unknown origin should warrant careful evaluation for an underlying occult tumor (see Boxes 31.7 and 31.8).

Patients with facial pain or headache should undergo a comprehensive medical history and careful physical examination with particular attention paid to the cranial neurologic examination. Consideration should be given to obtaining appropriate imaging studies, including computed tomography (CT), magnetic resonance imaging (MRI), and magnetic resonance angiography.

**TEMPOROMANDIBULAR DISORDERS**

Temporomandibular disorders (TMDs) are defined as a subgroup of craniofacial pain problems that involve the
temporomandibular joint (TMJ), masticatory muscles, and associated head and neck musculoskeletal structures. Patients with TMDs most frequently have pain, limited or asymmetrical mandibular motion, and TMJ sounds. The pain or discomfort is often localized to the jaw, TMJ, and muscles of mastication. Common associated symptoms include ear pain and stuffiness, tinnitus, dizziness, neck pain, and headache. In some cases the onset is acute and the symptoms are mild and self-limited. In other patients, a chronic TMD with persistent pain develops in association with physical, behavioral, psychological, and psychosocial symptoms similar to those of patients with chronic pain syndromes in other areas of the body (e.g., arthritis, low back pain, chronic headache, fibromyalgia, chronic regional pain syndrome). All requiring a coordinated interdisciplinary diagnostic and treatment approach.

At least three distinct and separate dysfunctions that can create or affect the symptoms described by patients with a TMD are recognized:

1. **Muscle disorders (myofascial pain disorder [MPD]).** MPD is related to muscle dysfunction, which often leads to muscle spasms, pain, and dysfunction. This type of dysfunction can occur in any skeletal muscle. The triggering area lies in the fascial coverings and attachment zones of the muscles, hence the term **myofascial**.

2. **Temporomandibular joint articular disorders (TMJDs).** TMJDs are related to specific problems in the TMJs. These problems may range from joint sounds to locking, pain, and degenerative changes in the joints themselves. Invariable, muscle dysfunction is a secondary effect of true TMJDs.

3. **Cervical spinal dysfunction (CSD).** This syndrome is related to the spinal column, the vertebrae, the ligaments, and muscles related to them. The majority of symptoms not directly related to the jaw muscles are triggered or affected by CSD syndrome.

Common associated signs and symptoms of TMDs that need to be evaluated are headache, facial pain, eye pain, ear symptoms, TMJ symptoms, neck pain, and arm and back symptoms.

**HEADACHE**

Symptoms of bilateral head and facial pain involve multiple postural muscles or the muscles of mastication. The pain is dull and aching in quality with a chronic or persistent temporal pattern. It is typically moderate in intensity, and patients often exhibit daily symptoms that can wax and wane in severity. Exacerbations of pain are often provoked by functional use of the affected muscles. Morning headaches may be related to nocturnal bruxism, sleep disorders, or both. Increasing pain during the day may be related to muscle use or maintenance of head posture.

**FACIAL PAIN**

Pain in the sides of the mandible and pain described by the patient as “sinus” pain in the zygomatic or orbital area may also have a musculoskeletal origin. Daytime clenching and acute or chronic stress, combined with a reduction in dental vertical dimension (height) related to loss of posterior teeth, can create muscle trigger points or muscle fatigue. This is particularly noticed by the patient after meals and reported as “a heavy and tired feeling” in the jaw muscles. Facial pain related to sinus and other pathologic conditions is discussed later in the chapter.

**EYE PAIN**

TMDs frequently include pain symptoms that involve the eye and periocular region. The pain is typically referred from other muscular sites, including the suboccipital region. Orbital pain symptoms are often described as unilateral, constant, and “boring.” This is frequently seen in patients with a history of trauma or chronic upper cervical vertebral subluxation or nerve root impingement related to the occiput and atlantoaxial region. In addition, entrapment of the greater occipital nerve at the occiput level can also produce this type of pain, which is often diagnosed as occipital neuralgia. It may frequently be amenable to physical medicine along with changes in head posture and mandibular position.

**EAR SYMPTOMS**

Pain, stuffiness, and tinnitus may have a musculoskeletal etiology. Mandibular posture related to the maxilla affects the masticatory elevator muscles. The medial pterygoids are intimately related in the left-to-right balance of the mandible on tooth closure. The tensor tympani and tensor palati are actually one muscle with a raphe that wraps around the hamular notch of the maxilla. Improper growth of the maxilla during development may affect eustachian tube function and contribute to middle ear infections in children and stuffiness and changes in ear pressure in adults.

Tinnitus and other types of sounds may also have a musculoskeletal etiology. Specifically, cervical factors and mandibular postural factors have been seen in subjects with tinnitus. A combination of physical medicine and dental mouth guard therapy has been effective in some patients with a history of trauma or childhood growth affecting proper expansion of the maxilla. Ear pain that is sharp and jabbing on movement of the mandible is frequently seen in patients with internal derangement of the TMJ. This type of pain is generally unilateral and ipsilateral to the joint in question. Ear pain and symptoms such as stuffiness in the absence of positive otologic findings are among the most common reasons for evaluation of dental- and maxillomandibular-related imbalance. Treatment can often alleviate the symptoms completely or reduce their impact on the patient in conjunction with standard medical intervention.
TEMPOROMANDIBULAR JOINT SYMPTOMS

Pain and sounds are very common with TMDs.\(^{35,36}\) The pain is typically unilateral and may be related to trauma or bruxism in the presence of missing posterior teeth; it can result in injury or anterior disk displacement without reduction and subsequent “locking” of the TMJ. Treatment often includes a combination of dental, medical, physical medicine, and mouth guard therapy plus stress management through biofeedback relaxation.

NECK PAIN

Neck stiffness and pain are commonly part of the umbrella of TMDs.\(^{37-39}\) Trauma, habitual posturing, and musculoskeletal tension will chronically affect the cervical area and create pain, stiffness, and trigger points in the muscles of the head and neck. It is well documented that the trigeminal and cervical nerve systems are interactive in the maintenance of head, neck, and jaw posture.\(^ {39,40}\) Examination of dental factors in patients with chronic neck pain is important\(^ {41,42}\) because studies examining the relationship between maxillomandibular position and the cervical spine have shown that loss of vertical dimension of the teeth and a deep bite can adversely affect cervical muscle function and lead to chronic stiffness, pain, and a reduction in range of motion.\(^ {42}\)

ARM AND BACK SYMPTOMS

Patients with TMJDs will often also have other musculoskeletal findings, including shoulder pain and pain radiating down the arm that may or may not be accompanied by tingling or numbness. Physical examination may reveal positive signs of thoracic outlet syndrome, costoclavicular syndrome, vertebral subluxation or nerve impingement of the brachial plexus of nerves, and even previously undiagnosed rotator cuff injuries.\(^ {41}\) Treatment requires a thoughtful multimodal approach to the various areas affected.

