need for treatment.\textsuperscript{40} This instrument is scored as follows: 5 to 10 indicates little or no disability, 10 to 20 indicates moderate disability, and higher than 20 denotes severe disability. The MIDAS questionnaire is an important part of a package of educational, investigative, and therapeutic measures and could play a major role in improving the care of patients with migraine and other types of headache.\textsuperscript{42,43-48} A randomized, placebo-controlled trial showed that the MIDAS grade provides a basis for selecting initial treatment in stratified care.\textsuperscript{49}

**MIGRAINE**

Migraine is a chronic neurologic disease characterized by episodic attacks of headache and associated symptoms. “Migraine” is derived from the Greek word “hemicrania” (Galen =200 A.D.).\textsuperscript{50} The diagnosis is based on retrospective reporting of headache characteristics and associated symptoms.\textsuperscript{51} The revised IHS diagnostic criteria for headache disorders\textsuperscript{3} (ICHD-2) provide the criteria for a total of seven subtypes of migraine.\textsuperscript{4}

**EPIDEMIOLOGY**

The prevalence of migraine is similar and stable in Western countries and the United States.\textsuperscript{52} Three large-scale population-based studies have been conducted in the United States, one in 1989,\textsuperscript{53}\textsuperscript{54} one in 1999,\textsuperscript{55,56} and one in 2004.\textsuperscript{57,58} The first American Migraine Study\textsuperscript{33} found that the prevalence of migraine was 17.6\% in women and 6\% in men. Two follow-up studies, the American Migraine Study II and the American Migraine Prevalence and Prevention Study (AMPPS), provided results identical to the first, thus indicating that the prevalence of migraine has been stable in the United States, at least over the last 15 years.\textsuperscript{58}

Before puberty, the prevalence of migraine is approximately 4\%;\textsuperscript{56} after puberty, it increases more rapidly in girls than in boys. It increases until approximately 40 years of age and then declines. Prevalence is lowest in Asian Americans, intermediate in African Americans, and highest in Caucasians.\textsuperscript{6} In the United States, the prevalence of migraine decreases as household income increases.\textsuperscript{5,53,56}

Migraine decreases sufferers’ QOL. The World Health Organization (WHO) ranks migraine among the world’s most disabling medical illnesses.\textsuperscript{59} Approximately 28 million Americans have severe, disabling migraine headaches.\textsuperscript{55} Migraine’s cost to employers is approximately $13 billion per year, and annual medical costs exceed $1 billion.\textsuperscript{6} Instruments to quantify migraine disability include the MIDAS\textsuperscript{39} and the HIT.\textsuperscript{21}

**DESCRIPTION OF THE MIGRAINE ATTACK**

The migraine attack can consist of premonitory, aura, headache, and resolution phases. Premontitory symptoms occur in 20\% to 60\% of migraineurs, hours to days before onset of the headache. They may include psychological, neurologic, constitutional, or autonomic features, such as depression, cognitive dysfunction, and bouts of food craving.\textsuperscript{60}

**AURA**

The migraine aura consists of focal neurologic symptoms that precede, accompany, or (rarely) follow an attack. Aura usually develops over a period of 5 to 20 minutes; lasts less than 60 minutes; can be visual, sensory, or motor; and may involve language or brainstem disturbances.\textsuperscript{3} Headache usually follows within 60 minutes of the end of the aura. Patients can have multiple aura types; most patients with a sensory aura also have a visual aura.\textsuperscript{61} Simple auras include scotomata (loss of vision), simple flashes (phosphenes), specks, geometric forms, and shimmering in the visual field. More complicated visual auras include teichopsia or fortification spectra (the characteristic aura of migraine), metamorphopsia, micropsia, macropsia, zoom vision, and mosaic vision. Paresthesias are often cheiro-aural: numbness starts in the hand, migrates up the arm, and jumps to involve the face, lips, and tongue.\textsuperscript{51,62} Weakness is rare, occurs in association with sensory symptoms, and is unilateral.\textsuperscript{63} Apraxia, aphasia, agnosia, states of altered

---

**Figure 30.1 MIDAS questionnaire.** (From Stewart WF, Lipton RB, Dowson AJ, et al. Development and testing of the Migraine Disability Assessment (MIDAS) Questionnaire to assess headache-related disability. Neurology. 2001;56:S20-S28.)
consciousness associated with déjà vu or jamais vu, and elaborate dreamy, nightmarish, trance-like, or delirious states can occur.60

HEADACHE PHASE
The median migraine attack frequency is 1.5 per month.53 The typical headache is unilateral, of gradual onset, throbbing (85%),64 moderate to marked in severity, and aggravated by movement.3 Pain may be bilateral (40%) or start on one side and become generalized. It lasts 4 to 72 hours in adults and 2 to 48 hours in children.3

Anorexia is common. Nausea occurs in almost 90% of patients, whereas vomiting occurs in about a third.55 Sensory hypersensitivity results in patients seeking a dark, quiet room.54,65 Blurry vision, nasal stuffiness, anorexia, hunger, tenesmus, diarrhea, abdominal cramps, polyuria, facial pallor, sensations of heat or cold, and sweating may occur. Depression, fatigue, anxiety, nervousness, irritability, and impairment of concentration are common. Symptom complexes may be generated by linked neuronal modules.66

FORMAL DIAGNOSTIC CRITERIA
The IHS subdivides migraine into migraine with aura (Box 30.2) and migraine without aura (Box 30.3).4 To diagnose migraine without aura, five attacks are needed. No single feature is mandatory, but recurrent episodic attacks must be documented.3 Migraine occurring for more than 3 days defines “status migrainosus.”3,4 Migraine occurring 15 or more days per month is called CM by the ICHD-2 (Box 30.4).57

Migraine with aura is subdivided into typical aura, prolonged aura, hemiplegic migraine, basilar-type migraine, and migraine with acute-onset aura. The IHS classification now allows the association of aura with other headache types. Prolonged aura lasts from 1 hour to 1 week, and persistent aura lasts for more than 1 week (but resolves); if neuroimaging demonstrates a stroke, a migrainous infarction has occurred.

MIGRAINE VARIANTS
Basilar-type migraine aura is characterized by brainstem symptoms: ataxia, vertigo, tinnitus, diplopia, nausea and vomiting, nystagmus, dysarthria, bilateral paresthesia, or a change in level of consciousness and cognition.3 It should be considered when patients have paroxysmal brainstem disturbances. Some have suggested that hemiplegic migraine should be diagnosed if weakness is present.63

Ophthalmoplegic migraine is due to an idiopathic inflammatory neuritis.68 There is enhancement of the cisternal segment of the oculomotor nerve, followed by resolution over a period of several weeks as the symptoms resolve.

Hemiplegic migraine can be sporadic or familial.51 Attacks are frequently precipitated by minor head injury.53 Familial hemiplegic migraine (FHM) is an autosomal dominant, genetically heterogenous disorder with variable

**Box 30.2 Diagnostic Criteria for Migraine with Aura**

A. At least 2 attacks fulfilling criteria B to E
B. Fully reversible visual and/or sensory and/or speech symptoms but no motor weakness
C. Homonymous or bilateral visual symptoms, including positive features (i.e., flickering lights, spots, lines) or negative features (i.e., loss of vision), and/or unilateral sensory symptoms, including positive features (i.e., visual loss, pins and needles) and/or negative features (i.e., numbness)
D. At least one of the following:
   1. At least one symptom developing gradually over a period of 5 or more minutes and/or different symptoms occurring in succession
   2. Each symptom lasting between 5 and 60 minutes
E. Headache that meets criteria B to D for migraine without aura begins during the aura or follows the aura within 60 minutes
F. Not attributed to another disorder

**Box 30.3 Diagnostic Criteria for Headache without Aura**

A. At least 5 attacks fulfilling criteria B to D
B. Headache attacks lasting 4 to 72 hours and occurring less than 15 days/mo (untreated or unsuccessfully treated)
C. Headache with at least 2 of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate or severe intensity
   4. Aggravated by or causing avoidance of routine physical activity (i.e., walking or climbing stairs)
D. During headache at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia and/or phonophobia
E. Not attributed to another disorder

**Box 30.4 Revised International Headache Society Criteria for Chronic Migraine**

A. Headache on 15 or more days per month for at least 3 months
B. Patient has had at least 5 attacks fulfilling criteria B to D for migraine without aura (see Box 30.3)
C. On 8 or more days per month for at least 3 months headache has fulfilled C1 and/or C2 below, that is, has fulfilled the criteria for pain and associated symptoms of migraine without aura
   1. Has at least 2 of the characteristics in a to d:
      a. Unilateral location
      b. Pulsating quality
      c. Moderate or severe pain intensity
      d. Aggravated by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
   And at least 1 of characteristics a or b:
      a. Nausea and/or vomiting
      b. Photophobia and/or phonophobia
   2. Treated and relieved by triptans or ergot before the expected development of C1 above
D. No medication overuse and not attributed to another disorder
penetration. FHM includes attacks of migraine without aura, migraine with typical aura, and episodes of prolonged aura, fever, meningismus, and impaired consciousness.\textsuperscript{69} Headache may precede the hemiparesis or be absent. The onset of hemiparesis may be abrupt and simulate a stroke. In 20% of unselected FHM families, patients have cerebellar symptoms and signs (nystagmus, progressive ataxia). All have mutations in \textit{CACNA1A}.\textsuperscript{50}

TREATMENT

Migraine varies widely in its frequency, severity, and impact on patients’ QOL. A treatment plan should consider not only the patient’s diagnosis, symptoms, and any coexistent or comorbid conditions but also the patient’s expectations, needs, and goals.\textsuperscript{71} Migraine treatment begins with making a diagnosis,\textsuperscript{51} explaining it to the patient, and developing a treatment plan that takes into account any coincidental or comorbid conditions.\textsuperscript{72} Comorbidity indicates an association between two disorders that is more than coincidental.