ETIOLOGY

In 1934, Costen, an otolaryngologist, evaluated 13 patients with pain in or near the ear, tinnitus, dizziness, a sensation of ear fullness, and difficulty swallowing.\(^ {43}\) He observed that these patients had many missing teeth and, as a result, their mandibles exhibited overclosure. The patients seemed to improve when their missing teeth were replaced and the proper vertical dimension of the occlusion was restored. The malocclusion and improper jaw position were perceived to be the cause of both “disturbed function of the temporomandibular joint” and the associated facial pain. Thereafter, the emphasis of treatment was on altering the affected patient’s occlusion.

More recently, advances in the understanding of joint biomechanics, neuromuscular physiology, autoimmune and musculoskeletal disorders, and pain mechanisms have resulted in changing concepts of the etiology of TMDs. These disorders are now considered multifactorial in etiology, with biologic, behavioral, environmental, social, emotional, and cognitive factors alone or in combination contributing to development of the signs and symptoms of TMDs.\(^ {15,16,44}\)

Various forms of trauma to the TMJ structures (ligaments, articular cartilage, articular disk, bone) can lead to intra-articular biochemical alterations that have been demonstrated to produce oxidative stress and the generation of free radicals. Subsequent inflammatory changes in synovial fluid with the production of a variety of pro-inflammatory cytokines can then lead to altered functioning of normal tissues and degenerative disease in the TMJ.\(^ {45-49}\)

Genetic marker studies involving catecholamine metabolism and adrenergic receptors suggest that certain genetic polymorphisms (e.g., in the catechol-O-methyl transferase [COMT] gene) might be associated with the changes seen in pain responsiveness and pain processing in patients with chronic TMDs.\(^ {50-52}\)

Differences in pain modulation between women and men with TMDs have been reported; women have been observed to demonstrate decreased thresholds to noxious stimuli and more hyperalgesia. In addition, in women with TMDs, some studies suggest that the affective component of pain may be enhanced during the low-estrogen phase of the menstrual cycle.\(^ {53-55}\)

Functional brain-imaging studies demonstrating changes in cortical circuitry support the concept that TMDs are very similar to other chronic pain disorders and may be related to abnormal pain processing in the trigeminal system.\(^ {56-58}\) In particular, muscle pain disorders appear to be associated with little, if any, abnormality of the muscles or peripheral tissues and may represent a central sensitization pain-producing process.

Finally, numerous biobehavioral studies support a connection between chronic TMDs and comorbid psychopathology (anxiety and depression disorders, post-traumatic stress disorder, and childhood physical, sexual, and psychological abuse).\(^ {59,65}\) TMDs fall into the 11th major category of the IHS classification (see Box 31.2).\(^ {1}\) The American Academy of Orofacial Pain has expanded on this IHS classification and subdivided TMDs into TMJDs and muscle disorders (Boxes 31.10 and 31.11).\(^ {15}\)
Disk derangement disorders and articular disk displacement are by far the most common TMJDs and are characterized by abnormal position of the articular disk in relation to the head of the condyle or temporal fossa. Disk displacement usually starts with the presence of a “clicking or popping” sound in the TMJ on opening and closing the mouth. Pain is typically an initial symptom as long as full function is present. Disk displacement is usually anterior or anteromedial in nature, although posterior and lateral displacement has been described in the literature. This may be related in part to the thinnest discal attachments being on the lateral pole of the condyle, as well as the medial direction of pull by the lateral pterygoid and inward direction of condylar movement during mouth opening.  

In disk displacement with reduction, a clicking sound on mouth opening and closing may be present. The term **reduction** is used to describe the misaligned disk temporarily coming back (or slipping back) to its proper interposition between the condyle and fossa during full opening (Figs. 31.1 and 31.2). On closing the mouth, the disk is again displaced as the teeth come closer together. This repetitive ongoing displacement on opening and closing produces a reciprocal noise (clicks) and is hence termed *reciprocal clicking*. This stage may actually represent a physiologic accommodative stage without any need for therapy other than discussion regarding its anatomic significance. With progression to the next stage, intermittent “locking” takes place as a result of the momentary impedance of the disk to the travel path of the condyle. This occurs as a sequela of a chronic clicking condition in subjects who tend to clench and grind their teeth at night (nocturnal parafunction) and have missing posterior teeth with subsequent overclosure of their bite. The teeth act as the doorstop for the TMJs and support the ultimate position of the TMJ on full closure. Good dental vertical dimension without shift on closure is essential in reducing the risk factors for progression (Fig. 31.3). Bite appliance therapy has been shown to be effective in relieving muscular and disk displacement problems.

Disk displacement without reduction is sometimes referred to as a “closed lock.” This suggests that the disk has been permanently displaced and the disk’s shape has been permanently changed such that it physically prevents the condyle of the mandible from translating to a full open position (Fig. 31.4). Jaw opening is limited to 22 to 25 mm, with pain and deviation of the mandible to the side of the lock. As a result, chewing capability is reduced because of pain, inflammation at the affected joint, and possible changes in the normal occlusion or “bite.” MRI of the TMJ is the “gold standard” for assessing soft tissue details of the articular.

cartilage and its displacement, whereas hard tissue CT scans are generally done to assess chronic osteoarthritic or bony changes.\textsuperscript{71,72}

TMJ dislocation is also known as open lock or condylar subluxation when the condyle translates beyond the anterior eminence of the articular fossa with subsequent trapping in this open-mouth position. Chronic hypertranslation can usually be managed by the subject physically manipulating the jaw. If the condition is chronic, the subject knows to relax the jaw-closing muscles and slip the condyle back into position. The most common subluxation occurs during yawning or opening the mouth widely. If the problem is related to trauma or to sudden acute translation, the subluxation is considered to be an acute dislocation and requires medical intervention in which the muscles are relaxed by anesthetics or analgesics followed by manual manipulation of the joint with a downward and backward motion. Follow-up with anti-inflammatory medication, ice, and rest or a dental appliance may be necessary until the acute stage subsides.\textsuperscript{73}

Inflammatory disorders, including capsulitis and synovitis, are relatively common in the TMJ secondary to macrotrauma or microtrauma, irritation, or infection. These disorders may be manifested as pain on function and inflammation with extreme tenderness on palpation of the TMJ. MRI may show effusions on the T2-weighted signal and an inability to completely bring the teeth together accompanied by pain in the ear. Joint inflammation may also be a result of polyarthitis of systemic origin, which is generally secondary to connective tissue diseases.