Conditions that occur in migraineurs with a higher prevalence than would be expected include stroke, myocardial infarction, angina, patent foramen ovale (aura), epilepsy, Raynaud’s syndrome, and affective disorders (depression, mania, anxiety, and panic disorder). Possible associations include essential tremor, mitral valve prolapse, and irritable bowel syndrome.

Pharmacologic treatment of migraine may be acute (abortive) or preventive (prophylactic), and patients with frequent, severe headaches often require both approaches. Acute treatment attempts to relieve or stop the progression of an attack or the pain and impairment once an attack has begun. It is appropriate for most attacks and should be used a maximum of 2 to 3 days per week. Preventive therapy is given, even in the absence of a headache, in an attempt to reduce the frequency, duration, or severity of attacks. Additional benefits include improving responsiveness to acute attack treatment, improving function, and reducing disability.

PHARMACOTHERAPY FOR ACUTE MIGRAINE HEADACHE

Acute treatment can be specific (ergots and triptans) or nonspecific (analgesics and opioids). Nonspecific medications control the pain of migraine and other pain disorders, whereas specific medications are effective for migraine (and certain other) headache attacks but are not useful for non–headache–related pain disorders. Triptans are effective for mild, moderate, and severe migraine attacks.\textsuperscript{73}

The choice of treatment depends on attack severity and frequency, associated symptoms, coexistent disorders, previous treatment response, and the medication’s efficacy and potential for overuse and adverse events (AEs). A nonoral route of administration and an antiemetic should be considered when severe nausea or vomiting is present.\textsuperscript{74} Injections provide rapid relief. Headaches can be stratified by severity and disability (using the MIDAS or the HIT). Analgesics are used for mild to moderate headaches.\textsuperscript{74} Triptans and dihydroergotamine (DHE) are first-line drugs for severe attacks and for less severe attacks that do not adequately respond to analgesics.\textsuperscript{75} Patients with moderate or severe headaches and moderate or severe disability (based on the MIDAS) who were stratified to treatment with a triptan did better than patients given aspirin and metoclopramide.\textsuperscript{75} Early intervention prevents escalation and may increase efficacy.\textsuperscript{76} Triptans can prevent the development of cutaneous allodynia, and cutaneous allodynia predicts triptans’ effectiveness.\textsuperscript{77} Before deciding that a drug is ineffective, at least two attacks should be treated. It may be necessary to add an adjuvant or change the dose, formulation, or route of administration. If the response is inadequate, the headache recurs, or AEs are bothersome, a change in medication may be needed. Limiting acute treatment to 2 to 3 days a week can prevent medication overuse headache (MOH). When headaches are very frequent, early intervention may not be appropriate.

All treatments occasionally fail; therefore, rescue medications (opioids, neuroleptics, and corticosteroids) are needed. They provide relief but often limit function because of sedation or other AEs.

PREVENTIVE TREATMENT

Preventive treatment is given in an attempt to reduce the frequency, duration, or severity of attacks. Additional benefits include improving responsiveness to acute attack treatment, improving function, and reducing disability. Preventive treatment may avert episodic migraine’s progression to CM and result in reductions in health care cost. Silberstein and colleagues retrospectively analyzed resource utilization information in a large claims database. The addition of migraine preventive drug therapy to therapy that consisted of only an acute medication was effective in reducing resource consumption. When the 6 months after the initial preventive medication was compared with the 6 months preceding preventive therapy, office and other outpatient visits with a migraine diagnosis decreased 51.1%, emergency department visits with a migraine diagnosis decreased 81.8%, computed tomography (CT) scans with a migraine diagnosis decreased 75.0%, magnetic resonance imaging (MRI) with a migraine diagnosis decreased 88.2%, and other migraine medication dispensing decreased 14.1%.\textsuperscript{78}

Preventive medications reduce attack frequency, duration, or severity.\textsuperscript{51,79} According to the U.S. Headache Consortium Guidelines,\textsuperscript{80} as recently revised,\textsuperscript{51} indications for preventive treatment include the following:

- Recurring migraine that significantly interferes with the patient’s QOL and daily routine despite acute treatment
- Failure of, contraindication to, or troublesome AEs from acute medications
- Acute medication overuse
- Very frequent headaches (>1/wk) (risk for CM or medication overuse)
- Patient preference
- Special circumstances such as hemiplegic migraine; frequent, very long, or uncomfortable auras; or attacks with a risk for permanent neurologic injury

Prevention is not being used to the extent that it should be. Results from the American Migraine Study I and II and the Philadelphia Phone Survey 2 demonstrated that migraine preventive therapy is underused; only 13% of all migraineurs currently use preventive therapy to control their attacks.\textsuperscript{58} In the American Migraine Study II, 25% of all people with migraine, or more than 7 million people, experienced more
than three attacks per month, and 53% of those surveyed reported either having severe impairment because of their attacks or needing bed rest. According to the AMPPS, 38.8% of patients with migraine should be considered for (13.1%) or offered (25.7%) migraine preventive therapy.

Preventive medication groups include β-adrenergic blockers, antidepressants, calcium channel antagonists, serotonin antagonists, anticonvulsants, and nonsteroidal anti-inflammatory drugs (NSAIDs). The choice is based on efficacy, AEs, and coexistent and comorbid conditions. The drug chosen is started at a low dose and increased slowly until therapeutic effects develop or the ceiling dose is reached. A full therapeutic trial may take 2 to 6 months. Acute headache medications should not be overused. Women of childbearing potential should be on adequate contraception.

Preventive treatment is often recommended for only 6 to 9 months, but until now no randomized, placebo-controlled trials have been performed to investigate migraine frequency after preventive treatment has been discontinued. Diener and associates assessed 818 migraine patients who were treated with topiramate for 6 months to see the effects of discontinuation of topiramate. Patients received topiramate in a 26-week open-label phase. They were then randomly assigned to continue this dose or switch to placebo for a 26-week, double-blind phase. The mean increase in number of migraine days was greater in the placebo group (1.19 days in 4 weeks, 95% confidence interval [CI] = 0.71 to 1.66, P < 0.0001) than in the topiramate group (0.10, −0.36 to 0.56, P = 0.57). Patients in the placebo group had a greater number of days on acute medication than did those in the topiramate group (mean difference between groups of −0.95, −1.49 to −0.41, P = 0.0007). Sustained benefit was reported after topiramate was discontinued, although the number of migraine days did increase. These findings suggest that patients should be treated for 6 months with the option to continue to 12 months. If headaches are well controlled, medication can be tapered and discontinued. Dose reduction may provide a better risk-to-benefit ratio.

Behavioral and psychological interventions used for prevention include relaxation training, thermal biofeedback, and cognitive-behavioral therapy. Coexistent diseases have important implications for treatment. In some instances, two or more conditions may be treated with a single drug. If individuals have more than one disease, certain categories of treatment may be relatively contraindicated.

The preventive medications with the best documented efficacy are divalproex, topiramate, and the β-blockers. The choice is based on a drug’s proven efficacy, the physician’s informed belief about medications not yet evaluated in controlled trials, the drug’s AEs, the patient’s preferences and headache profile, and the presence or absence of coexisting disorders. The drug chosen should have the best risk-to-benefit ratio for the individual patient and take advantage of the drug’s side effect profile. An underweight patient would be a candidate for one of the medications that commonly produce weight gain, such as a tricyclic antidepressant (TCA); in contrast, one would try to avoid these drugs and consider topiramate when the patient is overweight. Tertiary TCAs that have a sedating effect would be useful at bedtime for patients with insomnia. Older patients with cardiac disease or patients with significant hypotension may not be able to use TCAs, calcium channel blockers, or β-blockers but could use divalproex or topiramate. Athletic patients should use β-blockers with caution. Medications that can impair cognitive functioning should be avoided when patients are dependent on their faculties.

Comorbid and coexistent diseases have important implications for treatment. The presence of a second illness provides therapeutic opportunities but also imposes certain therapeutic limitations. In some instances, two or more conditions may be treated with a single drug. However, there are limitations to using a single medication to treat two illnesses. Giving a single medication may not treat two different conditions optimally; although one of the two conditions may be treated adequately, the second illness may require a higher or lower dose, and therefore the patient is at risk for the second illness not being treated adequately. Therapeutic independence may be needed should monotherapy fail. Avoiding drug interactions or increased AEs is a primary concern when using polypharmacy. For some patients, a single medication may adequately manage any comorbid conditions. However, this is likely to be the exception rather than the rule. Polytherapy may enable therapeutic adjustments based on the status of each illness. TCAs are often recommended for patients with migraine and depression. However, appropriate management of depression often requires higher doses of TCAs, which may be associated with more AEs. A better approach might be to treat the depression with a selective serotonin reuptake inhibitor or selective serotonin-norepinephrine reuptake inhibitor and treat the migraine with an anticonvulsant. Migraine and epilepsy may both be controlled with an antiepileptic drug, such as topiramate or divalproex sodium. Divalproex and topiramate are the drugs of choice for a patient with migraine and bipolar illness. When individuals have more than one disease, certain categories of treatment may be relatively contraindicated. For example, β-blockers should be used with caution in a depressed migraineur, whereas TCAs or neuroleptics may lower the seizure threshold and should be used with caution in an epileptic migraineur.

Although monotherapy is preferred, it is sometimes necessary to combine preventive medications. Antidepressants are often used with β-blockers or calcium channel blockers, and topiramate or divalproex sodium may be used in combination with any of these medications. Pascual and colleagues found that combining a β-blocker and sodium valproate could lead to increased benefit in patients with migraine previously resistant to either drug alone. Fifty-two patients (43 women) with a history of episodic migraine with or without aura and previously unresponsive to β-blockers or sodium valproate monotherapy were treated with a combination of propranolol (or nadolol) and sodium valproate in an open-label fashion. Fifty-six percent had greater than a 50% reduction in migraine days. This open trial supports the practice of combination therapy. Controlled trials are needed to determine the true advantage of this combination treatment in patients with episodic migraine and CM.

**SUMMARY**

Migraine is an extremely common neurobiologic headache disorder that is due to increased central nervous system...
excitability. It ranks among the world’s most disabling medical illnesses. Diagnosis is based on the headache’s characteristics and associated symptoms. The economic and societal impact of migraine is substantial. It affects sufferers’ QOL and impairs work, social activities, and family life. There are many acute and preventive migraine treatments on the market. Acute treatment is either specific (triptans and ergots) or nonspecific (analgesics). Disabling migraine should be treated with triptans. Increased headache frequency is an indicator for preventive treatment. Preventive treatment decreases migraine frequency and improves QOL. More treatments are being developed, which provides hope to the many sufferers whose migraines are still uncontrolled.

**CHRONIC DAILY HEADACHE**

Chronic daily headache (CDH) refers to headache disorders experienced very frequently (15 or more days per month), including those associated with medication overuse (MOH). CDH can be divided into primary and secondary varieties. Primary CDH is not related to a structural or systemic illness. Population-based studies in the United States, Europe, and Asia suggest that 4% to 5% of the general population have primary CDH, and that 0.5% have severe headaches on a daily basis. In population samples, chronic tension-type headache (CTTH) is the leading cause of primary CDH. CDH patients account for the greatest number of consultations in headache subspecialty practices. They often overuse medication, which may play a role in initiating or sustaining the pattern of pain. Anxiety, depression, and other psychological disturbances may accompany the headaches.

Once secondary headache (including MOH) has been excluded, frequent headache sufferers are subdivided into two groups based on headache duration. When headache duration is less than 4 hours, the differential diagnosis includes cluster headache, paroxysmal hemicrania, idiopathic stabbing headache, hypnic headache, and short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT syndrome). When headache duration is longer than 4 hours, the major primary disorders to consider are CM (see Box 30.4), hemicrania continua (HC), CTTH (Box 30.5), and new daily persistent headache (NDPH). CM, NDPH, and HC are primary CDH disorders that are now included in the second IHS classification. Transformed migraine (TM) is similar but not identical to CM.

CM (see Box 30.4) has been called TM. Most patients with this disorder are women, 90% of whom have a history of migraine without aura. Patients often report a process of transformation characterized by headaches that become more frequent over a period of months to years, with the associated symptoms of photophobia, phonophobia, and nausea becoming less severe and less frequent. A pattern of daily or nearly daily headaches often develops that phenomenologically resembles a mixture of tension-type headache (TTH) and migraine. That is, the pain is often mild.

### Box 30.5 Diagnostic Criteria for Tension-Type Headache

#### Infrequent Episodic Tension-Type Headache (IHS Diagnostic Criteria)

A. At least 10 previous headache episodes fulfilling criteria B to E listed below. Number of days with such headache less than 1 day/mo (<12 days/yr)

B. Headache lasting from 30 minutes to 7 days

C. At least 2 of the following pain characteristics:
   1. Pressing or tightening (nonpulsating) quality
   2. Mild or moderate intensity (may inhibit but does not prohibit activities)
   3. Bilateral location
   4. No aggravation by walking stairs or similar routine physical activity

D. Both of the following:
   1. No nausea or vomiting (anorexia may occur)
   2. Photophobia and phonophobia are absent or one but not the other is present

E. Not attributed to another disorder

#### Frequent Episodic Tension-Type Headache

A. At least 10 episodes fulfilling criteria B to F. Fifteen or more days/mo with such headache for at least a 3-month period (≥180 days/yr)

B. Headache lasting hours or may be continuous

C. At least 2 of the following pain characteristics:
   1. Pressing or tightening (nonpulsating) quality
   2. Mild or moderate severity (may inhibit but does not prohibit activities)
   3. Bilateral location
   4. Not aggravated by walking stairs or similar routine physical activity

D. Both of the following:
   1. No more than one of the following: photophobia, phonophobia, or mild nausea
   2. No moderate or severe nausea and no vomiting

E. No medication overuse

F. Not attributed to another disorder

IHS, International Headache Society.
to moderate and is not always associated with photophobia, phonophobia, or gastrointestinal features. Other characteristics of migraine, including aggravation by menstruation and other trigger factors, as well as unilaterality and gastrointestinal symptoms, may persist. Attacks of full-blown migraine superimposed on a background of less severe headaches occur in many patients. The term TM has been used to refer to this process. The term CM is now being used by the IHS, in part because a history of transformation is often missing.

**DRUG OVERUSE AND MEDICATION OVERUSE (REBOUND) HEADACHE (BOX 30.6)**

MOH was previously called rebound headache, drug-induced headache, and medication misuse headache. Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans. Although stopping the acute medication may result in the development of withdrawal symptoms and a period of increased headache, subsequent improvement in headache usually occurs. Many primary CDH patients who were withdrawn from ergotamine and analgesics and given no further therapy no longer had daily headaches, although about 40% still had episodic migraine attacks.

**DEFINITION AND CLASSIFICATION OF MEDICATION OVERUSE HEADACHE**

In 1988 the IHS used the term “drug-induced headache” for MOH. Overuse is now defined in terms of treatment days per month (see Box 30.6).

The epidemiology of MOH is uncertain. In European headache centers, 5% to 10% of patients have drug-induced headache. One series of 3000 consecutive headache patients reported that 4.3% had drug-induced headaches. Experience in the United Kingdom (P. Goadsby, personal communication) suggests that drug-associated headache is more common than the literature suggests. In American specialty headache clinics, as many as 80% of patients with primary CDH were reported to use analgesics on a daily or nearly daily basis. Other headache clinics have reported a smaller percentage but a majority nonetheless. In India, in contrast, medication overuse is less common.

**Box 30.6 Headache Attributed to Medication Overuse**

A. Headache present on more than 15 days/mo
B. Regular overuse for more than 3 months of one or more acute or symptomatic treatment drugs as defined under subforms of 8.2.
1. Ergotamine, triptans, opioids, or combination analgesic medications on 10 or more days/mo on a regular basis for more than 3 months
2. Simple analgesics or any combination of ergotamine, triptans, analgesics, and opioids on 15 days/mo or more on a regular basis for more than 3 months without overuse of any single class alone
C. Headache has developed or markedly worsened during medication overuse

Diener and colleagues summarized 29 studies that included 2612 patients with chronic MOH. Migraine was the primary headache in 65% of patients, TTH in 27%, and mixed or other headaches (i.e., cluster headache) in 8%. Women had more drug-induced headache than men did (3.5:1; 1533 women, 442 men). This ratio is slightly higher than one would expect because of the usual gender differences in migraine frequency. The mean duration of primary headache was 20.4 years. The mean admitted time of frequent drug intake was 10.3 years in one study, and the mean duration of daily headache was 5.9 years. Results from headache diaries show that the number of tablets or suppositories taken daily averaged 4.9 (range, 0.25 to 25). Patients averaged 2.5 to 5.8 different pharmacologic components simultaneously (range, 1 to 14).