**OSTEOARTHRITIS (NONINFLAMMATORY)**

Primary osteoarthritis is a degenerative condition of the joints characterized by hard tissue abrasion and degradation of the articular surface of the condyle related to overload. It is frequently seen in patients with a long history of missing teeth or maloccluded dentures. This process is generally slow, is not associated with symptoms of pain during the early stages, and may remain relatively benign over the life of the individual. Primary osteoarthritis is usually identified by radiographic screening of hard tissue (e.g., dental panoramic image), a tomograph or dental CT scan, or the presence of grating (crepitus) noises in the joint during movement (Figs. 31.5 and 31.6).

Secondary osteoarthritis is usually identified by a history of a single previous event such as trauma or infection or may result from rheumatoid arthritis. An idiopathic degenerative condition primarily affecting adolescent girls is termed condylysis. It involves sudden lysis of the condyle that creates a rapid change in the bite of the individual with a shift of the jaw and resultant open bite that is notable by the subject. The etiology of condylysis is not clear, but it has been known to be associated with rheumatoid arthritis in young girls.\textsuperscript{47,48,73}

Ankylosis is usually related to trauma to the joint with subsequent bleeding and restricted mandibular movement; the ankylosis may be fibrous or bony in nature. Fibrous ankylosis generally occurs in the upper joint compartment as a result of adhesions forming after joint bleeding and prolonged immobility. Limited jaw opening (usually one to two fingers placed horizontally between the central incisors) is typically present. Bony ankylosis has no movement associated with it. Both conditions may require surgical release followed by postsurgical mobilization techniques.

**FRACTURE**

Trauma to any part of the face may result in bony fractures of the condylar neck, condylar head, body of the mandible, and maxilla and temporal fossa and may result in a reduction in opening, pain, and fibrosis of the bony ankylosis if untreated. Uncomplicated (nondisplaced) fractures require no immediate treatment as long as function is not compromised.

**COMMON CLINICAL MUSCLE DISORDERS**

**LOCALIZED MYALGIA**

Masticatory muscle injury can occur as a result of acute muscle strain or direct trauma. Soft tissue injury results in bleeding, inflammation, and swelling, which causes myalgia, muscle spasm, muscle splinting, or myositis.\textsuperscript{74} Myofascial trigger points may develop in many locations within the
Injury results in a deep sharp ache on contraction of the muscle. Depending on the area of injury, the pain may emanate from the tendon attachments (tendonitis), fascial component (myofascitis), or body of the muscle (myospasm and myositis). The temporalis tendon attachment to the coronoid process is the most frequent site of masticatory tendonitis. In the presence of acute or chronic internal derangement of the TMJ complex, the muscles that support and move the joints can be secondarily affected. Protective muscle splinting is used to prevent further injury to the joint. Immobilization of the injured joint is frequently seen with anterior disk displacement without reduction (closed lock). Splinting of the masticatory elevator muscles is maintained until the joint is healed.

Myalgia secondary to injury to the cervical spine can affect the masticatory muscles and result in headaches and facial pain. Once the masticatory muscles are secondarily involved, they affect mandibular position. Mandibular dysfunction results from masticatory muscle involvement and in tightening of the muscles of the cervical spine, thereby perpetuating the cycle. Consequently, a significant proportion of TMD patients also have a history of cervical injury, and treatment of this craniofacial and cervical syndrome requires that both the jaw and neck be treated in a multidisciplinary manner.

Muscle disorders may occur secondary to rotation, fixation, fusion, or injury to or locking of the facets of the cervical, thoracic, lumbar, and sacral vertebrae. The history, physical examination, and radiographic evaluation will elucidate the acuteness and severity of the vertebral problem. Disk herniations can secondarily affect the cervical muscles through protective splinting, which may eventually
lead to chronic postural changes. Nerve impingement and nerve root injuries can also affect muscle function. Cervical problems are frequent comorbid conditions seen in TMD patients. A reduction in the space between the posterior spine of the atlas and the base of the occiput may cause pain by compression of suboccipital tissues. The pain will be perceived as a headache starting from the back of the head.

**ORAL PARAFUNCTION**

Oral parafunction includes bruxism, clenching, lip biting, thumb sucking, and any other oral habit not associated with mastication, deglutition, and speech. Bruxism and clenching are the most common of the parafunctional activities and have a prevalence of up to 90% in the general population. In most patients, parafunction occurs in a milder intermittent form and does not require treatment. Whether moderate or severe, bruxism and clenching can damage oral structures and cause wear of the teeth, breakdown of the periodontium in the presence of inflammation, and internal derangement and muscular dysfunction.

Studies on bruxism and clenching have reported excessive force occurring for extended periods (normal tooth contact during a 24-hour period is about 20 minutes and takes place during chewing and swallowing). Parafun-ctional forces exceed normal masticatory forces, with the resultant force vector being primarily horizontal. Under such conditions, damage is likely to occur to the teeth and periodontium (Figs. 31.7 and 31.8). Ironically, most treatments are designed to protect the occlusion in function rather than in parafunction. The detrimental effects of parafunction will cause breakdown of the weakest structure, which may include the teeth, periodontium, TMJ, or muscles. The patient can therefore have both tooth and joint pathology.

Bruxism and clenching have been explained historically by theories of occlusion but have yet to be substantiated by research. Nocturnal bruxism is currently classified as a sleep disorder, the duration and intensity of which vary nightly depending on emotional stress and activities of the individual before sleep. Sleep studies have shown that bruxism occurs during body movement and the rapid eye movement stage of sleep and during the transition from a deeper to a lighter stage of sleep.

Numerous studies have been done on the personality characteristics of “bruxers.” People who clench and grind their teeth have been shown to exhibit higher degrees of anxiety, aggressiveness, and hostility. The conclusions of these and other studies have confirmed an emotional etiology of diurnal (daytime) parafunction, which includes lip biting, nail biting, thumb sucking, clenching, and habitual bruxism. The pathologic effects are the same as those for nocturnal parafunction.

**MYOFASCIAL PAIN DISORDER AND MUSCLE TRIGGER POINTS**

A myofascial trigger point is defined as a hyperirritable locus within a taut band of skeletal muscle that is located in muscular tissue or in its associated fascia or tendon. The spot is painful on compression and can evoke characteristic referred pain and autonomic phenomena. Numerous studies have confirmed an emotional etiology of diurnal (daytime) parafunction, which includes lip biting, nail biting, thumb sucking, clenching, and habitual bruxism. The pathologic effects are the same as those for nocturnal parafunction.