A prospective study of 98 patients investigated the pharmacologic features, such as the mean critical duration until onset of MOH, mean critical monthly intake frequency, and mean critical monthly dosages, as well as the specific clinical features of MOH, after the overuse of different acute headache drugs. In this study, triptan overuse far outnumbered ergot overuse. This reflects the fact that despite high cost, triptans have become widely used (and overused) and suggests that they are about to become the most important group causing MOH. Unlike patients who suffer from MOH following ergot or analgesic overuse, migraine patients (but not TTH patients) with triptan-induced headache did not describe the typical tension-type daily headache but rather a migraine-like daily headache (a unilateral, pulsating headache with autonomic disturbances) or a significant (and pure) increase in migraine attack frequency. Furthermore, the delay between frequent medication intake and the development of daily headache was shortest with triptans (1.7 years), longer with ergots (2.7 years), and longest with analgesics (4.8 years). Intake frequency (single dosages per month) was lowest for triptans (18 single dosages per month), higher for ergots (37 single dosages per month), and highest for analgesics (114 single dosages per month). Hence, triptans not only cause a different spectrum of clinical features but can also result in MOH faster and with lower dosages than needed with other substance groups.

In addition to exacerbating the headache disorder, drug overuse has other serious effects. Overuse of acute drugs may interfere with the effectiveness of preventive headache medications. Prolonged use of large amounts of medication may cause renal or hepatic toxicity in addition to tolerance, habituation, or dependence. (Tolerance refers to decreased effectiveness of the same dose of an analgesic, which often leads to the use of higher doses to achieve the same degree of effectiveness. Habituation and dependence are, respectively, the psychological and physical need to repeatedly use drugs.)

**EPIDEMIOLOGY**

In population-based surveys using the Silberstein-Lipton criteria, primary CDH was found to occur in 4.1% of Americans, 4.4% of Greeks, 3.9% of elderly Chinese, and 4.7% of Spaniards. Population-based estimates for the 1-year prevalence of CTTH are 1.7% in Ethiopia, 3% in Denmark, 2.2% in Spain, 2.7% in China, and 2.2% in the United States.
Scher and coworkers,\textsuperscript{96} using a validated computer-assisted telephone interview, ascertained the prevalence of CDH in 13,343 individuals aged 18 to 65 years in Baltimore County, Maryland. Those reporting 180 or more headaches per year were classified as having frequent headache. Three mutually exclusive subtypes of frequent headache were identified: TM, CTTH, and unclassified frequent headache. The overall prevalence of CDH was 4.1% (5.0% in women, 2.8% in men; 1.8:1 female-to-male ratio). Prevalence was highest in the lowest educational category for both men and women. More than half (52% of women, 56% of men) met the criteria for CTTH (2.2%), almost a third (33% of women, 25% of men) met the criteria for TM (1.3%), and the remainder (15% of women, 19% of men) were unclassified (0.6%). Overall, 30% of women and 25% of men who were frequent headache sufferers met the IHS criteria for migraine (with or without aura). On the basis of chance, migraine and CTTH would co-occur in 0.22% of the population; the fact that TM occurred in 1.3% of this population would suggest that their co-occurrence is more than random.

Castillo and associates\textsuperscript{115} sampled 2252 subjects older than 14 years in Cantalucia, Spain. Overall, 4.7% had CDH. According to the criteria of Silberstein and colleagues,\textsuperscript{99} none had HC, 0.1% had NDPH, 2.2% had CTTH, and 2.4% had TM. Nineteen percent of CTTH patients and 31.1% of TM patients had a history of acute medication overuse. Eight patients had a previous history of migraine without aura and now had primary CDH with the characteristics of TTH only. These headaches met the criteria for CM but could have been migraine and coincidental CTTH.

Wang and associates\textsuperscript{97} looked at the characteristics of primary CDH in a population of elderly Chinese (older than 65 years) in two townships on Kinmen Island. Seventy-seven percent of the eligible population (1533 of 2003) participated. Sixty patients (3.9%) had CDH. Significantly more women than men had primary CDH (5.6% and 1.8%, \(P < 0.001\)). Of the patients with primary CDH, 42 (70%) had CTTH (2.7%), 15 (25%) had CM (1%), and 3 (5%) had other CDH. Only 2% of patients had consulted a physician for headache in the previous year.

Lu and colleagues\textsuperscript{116} conducted a two-stage population-based headache survey of subjects 15 years or older in Taipei, Taiwan. Subjects who had experienced CDH in the past year were identified, interviewed, and followed up. CDH was defined as a headache frequency of greater than 15 days a month with a duration of more than 4 hours per day. Of the 3377 participants, 108 (3.2%) fulfilled the criteria for CDH, with a higher prevalence in women (4.3%) than in men (1.9%). TM was the most common subtype (55%), followed by CTTH (44%). Thirty-four percent of the CDH subjects overused analgesics.

The gradual evolution of the definition of CM has resulted in varying conclusions drawn from prevalence studies. Two reviews that defined chronic headache as being present on 15 or more days per month estimated its global prevalence to be 3% to 4%.\textsuperscript{117,118} A systematic review from 2010 focused on 12 worldwide, population-based incidence and prevalence studies that determined rates of CM with either the Silberstein-Lipton TM criteria and the ICHD-2R term CM,\textsuperscript{119} or the current ICHD-2R criteria for CM.\textsuperscript{120} The prevalence of CM in these studies ranged from 0.0% to 5.1% (initial estimates of these rates were typically in the range of 1.4% to 2.2%) and varied by WHO-defined geographic regions, as well as by gender.\textsuperscript{121} These estimates are imperfect because of the heterogeneity of definitions applied across studies and the lack of data from certain regions. Nevertheless, the target population is equally well defined by both the Silberstein-Lipton TM criteria and the ICHD-2R term CM, so the data presented are likely to give a reasonably accurate global perspective. The prevalence of CM in this systematic review also suggests that this condition represents approximately half of all cases of chronic primary headache. In further population-based studies—HUNT 2 and HUNT 3, published in 2011—the age-adjusted prevalence of CM was consistently 0.5% throughout an 11-year follow-up period.\textsuperscript{122}

**RISK FACTORS (BOX 30.7)**

Wang and associates\textsuperscript{97} ascertained that significant risk factors for CDH included analgesic overuse (odds ratio [OR] = 79), a history of migraine (OR = 6.6), and a Geriatric Depression Scale–Short Form score of 8 or higher (OR = 2.6). At follow-up, patients with persistent primary CDH had a significantly higher frequency of analgesic overuse (33% vs. 0%, \(P = 0.03\)) and major depression (38% vs. 0%, \(P = 0.04\)).

Granella and colleagues\textsuperscript{123} found that risk factors associated with the evolution of migraine without aura into TM included head trauma (OR = 3.3), analgesic use with every attack (OR = 2.8), and long duration of oral contraceptive use.

Scher and coworkers\textsuperscript{124} described factors that predict CDH onset and remission in an adult population. CDH was more common in women (OR = 1.65 [1.3 to 2.0]), those previously married (OR = 1.5 [1.2 to 1.9]), those with obesity (body mass index \(>30\)) (OR = 1.27 [1.0 to 1.7]), and those with less education. Obesity, high baseline headache frequency, high caffeine consumption, habitual daily snoring, and stressful life events were significantly associated with new-onset CDH.\textsuperscript{125} Having less than a high school education was associated with a threefold increased risk for CDH (OR = 3.56 [2.3 to 5.6]).

Bigal and colleagues,\textsuperscript{126} in a clinic-based study, looked for risk factors associated with CDH and its subtypes. TM without MOH (vs. episodic migraine) was associated with allergies, asthma, hypothyroidism, hypertension, and daily caffeine consumption.

Zwart and associates\textsuperscript{127} examined the relationship between analgesic use at baseline and the subsequent risk for chronic pain (≥15 days/mo) and analgesic overuse in a population-based study. In total, 32,067 adults reported the use of analgesics from 1984 to 1986 and at follow-up 11 years later (1995 to 1997). The risk ratios for chronic pain and for analgesic overuse in the different diagnostic groups (i.e., migraine, nonmigrainous headache, and neck pain) were estimated in relation to analgesic consumption at baseline. Individuals who reported using analgesics daily or weekly at baseline had a significantly increased risk of having chronic pain at follow-up. The risk was most evident for CM (relative risk \([RR]=13.3, 95\% CI = 9.3 \text{ to } 19.1\)) intermediate for chronic nonmigrainous headaches (\([RR]=6.2, 95\% CI = 5.0 \text{ to } 7.7\)), and lowest for chronic neck pain (\([RR]=2.4, 95\% CI = 2.0 \text{ to } 2.8\)). In subjects with chronic pain associated with analgesic overuse, the \(RR\) was 37.6 (95\% CI = 21.3 to 66.4) for CM, 14.4 (95\% CI = 10.4 to 19.9) for chronic nonmigrainous headaches, and 7.1 for chronic neck pain (95\% CI = 5.5 to 9.2). The \(RR\) for chronic headache (migraine and nonmigrainous headache combined) associated with analgesic overuse was 19.6 (95\% CI = 14.8 to 25.9) versus 3.1 (95\% CI = 2.4 to 4.2) for those without overuse. Analgesic overuse strongly predicts chronic pain and chronic pain associated with analgesic overuse 11 years later, especially in those with CM.