- Local tenderness over the trigger point
- Referred pain, tenderness, and autonomic phenomena
- Palpable taut band associated with the trigger points
- A local twitch response of a trigger point that is usually present in a palpable taut band
- Perpetuation of trigger points
- A therapeutic effect when stretching a muscle with trigger points
- Weakness and fatigability of muscles afflicted by trigger points
Myofascial pain often refers pain to the head and neck and is considered by some to constitute tension-type headaches. Myofascial pain and trigger points of the masticatory muscles can send pain to the eyes, ears, TMJ, and teeth, depending on the specific muscles. The pain is usually a dull or intense ache that varies but is strongly related to posture or muscle activity and can generally be localized by the patient on a diagrammatic representation of the body. The muscles of posture and mastication are commonly affected by trigger points. The pain may occur in the same dermatome, myotome, or sclerotome. Satellite trigger points may occur within the pain reference zone. Clinically, there is restricted movement with pain on passive stretching, and strong contraction will dramatically increase the pain. Resistive testing reveals weakness as a result of protective splinting.

Trigger points are palpated by rubbing the fingertip lightly along the long axis of the muscle. If present, a taut band will produce a local twitch response, which confirms the presence of the trigger point. Final confirmation is achieved with reproduction of the patient’s pain by digital pressure.76

Treatment of myofascial trigger points includes spraying the involved muscle with ethyl chloride or fluoromethane followed by stretching, hot compresses, and range-of-motion exercises. Trigger point injections of procaine (0.5% solution in saline) or lidocaine (2% without epinephrine) have also been used commonly (Fig. 31.9), along with botulinum toxin (Botox) more recently. Other techniques involve ischemic compression for 30 to 60 seconds and acupressure. Pharmacological treatments include analgesics, muscle relaxants, antidepressants, and NSAIDs. Physical therapy modalities such as myofascial release and craniosacral techniques, including postural correction and exercise, have also been effective in the management of myofascial trigger points. Stress, nutritional, and hormonal factors should also be addressed (Fig. 31.10).86

In the case of the masticatory muscles, occlusal appliances may be used.88 Dental guards or appliances have been found to be effective in reducing muscle symptoms and trigger points in mandibular elevators.

Figure 31.9  Trigger point injection for a trigger point of the masseter.
• The pain may be provoked by light touch on the face (trigger zones).

These criteria were incorporated, largely unchanged, into the official research diagnostic criteria published by the International Association for the Study of Pain and the IHS (see Box 31.3). TN appears to result from a chronic partial injury to the trigeminal sensory nerve root as it enters the brainstem. Consistent with this view is the presence of a separate disease process affecting the trigeminal nerve roots in 5% to 10% of patients with TN symptoms. This is generally multiple sclerosis or a benign tumor (schwannoma, meningioma) in the cerebellomedullary angle. These cases are usually termed symptomatic...
trigeminal neuralgia. In the remaining majority of TN cases, imaging studies and laboratory tests are negative. These cases are usually termed idiopathic trigeminal neuralgia. Despite the idiopathic label, increasing evidence documents that subtle forms of chronic nerve root injury (such as compression by a vascular loop) produce trigeminal root irritation in these cases.

In summary, the diagnosis of TN is based on a clinical history consistent with widely accepted, specific diagnostic criteria (Table 31.5). For patients that meet the criteria, a careful physical examination and cranial imaging studies are also essential to differentiate primary from symptomatic TN.

### Clinical Management

Both medical and surgical treatments are available to manage the severe pain attacks of TN. The present authors use a diagnostic and management algorithm for TN (Fig. 31.11). The patients should initially undergo a trial of medical therapy with an antiepileptic drug (AED) (Boxes 31.12 and 31.13). A series of clinical trials over the past 50 years have demonstrated that oral AEDs are effective for TN, with gabapentin, baclofen, or carbamazepine being the initial drug of choice. The AED dosage should be increased progressively to therapeutic "anticonvulsant" levels. Single-drug AED therapy provides substantial relief from the recurrent attacks of facial pain in the large majority of TN patients. If a patient does not respond to single-AED therapy, adding a second AED may increase the chance for a therapeutic response. Lack of response of the patient to AEDs warrants a search for other causes of the patient’s pain.

![Figure 31.11 Algorithm for the evaluation and management of trigeminal neuralgia (TN). AED, antiepileptic drug.](image-url)
Nonetheless, the clinical problem of atypical TN is a real set of TN patients who could be examined more closely. The term does not identify a meaningful subset, but the general diagnosis of atypical TN seems misleading since the symptoms of PTN respond poorly, if at all, to the AEDs or surgical therapies commonly used for TN. The general approach to the clinical management of PTN is similar to that for other forms of neuropathic pain and is discussed in Chapter 24.

### CONCLUSION

Pain syndromes that involve the face are very common in clinical practice. Many facial pain syndromes are also unique given the complex anatomy and specialized sensory innervation of the head, face, and neck. These syndromes represent a clinical diagnostic challenge and deserve special attention. The common descriptive terms for facial pain complaints are frequently misleading. Clinicians should be comfortable distinguishing painful conditions that arise from structural pathology, headache syndromes, oral and facial structures, TMJds, MPDs, and primary cranial neuralgias.

### KEY POINTS

- Pain syndromes that involve the face, head, and neck are very common in clinical practice. These syndromes are often unique and deserving of special attention.
- The common descriptive terms for cranial pain symptoms are frequently misleading. To avoid confusion, pain clinicians should be familiar with the International Headache Society’s diagnostic criteria for headache syndromes, myofascial pain disorders, and primary cranial neuralgias.
- Clinicians should be familiar with the clinically relevant features of craniofacial anatomy and the distinctive neurobiology of pain transmission in this region.
- Chronic/recurrent pain syndromes are extremely common in the head and neck, and myofascial pain

### ATYPICAL TRIGEMINAL NEURALGIA

Many authors use the diagnosis “atypical TN” to describe cases in which the clinical findings do not fully meet the standard diagnostic criteria for TN. However, there is general agreement that patients with atypical TN are less responsive to AEDs and surgical intervention than are patients with “standard” TN. It is reasonable to assume that the TN is probably neither homogeneous nor unique, but the general diagnosis of atypical TN seems misleading since the term does not identify a meaningful subset of TN patients who could be examined more closely. Nonetheless, the clinical problem of atypical TN is a real one because patients with complex facial pain disorders often have a spectrum of symptoms, some of which may be quite similar to the TN criteria.