Although data on the natural history of patients with CM is not available (because of the 10- to 15-year time scale that would be required for a population-based study of this condition), information from the AMPPS on the clinical evolution of this condition was published in 2011.\textsuperscript{128} Longitudinal data over a 3-year period were analyzed to determine rates of CM remission and to assess predictors of remission via logistic regression models. Three hundred eighty-three individuals who had CM in 2005 were identified and evaluated in 2006 and 2007. Among individuals with CM at baseline, 52.7\% continued to report this condition for at least 1 year of follow-up. The study also found that 34\% had persistent CM (defined as CM across all 3 years), whereas only 26\% had remission of CM (defined as fewer than 10 headache days per month).\textsuperscript{128} Over a 2-year period the individuals with persistent CM demonstrated increased disability, whereas those with remission showed decreased disability. Predictors of remission included a lower baseline headache frequency (15 to 19 headache days per month vs. 25 to 31 headache days per month; \(OR=0.29, 95\% CI = 0.11 \text{ to } 0.75\)) and the absence of allodynia (\(OR=0.45, 95\% CI = 0.23 \text{ to } 0.89\)).

**TREATMENT**

**OVERVIEW**

Patients with CDH can be difficult to treat, especially when the disorder is complicated by medication overuse, comorbid psychiatric disease, low tolerance of frustration, and physical and emotional dependency.\textsuperscript{94,129} We recommend the following steps. First, exclude secondary headache disorders; second, diagnose the specific primary headache disorder (CM, CTHH, HC, or NDPH); and third, identify comorbid medical and psychiatric conditions and exacerbating factors, especially medication overuse. Limit acute medications (with the possible exception of long-acting NSAIDs). Patients should start taking preventive medication (to decrease reliance on acute medication), with the explicit understanding that the drugs may not become fully effective until medication overuse has been eliminated.\textsuperscript{51} Some patients need to have their headache cycle terminated.\textsuperscript{61} Patients need education and continuous support during this process. Outpatient detoxification options, including outpatient infusion in an ambulatory infusion unit, are available. If outpatient treatment proves difficult or is dangerous, hospitalization may be required.\textsuperscript{92,130}

Two separate studies in Europe and the United States showed that topiramate at a dose of 100 mg daily was effective as preventive therapy for CM.\textsuperscript{131,132} The key difference between the two studies was that patients were allowed to take acute rescue medication as usual in the European trial\textsuperscript{131} but not in the U.S. trial.\textsuperscript{132} Remarkably, the benefits of topiramate extended to the subgroup of patients who were overusing acute medications, as demonstrated by the significant reductions in mean monthly migraine days in this group versus the placebo group.

The Phase III Research Evaluating Migraine Prophylaxis Therapy (PREEMPT 1 and 2) multicenter randomized clinical trials were conducted to evaluate the efficacy and safety of botulinum toxin type A as prophylactic treatment in adults with CM. A total of 1384 patients with CM were enrolled across trials\textsuperscript{133-135} Patients were stratified into groups according to whether they were overusing acute headache medications at baseline and were randomly assigned in a 1:1 ratio to treatment with either botulinum toxin type A or placebo injections. A total dose of 155 units of botulinum toxin type A was administered to 31 sites in seven head and neck muscles.\textsuperscript{133-135} The PREEMPT study results demonstrated significant improvement at the population level in multiple measures of headache symptoms, as well as improvement in patients’ functioning, vitality, psychological distress, and overall health-related QOL, in response to treatment with botulinum toxin type A.

Three studies have evaluated the safety and efficacy of occipital nerve stimulation (ONS) for the treatment of CM. They indicated that ONS could potentially be an effective treatment of patients with drug-refractory CM.\textsuperscript{156-158} In some cases, CDH reverts to episodic headache when preventive medication is initiated and acute medications are limited. In other cases, only moderate or no improvement may occur. Zeeberg and coworkers\textsuperscript{139} described the treatment outcomes of patients withdrawn from medication overuse. They studied 337 outpatients in whom MOH was diagnosed and who were treated and dismissed from the Danish Headache Centre in 2002 and 2003. A 46\% decrease in headache frequency from the first visit to dismissal was noted (\(P < 0.0001\)). Patients with no improvement 2 months after complete drug withdrawal (\(n = 88\)) subsequently responded to pharmacologic or nonpharmacologic prophylaxis (or both) with a 26\% decrease in headache frequency as measured from the end of withdrawal to dismissal. At dismissal, 47\% of patients were being maintained on prophylaxis. In this population, about half of MOH patients benefited from drug withdrawal alone.\textsuperscript{139}

**PROGNOSIS**

The AMPPS was published in 2011.\textsuperscript{128} Among individuals with CM at baseline, 52.7\% continued to report this
condition for at least 1 year of follow-up. The study also found that 34% had persistent CM (defined as CM across all 3 years), whereas only 26% had remission of CM (defined as fewer than 10 headache days per month). Over 2 years the individuals with persistent CM demonstrated increased disability, whereas those with remission showed decreased disability. Predictors of remission included a lower baseline headache frequency (15 to 19 headache days per month vs. 25 to 31 headache days per month; OR = 0.29, 95% CI = 0.11 to 0.75) and the absence of allodynia (OR = 0.45, 95% CI = 0.23 to 0.89). In addition, retrospective analysis suggests that there may be periods of stable drug consumption and periods of accelerated medication use. Patients treated aggressively generally improve. There are no literature reports of spontaneous improvement of rebound headache, although this may happen. We performed follow-up evaluations on 50 hospitalized primary CDH drug overuse patients who were treated with repetitive intravenous DHE and became headache free. Once detoxified, treated, and discharged, most patients did not resume daily analgesic or ergotamine use. Seventy-two percent continued to show significant improvement at 3 months, and 87% continued to show significant improvement after 2 years. This would suggest at least 70% improvement at 2 years in the initial group (35 of 50) if allowance is made for patients lost to follow-up.

Our 2-year success rate of 87% is consistent with the long-term success rates reported in the literature. In a series of 22 papers published between 1975 and 1999, the success rate of withdrawal therapy (often accompanied by pharmacologic or behavioral intervention, or both) for patients overusing analgesics, ergotamine, or both was between 48% and 91%, with the rate being reported as 77% or higher in 10 papers.

**TENSION-TYPE HEADACHE**

Epidemiologic studies of the general population have shown that TTH is the most common type of headache, with a lifetime prevalence of 69% in men and 88% in women. TTHs can begin at any age, but onset during adolescence or young adulthood is most common. The prognosis of TTH that nonmigraineurs experience supports this concept. What we call ETTH may be two distinct disorders. The first disorder may be mild migraine. The second may be a pure TTH that is not associated with other features of migraine (nausea, photophobia, or sensitivity to movement) or with attacks of severe migraine. The fact that sumatriptan is effective for the TTH that migraineurs experience but not for the TTH that nonmigraineurs experience supports this concept.

Patients with ETTH are no different from controls in terms of stress, depression, anxiety, emotional conflicts, sleeping problems, and fatigue. Patients with CTTH are often depressed.

**DIFFERENTIAL DIAGNOSIS**

Migraine is the headache disorder most frequently confused with TTH. Both can be bilateral, nonthrobbing, and associated with anorexia. Migraine is more severe, often unilateral, and frequently associated with nausea. Idiopathic intracranial hypertension, brain tumor headache, chronic sphenoid sinusitis, and cervical, ocular, and temporomandibular disorders need to be considered.

**EVALUATION**

Most patients with a long history of unchanged ETTH do not require extensive evaluation if they have normal findings on neurologic examination and are otherwise healthy. Patients with CTTH should be evaluated with CT or MRI, even if the results of general and neurologic examination are normal. A metabolic screen, complete blood count, electrolytes, and kidney and thyroid function studies are also appropriate.
MANAGEMENT

TTH patients usually self-medicate with over-the-counter analgesics (aspirin, acetaminophen, NSAIDs), with or without caffeine. If these medications are not effective, prescription NSAIDs or combination analgesic preparations can be used. Narcotics and combination analgesics that contain sedatives or caffeine should be limited because overuse may cause dependence. Symptomatic medication overuse can cause ETTH to convert to CTTH. Patients with both migraine and TTH benefit from specific migraine medication, such as sumatriptan or DHE (see Boxes 30.5 and 30.6).150,155

Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Medications used for prevention of TTH include antidepressants, β-blockers, and anticonvulsants. Antidepressants, the medication of first choice, should be started at a low dose and increased slowly every 3 to 7 days. An adequate trial period of at least 1 to 2 months must be allowed. The addition of biofeedback therapy or β-blocking agents may improve its therapeutic benefit.150,155

PROGNOSIS AND FUTURE PERSPECTIVES

ETTH is a benign recurrent condition that usually improves with time. Some patients, however, progress to CTTH, especially when analgesic overuse is present. The prognosis of patients with CTTH is controversial because many studies include patients with more severe headaches and coexisting conditions, such as migraine and psychiatric disorders.