### BOX 31.12 Anticonvulsants

- Phenytoin (Dilantin)
- Carbamazepine (Tegretol)
- Baclofen (Lioresal)*
- Clonazepam (Klonopin)
- Gabapentin (Neurontin)
- Lamotrigine (Lamictal)
- Topiramate (Topamax)
- Oxcarbazepine (Trileptal)
- Tiagabine (Gabitril)
- Levetiracetam (Keppra)
- Zonisamide (Zonegran)
- Pregabalin (Lyrica)

### BOX 31.13 Pharmacological Effect and Mechanism of Pain Relief

- CBZ: Na channel
- OXC
- CLO: GABA
- BAC: GABA_A
- GBP: Na, Ca channel
- LTG: Na channel, inhibit GLU
- TOP: Na channel, GABA, AMPA
- TGB: GABA RI
- Suppress spontaneous ectopic neuronal activity
- Reduce neuronal hypersensitivity
- Segmental inhibition of signaling

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; BAC, baclofen; CBZ, carbamazepine; CLO, clonazepam; GABA, γ-aminobutyric acid; GBP, gabapentin; GLU, glutamate; LTG, lamotrigine; Na, sodium; OXC, oxcarbazepine; TGB, tiagabine; TOP, topiramate.
KEY POINTS—cont’d

disorders are among the most common causes of pain and dysfunction in this group. Myofascial syndromes overlap with several common diagnoses, including temporomandibular joint myofascial pain dysfunction syndrome, tension headache, and most cases of occipital neuralgia. Clinicians should be aware of the diagnostic features, potential causes, and exacerbating factors for such disorders. They should also understand how these factors are associated with the various multidisciplinary options currently recommended for treatment.

• Clinicians should be aware of the unique anatomy and physiology of the temporomandibular joint and how jaw position and dental occlusion can contribute to myofascial pain symptoms.
• Bruxism and sleep disorders are common contributors to craniofacial pain that occurs in the morning.
• Bite appliances in conjunction with stress management and physical therapy may be a viable treatment option for patients with craniofacial and myofascial pain.
• Trigeminal neuralgia is a unique neurogenic disorder. Patients who meet the clinical diagnostic criteria for trigeminal neuralgia may benefit substantially from anticonvulsant drugs or surgical therapy. Patients with other forms of neurogenic facial pain have a poorer prognosis.

Chronic visceral pain is very common. Abdominal pain is among the main reasons for physician visits, with more than 12 million consultations occurring each year in the United States.1 Patients with visceral pain present unique challenges because the pain is often poorly localized and is associated with strong autonomic reactions and changes in visceral function. Pain management, in turn, may further alter visceral function, with opioid effects on the gastrointestinal tract providing a good example. These unintended treatment effects on visceral function can exacerbate the pain or lead to additional discomfort, thus showing that rational and effective pain management needs to be based on an understanding of the anatomic and physiologic basis of visceral function and pain.

**Physiologic Basis of Visceral Sensation and Pain**

**Anatomy and Physiology of Visceral Afferent Pathways**

Most viscera arise from midline structures and thus receive bilateral innervation. As a result, visceral stimuli activate both hemispheres of the brain, with a predominance of the left side in most right-handed individuals. In addition, organs in the chest cavity and most viscera within the abdomen receive dual afferent innervation, with vagal and spinal nerves conveying sensory input to the central nervous system (Fig. 32.1). Although vagal fibers do not reach the pelvic organs, the distal part of the colon, bladder, prostate, and uterus also have a complex sensory innervation, withafferents projecting through the thoracolumbar (hypogastric) and lumbosacral (pelvic) nerves to the spinal cord.

The vagus nerve is predominantly composed of afferent fibers (≥80%) that project via the nodose and jugular ganglia to the nucleus of the solitary tract in the brainstem. Spinal afferents pass through prevertebral (sympathetic) ganglia to reach the spinal cord. In addition, postsynaptic dorsal horn neurons within the central gray send their central processes through the spinal cord, a pathway that has only recently been recognized as being uniquely important in visceral pain.4

Most physiologic studies characterizing the properties of visceral sensory pathways rely on responses to defined mechanical stimuli. Vagal afferents form a relatively homogeneous group that is activated by low-intensity mechanical stimuli and encodes stimulus intensity over a wide range. The low threshold of activation is consistent with the presumed role of these sensory pathways in the regulation of physiologic processes. In contrast, two classes of mechanosensitive spinal afferents can be distinguished by their response characteristics: low-threshold fibers are similarly activated by low-intensity stimuli and continue to encode stimulus intensity over a wide range, whereas high-threshold fibers are activated by intense, potentially noxious intensities of mechanical stimuli. Thus, spinal high-threshold fibers resemble specialized nociceptors that have been described and characterized best in the skin, thus suggesting that they play a primary role in visceral nociception. However, because mechanosensitive visceral afferents encode stimulus intensity over a wide range and can become sensitized after a visceral insult, it is likely that both low- and high-threshold mechanosensitive afferents can contribute to visceral pain conditions. Finally, most visceral sensory neurons are polymodal, which means that they respond to multiple stimulus modalities, including endogenous and exogenous chemicals contained in luminal contents, temperature (heat or cold), and stretch.

**Mucosal Signaling and Visceral Sensation**

In the airways, gastrointestinal tract, and urinary bladder, nerve fibers are found in close proximity to epithelial cells, which often exhibit specializations consisting of secretory vesicles on the basal surface. This structural organization and functional studies suggest that vesicles in the nervous system. The best example is serotonin released from enteroendocrine cells in the gastrointestinal tract. The gut is the major source of this signaling molecule and contains 95% of the body’s serotonin. Much of this serotonin is stored in specialized enteroendocrine (enterochromaffin) cells and can be released by chemical or mechanical stimuli to activate intrinsic and extrinsic neurons. Within the urinary tract, epithelial cells release adenosine triphosphate, which acts on purinergic receptors (P2X receptors) and is involved in normal micturition, as well as in bladder pain. Finally, bladder epithelial cells also express the capsacin receptor transient receptor potential vanilloid-1 (TRPV1), an ion channel that is activated by acid, temperature, endogenous lipid mediators, and the pungent substance (capsaicin) contained in hot peppers. Animals with a targeted deletion of this channel display altered micturition behavior, again pointing to the importance of epithelial cells in visceral sensation.
SENSITIZATION OF VISCERAL AFFERENT PATHWAYS

Visceral afferents can become sensitized in response to inflammation or injury. The release of mediators, such as prostaglandins or bradykinin, rapidly alters the properties of ion channels and thereby leads to an increase in neuron excitability. In addition, cytokines and growth factors may trigger transcriptional changes that affect the properties of sensory neurons through changes in gene expression. The increased peripheral input (peripheral sensitization) may secondarily alter sensory processing in the central nervous system (central sensitization), with both contributing to visceral pain syndromes. One easily recognized consequence of sensitization of visceral afferent pathways is increased tenderness to palpation over a larger area than normal. Both peripheral and central mechanisms contribute to the increased sensitivity and expanded areas of referral, both of which are common in patients with irritable bowel syndrome, dyspepsia, and interstitial cystitis.

CENTRAL PROCESSING OF VISCERAL SENSATION AND PAIN

Vagal afferents project to the nucleus of the solitary tract and from there via the parabrachial nucleus and ventromedial thalamus to the insular cortex. They form many connections with the hypothalamus, supraoptic nucleus, anterior cingulate cortex, and amygdala, which is essential for autonomic and emotional responses to visceral stimulation. Spinal afferents also project to the thalamus but are preferentially found in the ventral posterolateral nucleus, which is connected to cortical areas, including the insula. The lateral components primarily serve discriminative functions associated with pain perception (e.g., location and intensity), whereas the medial thalamic nuclei, the main target of vagal input, are more closely linked to the emotional and autonomic responses triggered by pain. Consistent with the bilateral innervation of organs originating from midline structures, most visceral stimuli activate both cerebral hemispheres, albeit with a preferential activation of one—mostly the left—side. Studies using functional brain imaging have not demonstrated striking differences in the processing of visceral and nonvisceral pain. However, visceral pain preferentially activates the perigenual portion of the anterior cingulate cortex, whereas nonvisceral pain is primarily represented in the midcingulate cortex. The physical proximity or even overlap between processing of visceral pain and emotion in the perigenual portion of the anterior cingulate cortex provides a potential explanation for the stronger emotional response to painful visceral than to nonvisceral stimuli.

VISCERAL PAIN STIMULI

Visceral events that can produce conscious sensation or acute pain in humans include traction on the mesentery, distention of hollow organs, strong contractions of muscle layers surrounding such hollow organs, ischemia, and chemical irritants. Routine endoscopic interventions have established that cutting or burning—two clearly nocuous stimuli when applied to the skin—are not perceived when applied to viscera, thus setting visceral apart from nonvisceral sensation. Because of its sensitizing influences on sensory pathways, visceral inflammation can trigger pain or increase the excitability of visceral afferent pathways (e.g., enhancing low-threshold input into a noxious range), which can become chronic (e.g., chronic pancreatitis). Finally, though not studied in as much detail, malignancies can trigger chronic pain as a result of direct effects of the tumor on afferent nerves (e.g., nerve compression, release of chemicals) or as a result of indirect effects such as distention of a hollow organ.
is comparable to that achieved with conventional analgesic therapy but may be associated with fewer side effects.\textsuperscript{29}

**CELIAC PLEXUS AND SPLENCHIC NERVE BLOCK**

Spinal afferents innervating organs in the upper part of the abdomen traverse the celiac plexus, with two distinct ganglia located caudal to the origin of the celiac artery. The afferents travel centrally behind the crura of the diaphragm in the splanchnic nerves. The traditional dorsal approach uses the 12th rib and spinal process of the first lumbar vertebra as landmarks.\textsuperscript{30,31} With the patient in the prone position, a needle is advanced about 7 cm lateral to the midline at a 30- to 45-degree angle and tilted slightly cranially to reach the lateral wall of the body of the first lumbar vertebra. The needle is then moved anteriorly by about 2 cm. If aspiration does not yield return of blood, water-soluble contrast material (3 to 5 mL), often mixed with a local anesthetic, is injected under fluoroscopic control. To better directly target the celiac plexus, the needle can be placed about 2 cm more anterior, which requires piercing the diaphragmatic crura and positions the needle close to the anterolateral aspect of the aorta. Severely ill patients with respiratory compromise and patients with significant ascites or recent abdominal surgery often poorly tolerate being in the prone position for the time required to complete this procedure. Therefore, an anterior approach has been developed in which the needle is advanced from the epigastric area toward the body of the first lumbar vertebra. If the appropriate position is confirmed, the neurolytic agent, generally phenol or ethanol, is administered. Current approaches rely mostly on the tissue destructive properties of ethanol, which is used in concentrations between 50\% and 99\% and volumes between 20 and 50 mL per injection. Injections are generally performed bilaterally to effectively destroy the afferent pathways. A recent report suggested that radiofrequency ablation may provide an alternative to chemical neurolysis.\textsuperscript{32} Although this approach has since been adopted by others, well-designed studies on visceral pain syndromes are still missing.

Various imaging techniques have been used with the intent of improving the efficacy of neurolysis and decreasing the potential for adverse effects. The celiac ganglia are too small to allow direct visualization with CT or transabdominal ultrasound. Using endoscopic ultrasonography, the scanner can be brought into close proximity to the plexus. However, the ganglia do not differ in echogenicity from surrounding structures, thus again not allowing direct imaging of the target structure. Therefore, all these approaches rely on identifying the celiac artery as the main landmark. CT allows guidance of the needle to the target area and three-dimensional reconstruction of the area affected by the neurolytic agent based on the spread of radioopaque contrast material.\textsuperscript{33} Although ultrasound allows real-time guidance without exposure to radiation, air in the overlying structures often interferes with sound penetration and imaging, thus limiting its utility in patients undergoing celiac plexus block.\textsuperscript{34} Endoscopic ultrasound with an endoscopically advanced needle has been used successfully. Close inspection may identify tumor infiltration as a negative prognostic criterion and hence help in appropriate patient selection.\textsuperscript{35} In addition, ethanol injection alters the echogenicity of the affected tissue, thus allowing direct visualization of spread of

**CLINICAL IMPLICATIONS**

Current evidence suggests that spinal afferents primarily serve the discriminatory function of nociception, encoding location and intensity of visceral pain. Thus, treatment strategies, such as regional block or surgical dissection, generally target spinal afferent pathways.

Unilateral nerve blocks are often ineffective, which is partly due to the fact that most viscera receive bilateral innervation and are innervated by two sets of nerves.

Visceral pain is a complex experience associated with strong emotional and autonomic reactions. The emotive component of visceral pain is at least in part due to the central projections of spinal and vagal sensory pathways, both of which can activate the perigenual area of the anterior cingulate cortex, an area closely associated with emotional processing. The complex innervation of most viscera by spinal and vagal afferent pathways provides an explanation for the often only partial or temporary effects of regional blocks.

Impaired function of viscera, such as decreased transit of material in the gut, may significantly contribute to pain due to distension or strong contractions of visceral muscles or the composition of luminal contents. Thus, effective pain management needs to combine analgesic therapies with treatment strategies targeting specific visceral function.