Box 30.8 Cluster Headache

A. At least 5 attacks fulfilling criteria B to E
B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 minutes if untreated
C. Headache accompanied by at least 1 of the following:
   1. Ipsilateral conjunctival injection and/or lacrimation
   2. Ipsilateral nasal congestion and/or rhinorrhea
   3. Ipsilateral eyelid edema
   4. Ipsilateral forehead and facial sweating
   5. Ipsilateral miosis and/or ptosis
   6. Sense of restlessness or agitation
D. Attacks having a frequency from 1 every other day to 8 per day
E. Not attributed to another disorder

Episodic Cluster Headache

A. Attacks fulfilling the above criteria A to E for Cluster Headache
B. At least two cluster periods lasting 7 to 365 days and separated by pain-free remission periods of 1 month or longer

Chronic Cluster Headache

A. Attacks fulfilling criteria A to E for Cluster Headache
B. Attacks recurring longer than 1 year without remission periods or with remission periods lasting less than 1 month

Paroxysmal Hemicrania

A. At least 20 attacks fulfilling criteria B to F

B. Attacks of severe unilateral orbital, supraorbital, or temporal pain lasting 2 to 30 minutes
C. Headache accompanied by at least 1 of the following:
   1. Ipsilateral conjunctival injection and/or lacrimation
   2. Ipsilateral nasal congestion and/or rhinorrhea
   3. Ipsilateral eyelid edema
   4. Ipsilateral forehead and facial sweating
   5. Ipsilateral miosis and/or ptosis
D. Attacks having a frequency higher than 5 per day for more than half of the time, although periods with lower frequency may occur
E. Attacks prevented completely by therapeutic doses of indomethacin
F. Not attributed to another disorder

Episodic Paroxysmal Hemicrania

A. Attacks fulfilling criteria A to F for Paroxysmal Hemicrania
B. At least two attack periods lasting 7 to 365 days and separated by pain-free remission periods of 1 month or longer

Chronic Paroxysmal Hemicrania

A. Attacks fulfilling criteria A to F for Paroxysmal Hemicrania
B. Attacks recurring more than 1 year without remission periods or with remission periods lasting less than 1 month

CLUSTER HEADACHE AND OTHER TRIGEMINAL AUTONOMIC CEPHALGIAS (BOX 30.8)

The short-lasting primary headache syndromes may be conveniently divided into those that exhibit marked autonomic activation and those without autonomic activation. This group includes cluster headache (episodic or chronic), paroxysmal hemicrania (episodic or chronic), and SUNCT syndrome.

PATHOGENESIS AND PATHOPHYSIOLOGY

The pathogenesis of cluster headache involves the trigeminal-autonomic system, as demonstrated by a marked increase in the level of calcitonin gene–related peptide in the cranial venous circulation during attacks. Activation of the parasympathetic system has been corroborated by the finding of dramatically elevated levels of vasoactive intestinal polypeptide during attacks with robust ipsilateral autonomic features. Cluster events are probably related to alterations in the circadian pacemaker, which may be due to hypothalamic dysfunction. Attacks increase following the beginning and end of daylight saving time, and there is loss of the circadian rhythm for blood pressure, temperature, and hormones, including prolactin, melatonin, cortisol, and β-endorphins. Evidence for the role of the hypothalamus in the pathogenesis of cluster headache has come from functional and morphometric neuroimaging. Using positron emission tomography, May and colleagues demonstrated marked activation in the ipsilateral ventral hypothalamic gray matter during nitroglycerin-induced acute cluster
headache attacks.\textsuperscript{159} Neurogenic inflammation, dysfunction of the carotid body chemoreceptor, an imbalance in central parasympathetic and sympathetic tone, and increased responsiveness to histamine have been proposed as the cause of cluster headache.\textsuperscript{160}

**Epidemiology and Risk Factors**

With an incidence of 0.01\% to 1.5\% in various populations, the prevalence of cluster headache is lower than that of migraine or TTH. Men have a higher prevalence than women do, and African American patients have a higher prevalence than Caucasian patients do. Recent evidence suggests a progressively decreasing male preponderance: the male-to-female ratio based on the year of onset in Mannzoni’s study\textsuperscript{161} decreased from 6.2:1 in the 1960s to 2.1:1 in the 1990s.\textsuperscript{162} A family history of cluster headache is rare. The most common form of cluster headache is episodic cluster. The rarest form is chronic cluster headache without remissions, with only about 1\% of patients suffering from this variety of cluster. Cluster headache can begin at any age but generally commences in the late twenties. Cluster headache rarely begins in childhood, and it develops in only about 10\% of patients when they are in their sixties.\textsuperscript{160,163}

**Clinical Features and Associated Disorders**

Patients with cluster headache have multiple episodes of short-lived but severe, unilateral, orbital, supraorbital, or temporal pain. At least one of the following associated symptoms must occur: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, facial sweating, miosis, ptosis, and eyelid edema. Episodic cluster consists of headache periods of 1 week to 1 year, with remission periods lasting at least 14 days, whereas chronic cluster headache has either no remissions or remissions that last less than 14 days.\textsuperscript{160,163}

The pain of a cluster attack increases to excruciating levels rapidly (within 15 minutes). The attacks often occur at the same time each day and frequently awaken patients from sleep. If the condition is left untreated, the attacks usually last from 30 to 90 minutes, but they may last as long as 180 minutes. The pain is deep, constant, boring, piercing, or burning in nature and located in, behind, or around the ear, neck, or shoulders. During an attack, patients often feel agitated or restless and feel a need to isolate themselves and move around. Gastrointestinal symptoms are uncommon. A small subset of patients experience a typical migraine aura before a cluster headache attack.\textsuperscript{164} Attack frequency varies from one every other day to eight per day, with cluster periods lasting a week to a year. Remissions between cluster periods generally last from 6 months to 2 years. Most patients have one or two cluster periods per year that last 2 to 3 months, with one to two attacks per day.\textsuperscript{160}

Peptic ulcer disease is the only known associated medical disorder. Secondary cluster-like headache may be due to structural lesions near the cavernous sinuses.\textsuperscript{160,163}

**Differential Diagnosis**

The differential diagnosis of cluster headache includes chronic paroxysmal hemicrania, migraine, trigeminal neuralgia, temporal arteritis, pheochromocytoma, Raeder’s paratrigeminal syndrome, Tolosa-Hunt syndrome, sinusitis, and glaucoma.\textsuperscript{160} Raeder’s syndrome has characteristics similar to cluster headaches. It may be associated with severe pain, unilateral and supraorbital distribution, and an associated partial Horner syndrome. It is distinct from cluster headache in that there are no distinct attacks and the pain is constant.

**Evaluation**

No studies have addressed the need for testing in patients with cluster-like headache. In most cases a careful history is all that is needed to make the diagnosis. MRI of the head is justified only for atypical cases or those with abnormal findings on neurologic examination (except when the abnormality is Horner’s syndrome).

**Management**

Patients with cluster headaches should avoid alcohol and nitroglycerin, yet other dietary and drug restrictions have little effect. Pharmacologic treatment of cluster headaches is divided into acute and preventive therapy, and recommendations are based mainly on uncontrolled trials.\textsuperscript{160,163} Because oral preparations are absorbed slowly, they are not recommended for acute attacks. Effective acute treatments that provide a rapid onset of action include oxygen, sumatriptan, DHE, and (perhaps) topical local anesthetics. Inhaled oxygen, 7 to 10 L/min for 10 minutes following onset of the headache, is 70\% effective and is often the first choice of treatment. Parenteral injections of sumatriptan or DHE provide significant relief in about 80\% of patients. An intranasal local anesthetic provides relief for some patients.\textsuperscript{160,163}

Most patients with cluster headache require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only acute medication. In addition, ergotamine, DHE, sumatriptan, and oxygen may just postpone rather than abort the attack. Preventive therapy for cluster headache includes ergotamine, calcium channel blockers, lithium, corticosteroids, divalproex, topiramate, melatonin, and capsaicin. Occasionally, indo-methacin is effective. If medical therapy fails completely, surgical intervention may be beneficial in psychologically stable patients with strictly unilateral chronic cluster headache. The surgery consists of neuronal ablative procedures directed toward the sensory input of the trigeminal nerve and autonomic pathways and is effective in 75\% of patients.\textsuperscript{165} Gamma knife radiosurgery was reported to be effective in six medically recalcitrant cluster headache patients, but delayed radiation necrosis can occur.\textsuperscript{166} Deep brain (hypothalamic) stimulation has been reported to be effective for intractable chronic cluster headache.\textsuperscript{167} Since cluster headache is a chronic headache disorder that may last for the patient’s lifetime, the prognosis is guarded. Drug therapy may help convert some patients from chronic to episodic cluster headache.\textsuperscript{160}

Deep brain stimulation of the posterior hypothalamus (hDBS) and ONS along the greater occipital nerve have been introduced and evidence is accumulating. Deep brain stimulation was developed on the basis of findings of activation in the posterior part of the lateral portion of the hypothalamus.\textsuperscript{165} Both hDBS and ONS have thus far resulted in positive outcomes in patients with drug-resistant chronic
Clusters headaches (about a 50% reduction in attacks), but long-term studies have revealed that a positive outcome, especially with ONS, may take weeks to months of stimulation to be reached, thus pointing at long-term brain alterations in pain processing as a mechanism. With both hDBS and ONS the pain and autonomic symptoms return to baseline levels when the stimulator is turned off. So far no predictors of treatment response have been found, and greater occipital nerve block does not predict ONS response.