**REGIONAL BLOCK AND NEURAL ABLATION**

Surgical and nonoperative approaches have been developed to perform transient nerve blocks or more permanently destroy the sensory pathways involved in visceral pain. In view of concerns about the irreversible nature of nerve ablation or neurolysis, most studies targeting visceral sensory pathways have involved patients with inoperable cancer and a relatively short life expectancy. Because these patients are typically seen in advanced stages of their disease with poor performance status, surgical denervation plays only a minor role in treatment. Chemical neurolysis, generally performed with high concentrations of ethanol, can achieve comparable results without subjecting patients to the risk associated with an operation. Since the first description by Kappis nearly 100 years ago,\textsuperscript{23} several techniques have been developed to optimize the targeted delivery of neurolytic agents or minimize the likelihood of adverse effects, or both. Most of these approaches use imaging methods, such as fluoroscopy, ultrasound, or computed tomography (CT). However, despite this wealth of literature, few systematic studies have addressed the efficacy, outcomes, or adverse effects of these interventions. Problems assessing the effects of visceral pain management with peripheral blocks are further confounded by differences in type, concentration, and amount of the neurolytic agent, primarily ethanol; differences in both definition and measurement end points; and differences in follow-up time. Only five randomized controlled trials comparing ablative therapies with conventional pharmacologic pain management have been published.\textsuperscript{34-38} All but one of them showed at least transiently improved pain levels and a concomitant decrease in opioid use. A recently conducted meta-analysis concluded that at least for pancreatic cancer, the pain relief achieved with neurolytic blocks
the neurolytic agent. Only one trial directly compared the endoscopic and conventional transcutaneous approaches for celiac plexus block, and it suggested superiority of the endoscopic approach.

**SURGICAL NERVE ABLATION**

One randomized controlled trial and several small case series have used surgical approaches to ablate the celiac ganglia or splanchnic nerves. The direct visualization during surgical exploration allows targeted injection of neurolytic agents into the celiac plexus if curative resection cannot be performed. Because of advances in preoperative imaging, fewer patients currently undergo exploratory laparotomy, thus limiting the number of patients in whom an intraoperative celiac plexus block might be performed. With the advent of minimally invasive surgery, thoracoscopic resection of splanchnic nerves has been reported. As is true for the less invasive procedures, approaches have not been standardized, with unilateral and bilateral resection with or without vagotomy being performed to achieve pain control in these patients.

**EFFICACY OF NEURAL BLOCK ANDABLATION**

Differences in patient selection, techniques, and outcome measures complicate comparison of published results. A meta-analysis published in 1995 concluded that nearly 90% of patients with various malignancies experienced good pain relief for about 3 months after the procedure. Even though most case series report similar results, it is important to determine whether ablative therapy actually improves pain control or quality of life (or both) over that of conventional treatment involving the systemic use of analgesic substances. Two small randomized controlled trials demonstrated similar pain control but fewer adverse effects as a result of opioid consumption in patients treated with neuropathic blocks. Subsequent studies have pointed to a slight advantage of ablative treatment over pharmacotherapy. Intraoperative celiac plexus block with 50% ethanol led to stable pain levels in patients with inoperable pancreatic cancer, whereas patients receiving saline injection as control experienced a significant increase in pain scores during follow-up. This improvement in pain control was associated with significantly lower use of opioids. In a post hoc analysis, patients with significant pain lived longer than controls if they underwent celiac plexus block. However, there was no overall survival benefit when the comparison involved use of the original study design as a template for the analysis. Three subsequent trials comparing neurolytic celiac plexus block with analgesic therapy confirmed better pain relief after ablative therapy. In two studies, the improvement was transient, with progressive recurrence of pain after about 1 to 2 months. Most patients still required opioids, albeit in lower dosages than needed by controls in the two smaller studies. A recent study by Wong and coworkers did not confirm this decrease in opioid consumption. Consistent with the results shown by Kawamata and colleagues, their results also demonstrated that appropriate dosing of opioids achieves good pain control and a comparable quality of life that does not differ between treatment groups. None of these investigations demonstrated a significant effect of neurolytic plexus block on patient survival.

Because cancer progression may affect the efficacy of ablative procedures, one small study randomly enrolled patients to receive early or late neurolytic blocks, with stages being defined by the use of low or high dosages of opioids, respectively. Although both groups reported better pain control than medically treated controls did, there were no significant differences between the groups.

A randomized controlled trial reported better pain control after bilateral splanchnic nerve block than after celiac plexus blockade. This assessment was based on a more significant decrease in pain intensity from baseline scores rather than a difference in the primary end point—pain measured by visual analog scale. Thus, confirmatory studies are needed to establish whether splanchnic nerve destruction is indeed superior to neurolysis of the celiac plexus. De Cicco and associates used CT scanning to examine the spread of contrast material injected before the neurolytic agent. In their retrospective study, the pattern was a good predictor of pain control, with optimal results being achieved in patients in whom the contrast agent spread bilaterally above and below the origin of the celiac artery. However, case series using CT guidance do not report better response rates than when the conventional approach is used.

Similarly, the results of surgical interventions with neurolytic or neuroablative therapy remain inconclusive. Although the only randomized controlled trial demonstrated good pain relief and a decrease in opioid consumption, a case series evaluating different palliative operations for pancreatic cancer did not confirm the decrease in opioid use after celiac plexus block. Smaller case series report improved pain control in about 60% to 80% of patients after thoracoscopic splanchnic colectomy performed unilaterally or bilaterally with or without vagotomy. Poor definition of end points, limited assessment of analgesic effects, lack of appropriate control groups, and the fact that comparable results were obtained with a variety of often quite different approaches clearly demonstrate the need for appropriately designed studies. Splanchnicectomy reduces opioid requirements in comparison to systemic pharmacotherapy, but not in comparison to celiac plexus block. Overall, the current data suggest acceptable pain relief with at least a transient decrease in opioid requirements but do not support the superiority of one ablative approach over another. Thus, the choice that patients and physicians face should primarily focus on the available expertise when selecting one technique over another.

**NERVE BLOCK OR ABLATIVE THERAPY FOR BENIGN DISORDERS**

As described earlier, the pain relief after a neurolytic block is often transient, which decreases the enthusiasm to use such approaches in patients with benign disorders and long life expectancy. Therefore, less information is available about the efficacy of nerve blocks in such patients. Several case series combining about 400 patients with chronic pancreatitis have been published, thus making this the largest patient group with benign diseases. Initial response rates
varied between 30% and 90%, with limited follow-up in the majority of cases. Because of concerns about the use of neurolytic agents, the largest series combined bupivacaine with triamcinolone. Although about half the patients reported an initial benefit, sustained responses after 24 weeks were seen in only 10%. Though commonly practiced, a recently completed randomized controlled trial showed no additional benefit of triamcinolone, with response rates of about 15% 1 month after celiac plexus block with bupivacaine.67 Moore and coauthors reported the results of stellate ganglion and paravertebral blocks with bupivacaine in 59 patients with refractory angina, a thoracic visceral pain, secondary to coronary artery disease. About 60% of the patients experienced pain relief for more than 2 weeks. However, the benefit was transient and most patients required multiple interventions to maintain some benefit. Interestingly, the limited experience with differential neural blocks suggests that primary visceral pain was present only in about a fifth of patients with chronic pancreatitis, with the majority experiencing “central pain,” defined as persistent pain despite surgical anesthesia through the epidural administration of lidocaine. Overall, the data highlight the complex etiology of chronic pain syndromes in patients with benign disorders and do not support the routine use of ablative therapies in these patients.