**SPHENOPALATINE GANGLION STIMULATION**

In 2010 Ansarinia and coauthors described the acute effect of external electrical stimulation in eight patients with cluster headache, of whom four achieved complete freedom from pain, three achieved a reduction in pain, and one had no change. More sophisticated systems have been developed, and an ongoing European multicenter study is now testing the effect of an electrode implanted directly in the sphenopalatine fossa very close to the sphenopalatine ganglion (SPG). The preliminary results are very promising: there appears to be a significant preventive effect in addition to an acute abortive effect. The side effects have been limited, so the therapy looks promising for severely affected chronic cluster headache patients; however, long-term studies are needed. Furthermore, important insight in the pathophysiology of cluster headache and the mechanisms of SPG stimulation can be achieved.

**CHRONIC PAROXYSMAL HEMICRANIA**

Chronic paroxysmal hemicrania resembles cluster headache in character but is distinguished by its dramatic responsiveness to indomethacin therapy. The pathophysiology of chronic paroxysmal hemicrania is unknown. The changes in intraocular pressure that occur during attacks suggest autonomic dysfunction, and the periodicity of this disorder suggests a central generator. In contrast to cluster headache, chronic paroxysmal hemicrania is a rare disorder that affects women more than men (ratio of approximately 7:1). Its prevalence is approximately 2% that of cluster headache.

Like patients with cluster headache, those with chronic paroxysmal hemicrania have severe unilateral headaches associated with unilateral nasal stuffiness, lacrimation, conjunctival eye tearing, ptosis, and eyelid edema. Headaches average 13 minutes in duration and occur an average of 11 times per day. Occasionally, patients experience a continuous dull ache between attacks. Ten percent of patients can trigger attacks by flexing, rotating, or pressing the upper portion of the neck. Typically, no remissions occur. Rarely, a patient has episodic paroxysmal hemicrania with remissions that last weeks or months. Patients may evolve from the episodic to the chronic form of the illness. By definition, chronic and episodic hemicrania is responsive to indomethacin. No other medical or psychiatric disorders have been associated with chronic paroxysmal hemicrania.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of chronic paroxysmal hemicrania is similar to that for cluster headache. In addition, patients with “jabs and jolts syndrome” occasionally resemble those with chronic paroxysmal hemicrania. A rare headache disorder called SUNCT syndrome should be considered, although these headaches are much shorter in duration (15 to 30 seconds) and occur much more frequently (many times per hour) than those of chronic paroxysmal hemicrania.

**EVALUATION**

When evaluating a patient with chronic paroxysmal hemicrania, a trial of indomethacin is necessary to establish the diagnosis. Brain imaging with MRI or CT should be undertaken to exclude symptomatic causes of apparent chronic paroxysmal hemicrania. The treatment of choice is indomethacin (in a dose of up to 200 mg/day). Aspirin may also be beneficial, but it does not usually afford complete relief. Chronic paroxysmal hemicrania may last indefinitely, but the indomethacin requirement may be reduced over time. Temporary remissions and spontaneous cures have been described. Selective prostaglandin synthesis inhibitors, or indomethacin-like drugs without the gastrointestinal side effects of the current NSAIDs, are in development and may be beneficial.

**SUMMARY**

Headache is a problem that has plagued humans since the beginning of recorded time. Headaches can severely interfere with daily functioning and productivity. Migraine is a chronic neurologic disease characterized by episodic attacks of headache and associated symptoms. The migraine attack can consist of premonitory, aura, headache, and resolution phases. The IHS subdivides migraine into migraine with aura and migraine without aura. Migraine varies widely in its frequency, severity, and impact on patients’ QOL. Pharmacologic treatment of migraine may be acute (abortive) or preventive (prophylactic), and patients with frequent, severe headaches often require both approaches. CDH refers to headache disorders experienced very frequently (15 or more days per month), including headaches associated with medication overuse. The major primary disorders to consider are CM, HC, CTTH, and NDPH. MOH was previously called rebound headache, drug-induced headache, and medication misuse headache. Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans. Patients with CDH can be difficult to treat. First, exclude secondary headache disorders; second, diagnose the specific primary headache disorder; and third, identify comorbid medical and psychiatric conditions. Limit acute medications. Patients should start taking preventive medication, with the explicit understanding that the drugs may not become fully effective until medication overuse has been eliminated. TTH is the most common type of headache, with a lifetime prevalence of 69% in men and 88% in women. ETTH is now classified as either infrequent (<1 day/mo or 12 days/yr) or frequent (>1 but <15 days/mo or >12 but <180 days/yr). Patients with TTH usually self-medicate with over-the-counter analgesics, with or without caffeine. Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Cluster headache and other trigeminal cephalgias are short-lasting primary headache syndromes that may...
be conveniently divided into those that exhibit marked autonomic activation and those without autonomic activation. This group includes cluster headache, paroxysmal hemicrania, and SUNCT syndrome. Patients with cluster headache have multiple episodes of short-lived but severe unilateral, orbital, supraorbital, or temporal pain. Chronic paroxysmal hemicrania resembles cluster headache in character but is distinguished by its dramatic responsiveness to indomethacin therapy.

Because of the complex anatomy and specialized sensory innervation of the head and neck, craniofacial pain disorders merit special consideration. Many craniofacial syndromes are unique and represent a clinical diagnostic challenge. This chapter presents an introduction to practical issues regarding assessment and treatment of common craniofacial pain disorders in accordance with the diagnostic classification scheme of the International Headache Society (IHS) (Boxes 31.1 to 31.3).1

PAIN CAUSED BY PATHOLOGY OF THE HEAD, FACE, AND ORAL CAVITY

The specialized structures of the head and face have a rich sensory innervation supplied by the trigeminal system, lower cranial nerves, and upper cervical roots. Accordingly, pain is one of the most prominent symptoms of disease in this area. In most cases the acute pain symptoms closely correlate with other signs and symptoms of disease. However, correlation between pain and other symptoms may not be evident in a number of more complex, chronic pain problems, particularly those involving the masticatory system.2

DENTAL PAIN

Tooth pulp has a specialized and possibly exclusively nociceptive innervation.2,3 In contrast, periodontal tissues are innervated by a wide variety of sensory afferents. Dentin and pulp are closely related and function as a unit. In other words, all procedures performed on dentin are essentially performed on dentin and pulp, the pulpodental complex.2

Dental pain is usually well localized, and the quality of the pain can range from a dull ache to severe electric shocks, depending on the specific etiology and extent of disease (Box 31.4). Dental pain is typically provoked by thermal or mechanical stimulation of the damaged tooth. Clinical and radiographic findings of dental decay, tooth fracture, or abscess drainage may confirm the source of dental pain.

DENTIN SENSITIVITY

Exposed dentin (open cavities, exposed cervical dentin) is markedly sensitive to changes in temperature, to touch, and to sweets. When exposed, dentin is stimulated (cold, sweet, touch); a sharp pain of short duration is experienced immediately following stimulation. “Conduction of pain” through dentin has received quite a lot of attention both clinically and in research. Treatment of sensitive dentin has attracted the attention of industry, and quite a few products are commercially available. Through the years, hundreds of methods have been advocated for the treatment of sensitive dentin, thus showing that no method is really effective.

PULP INFLAMMATION AND PAIN

The duration of pain is commonly used as a clinical yardstick for determining whether the symptoms are caused by sensitive dentin or pulp inflammation. If a cold test results in pain that lasts for a few seconds, the cause is considered to be sensitive dentin. Lingering pain is taken as an indication of pulp inflammation. This clinical yardstick is crude and inexact, but no better method exists. So if the pain lasts beyond seconds or lingers when the stimulus is removed, it is considered an indication for endodontic intervention. Pulp inflammation as a result of dental caries (decay) needs to be treated surgically and medically with routine dental restorative or endodontic therapy (or both).

Pulp inflammation, if left untreated, will spread apically and the inflammatory process will extend outside the apical foramen. Therefore, in the late stages of pulp inflammation, there is no border between pulp and periapical inflammation, and symptoms from the two types of processes can be mixed.

PERIAPICAL INFLAMMATION AND PAIN

Bacterial by-products seep out through the apical foramen and create a local response to the canal infection. The periapical inflammation does not cause symptoms during most of its existence. There appears to be a balance between the infection and defense forces. It is important to keep this in mind when examining a patient in pain. A radiolucent area does not equal pain. The patient’s history, including findings on clinical examination and radiographs, determines the need for therapy. All the classic symptoms of inflammation are involved in an exacerbated periapical inflammation—pain, swelling, redness, and lack of function. The tooth is tender to percussion and periapical palpation. To make the tooth free of symptoms, the infection has to be removed, which involves cleaning the root canal with antiseptic irrigants. Occasionally, a periapical inflammation flares up before radiographic signs are visible. These teeth are extremely painful and tender to percussion, and neither the patient nor the clinician has any problem localizing such teeth. Usually, treatment of a periapical flare-up does not require the use of antibiotics. Root canal cleaning and, when appropriate, drainage of an abscess through the canal or through an incision take care of the infection. This rids the patient of pain. If the patient has fever and malaise or an abscess develops, the use of antibiotics is necessary.

Acute dental pain typically responds to local treatment (e.g., ice packs and reduced mechanical stimulation) or to systemic nonsteroidal anti-inflammatory drugs (NSAIDs).
Opioid analgesics are also occasionally indicated, depending on the extent of objective pathology. Opioids should be used only short-term and in combination with NSAIDs. In many cases, treatment with antibiotic agents is appropriate and palliative until a definitive dental intervention is performed.

**DISORDERS OF THE PERIODONTIUM (PERIODONTAL DISEASE)**

Chronic periodontal disease is an immune-mediated inflammatory process initiated by pathogenic oral microorganisms that results in focal or generalized areas of destruction of the tooth-supporting structures and surrounding bone. Chronic periodontitis is not generally a chronically painful disorder. Typically, patients may notice gingival sensitivity and tenderness or gingival enlargement because of inflammation and bleeding with brushing or probing examination. There is loss of gingival attachment around the necks of and soft tissue pocketing around the roots of the tooth with loss of bone support, which may result in tooth sensitivity, tenderness, and mobility. In the presence of an acute infection in the periodontal tissues, tenderness to the touch, erythema, and bleeding may be evident. An acute periodontal abscess may cause swelling and purulence (Table 31.1). When inflammation or infection (i.e., acute pericoronitis) occurs in the soft tissue or bone around an erupting or partially erupted tooth (particularly third molars, otherwise known as “wisdom teeth”), similar signs and symptoms may be seen, with pain being a primary symptom.

The pain of periodontal disorders is also generally responsive to NSAIDs, opioid analgesic agents, or combination analgesic agents. An acute abscess may also have to be locally incised and drained. Areas of generalized periodontitis may be treated by tooth scaling and curettage of the gingival pocket and possibly by local or systemic antibiotic therapy.

**ORAL MUCOUS MEMBRANE DISORDERS**

Diseases of the oral mucosa are numerous and due to a variety of local and systemic causes. Typically, these diseases are accompanied by pain and oral mucosal lesions, including vesicles, bullae, erosions, erythema, or red and white patches (Box 31.5). Pain may be a symptom of the primary disease process, secondary to an associated process (i.e., infection),

### Box 31.5 Common Painful Mucosal Conditions

#### Infections
- Herpetic stomatitis
- Varicella zoster
- Candidiasis
- Acute necrotizing gingivostomatitis

#### Immune/Autoimmune
- Allergic reactions (toothpaste, mouthwashes, topical medications)
- Erosive lichen planus
- Benign mucous membrane pemphigoid
- Aphthous stomatitis and aphthous lesions
- Erythema multiforme
- Graft-versus-host disease

#### Traumatic and Iatrogenic Injuries
- Factitial, accidental (burns: chemical, solar, thermal)
- Self-destructive (rituals, obsessive behavior)
- Iatrogenic (chemotherapy, radiation)

#### Neoplasia
- Squamous cell carcinoma
- Mucoepidermoid carcinoma

#### Adenocystic carcinoma
- Brain tumors

#### Neurologic
- Burning mouth syndrome, glossodynia
- Neuralgias
- Postviral neuralgias
- Post-traumatic neuropathies
- Dyskinesias and dystonias

#### Nutritional and Metabolic
- Vitamin deficiencies (B12, folate)
- Mineral deficiencies (iron)
- Diabetic neuropathy
- Malabsorption syndromes

#### Miscellaneous
- Xerostomia secondary to intrinsic or extrinsic conditions
- Referred pain from esophageal or oropharyngeal malignancy
- Mucositis secondary to esophageal reflux
- Angioedema
or related to damaged oral mucosa (i.e., mouth movements, chewing foods, thermal, chemical). The pain is often treated with both systemic and local analgesic agents.

**DISORDERS OF THE MAXILLA AND MANDIBLE**

Numerous disorders of the bony substrate of the jaws can be associated with pain. These disorders are generally classified as being of odontogenic or nonodontogenic origin, cystic, cystic- or tumor-like, or benign or malignant (either primary or metastatic disease). There are often additional findings on the history or physical examination that warrant further evaluation (i.e., swelling, mass, discoloration, numbness, weakness, bleeding, drainage, tooth loss or mobility). Pain can be treated symptomatically until a definitive diagnosis is established and definitive therapy is initiated (Table 31.2).

**SALIVARY GLAND DISORDERS**

Disorders of the three pairs of the major salivary glands (parotid, submandibular, and sublingual) and the many hundreds of minor salivary glands within the oral cavity may also produce pain as a primary or associated complaint. These disorders are often accompanied by other signs and symptoms (including swelling, drainage, cervical adenopathy, or generalized symptoms of systemic infection), depending on the etiology of the disorder. Disorders of the parotid gland can extend locally to produce otologic symptoms or cranial nerve (V, VII, or IX) involvement. Disorders of the submandibular gland may result in symptoms of impaired swallowing or impairment of cranial nerves V, IX, and XII (Box 31.6).

<tr>
<td>Diagnostic features</td>
<td>Pain localized in the pre-auricular area during jaw function. Usually presence of a painful click or crepitus during mouth opening. Limited opening (&lt;35 mm), deviated or painful jaw movements</td>
<td>Tenderness of the masticatory muscles. Dull, aching pain exacerbated by jaw function or palpation</td>
<td>Diffuse dull or aching pain affecting multiple groups of muscles of the head and neck region, as well as other parts of the body</td>
</tr>
<tr>
<td>Diagnostic evaluation</td>
<td>Internal derangement of the TMJ with abnormal function of the disk-condyle complex and/or degeneration of the joint surface. Palpation is painful. Possible joint swelling in acute phases. MRI, CT, etc., of the joint may rule out tumors and advanced degenerative stages</td>
<td>Tenderness during palpation of the masticatory muscles and tendons. Possible limited range of jaw movement and during passive stretching examination. Can be associated with a parafuncional habit (bruxism—early morning pain)</td>
<td>Presence of trigger or tender points in one or more groups of muscles. Pain can radiate to distant areas with stimulation or not of the trigger points. Rule out the presence of lupus erythematosus</td>
</tr>
<tr>
<td>Treatment</td>
<td>Patient education and self-care Medication: NSAIDs, nonopiate analgesics</td>
<td>Patient education and self-care Medication: topical and systemic NSAIDs, nonopiate analgesics, muscle relaxants, antidepressants (usually TCAs), anxiolytics, anticonvulsants, BTX, trigger point injections, vapocoolant spray</td>
<td>Same as for muscle disorders</td>

**BURNING MOUTH/TONGUE DISORDER (ORAL BURNING)**

Burning mouth/tongue disorder (BMD) is an idiopathic pain condition of the oral mucous membranes. It can be focal (inside of the lips or tongue) or generalized and is typically described as a constant, bilateral painful burning sensation. BMD generally affects middle-aged or older women and has been attributed to numerous oral disorders (e.g., mucous membrane disease, Sjögren’s syndrome/dry mouth, fungal infections) and systemic diseases (e.g., vitamin deficiencies, diabetes mellitus, immune connective tissue disorders, vasculitides). More recent evidence suggests that BMD is more likely a neuropathic pain disorder of either peripheral or central origin. Some recent taste-testing data and functional brain imaging studies seem to support this hypothesis (Table 31.3). Current treatments of BMD focus on this hypothesis and the use of both topical (oral mucosa) and systemic
antineuropathic pain medications (see Chapters 24 and 38); however, there is little evidence that such treatments are effective for BMD.

**SINUS DISORDERS**

Patients frequently describe their facial pain problem as a “sinus headache.” However, sinus disorders do not cause chronic headaches, and the clinician should look for a more specific cause of the pain symptoms in such cases. Diseases of the nose and paranasal sinuses typically cause acute pain associated with multiple other symptoms that are generally related to the specific nasal or sinus disease (i.e., allergic, inflammatory, infectious) (Table 31.4). Acute dentoalveolar pathology of the maxillary posterior teeth can often be accompanied by signs and symptoms consistent with sinus disease. In addition, acute dentoalveolar inflammation or infection (dental abscess) can cause secondary maxillary sinus inflammation or infection. These disorders are typically acute in nature but can become chronic. This condition is often confused with other facial pain and headache disorders.

**DISORDERS OF THE EYE AND EAR**

Because numerous disorders can cause pain in and around the eye and ear, patients need to be evaluated for any primary ophthalmologic or otologic disease. Very often pain in and around these structures is also associated with a variety of other craniofacial and headache syndromes (Boxes 31.7 to 31.9).

**TUMORS**

Numerous intracranial and extracranial tumors can cause oral cavity, oropharyngeal, facial, and head pain as a primary symptom. Cancers of the upper aerodigestive tract, jaws, base of the skull, and neck may all be accompanied by pain along with other associated signs and symptoms. In addition, numerous intracranial tumors and lesions (i.e., vascular malformations) can be manifested as facial pain and headache. These are primarily tumors of the cerebellopontine angle; however, various primary brain neoplasms and metastatic disease have been associated with facial pain and headache. Headache and facial pain of