**ADVERSE EFFECTS OF NEUROLYTIC BLOCKS**

Transient pain is the most common side effect reported when ethanol is used as the neurolytic agent. Although the use of local anesthetic before the ethanol injection decreases the incidence of this adverse effect, at least 10% to 30% of patients experience significant pain within the first hours after the procedure. The destruction of sympathetic efferent pathways causes vasodilation of the splanchic vessels, which results in hypotension in up to 20% of patients. Similarly, the unopposed parasympathetic drive can lead to diarrhea, which again is reported by about a fifth of patients. All these problems can generally be managed medically with appropriate premedication, hydration, postprocedural observation, and appropriate symptomatic therapy. More significant adverse effects are rare but have been reported for all the different approaches.

The posterior approach may traverse the kidney, as well as the pleural space, thereby potentially leading to hematuria or pneumothorax. The anterior approach requires advancing the needle through the liver, stomach, and colon. Although this is largely inconsequential, clinically relevant perforation can occur and may be difficult to diagnose because of the neurolytic block and often concomitantly administered analgesia. Therefore, all patients should be well hydrated, receive an intravenous fluid bolus before performance of the nerve block, and remain under observation for at least 2 to 4 hours after the procedure. Delivery of neurolytic agents in close proximity to major vessels is another potential source of complications. In all cases, aspiration should ensure that the needle is not inside a vessel before the neurolytic agent is injected. However, indirect effects, such as mesenteric venous thrombosis, may occur rarely despite these precautions. Spread of the neurolytic agent within the retroperitoneal space with injury to the lumbar nerves has been reported. Paraparesis is the most feared and mostly irreversible complication that is thought to be caused by injury to the nutrient vessels supplying the spinal cord. Even though sufficiently powered studies addressing the likelihood of these adverse effects are not available, current evidence suggests that the incidence does not differ between the different approaches.

**CLINICAL IMPLICATIONS**

Neurolytic celiac or splanchnic nerve block is a moderately effective method to decrease pain in patients with intra-abdominal malignancies, and has been best studied in patients with pancreatic cancer. The benefit is often transient, and may decrease the need for opioids, but does not affect life expectancy or quality of life compared to conventional pain management. Adverse effects occur in about 20% of patients, are largely minor and transient and can be managed by appropriate medical therapy. Approaches using different imaging techniques or even direct operative visualization do not seem to affect outcome or the incidence of side effects.

**EPIDURAL ANALGESIA AND VISCERAL PAIN**

Epidural block or pharmacotherapy and surgical myelotomy can be performed to treat chronic visceral pain syndromes. Two aspects unique to visceral pain syndromes warrant some specific discussion of spinal treatment targets. First, preliminary studies suggest that patients with ischemic heart disease may derive significant benefit from epidural blocks. Second, unlike nonvisceral pain, which is primarily relayed to supraspinal sites via the spinothalamic tract, functional and neuroanatomic studies have convincingly demonstrated that a dorsal column ascending pathway plays an important role in visceral pain. Only few studies have systematically evaluated the clinical efficacy of these approaches over long periods, thus limiting the ability to fully assess their therapeutically.
with epidural drug delivery, which is addressed in more detail in Chapters 18 and 43.69-71

**SPINAL CORD STIMULATION AND VISCERAL PAIN**

Recently, several case reports described significant improvement in severe visceral pain with spinal cord stimulation. The largest series compiled data from a total of 70 patients with refractory thoracic, abdominal, or pelvic pain syndromes.72 Less than 10% did not respond to the temporarily implanted electrodes; responders were offered a permanent device, which was surgically implanted and led to maintenance of improvement with lower opioid requirements in the majority of patients. Though promising, no prospectively designed trial has been published, and assessment of long-term results was based on physician rather than patient reporting.

**MYELOTOMY AND VISCERAL PAIN**

Since its introduction about 20 years ago, midline myelotomy has been used to treat patients with refractory pain from visceral malignancies.73 The nature of this intervention as a “rescue” treatment in patients who failed other therapies limits the ability to judge its clinical efficacy. No randomized controlled trials have determined its efficacy or adverse effects in comparison to optimized standard treatment. Case series are typically limited to patients with advanced malignancies and have reported improved pain control in about 60% of patients, with symptoms recurring in up to half of the patients.74-76

**CLINICAL IMPLICATIONS**

While systematic studies have not specifically addressed the efficacy of epidural drug delivery in patients with chronic visceral pain syndromes, currently available data support its use in patients with refractory pain due to ischemic heart disease. Initial data on spinal cord stimulation are promising, but require confirmation through well-designed prospective trials. As is true for all ablative therapies, midline myelotomy appears to provide only partial and transient pain relief. In the absence of more conclusive studies, myelotomies should be reserved for patients with intractable pain due to terminal disease.

**MECHANISM-ORIENTED PHARMACOTHERAPY FOR VISCERAL PAIN**

Visceral pain is often associated with abnormalities in organ function, such as constipation, nausea, cardiac failure, or dysuria. These abnormalities may cause pain or contribute to pain caused by the pain syndrome or its treatment. Thus, evaluation of patients with visceral pain syndromes should always go hand in hand with appropriate functional evaluation of the affected organ system.

**SEROTONIN AND GASTROINTESTINAL PAIN MANAGEMENT**

As described earlier, the gastrointestinal tract contains 95% of the body’s serotonin (5-hydroxytryptamine [5-HT]), where it is involved in many different functions. Different serotonin receptors are found on neurons, smooth muscle, and epithelial cells. The ligand-gated 5-HT3 receptor has been found on vagal and spinal afferents and is involved in visceral sensation, including the perception of nausea.77,78 Metabotropic 5-HT receptors exert more complex effects on gut function because they act on multiple targets, including muscle and nerve cells, with limited studies suggesting that 5-HT3 agonists and 5-HT1 antagonists may decrease visceral sensation in experimental animals and healthy volunteers.79,80 Currently, selective 5-HT3 receptor antagonists and 5-HT4 receptor agonists are available for clinical use. Although there is some experience with other serotonin receptor blockers, this experience is limited to mostly demonstrating physiologic changes in healthy controls or short-term effects in patients with mild abdominal discomfort. Antidepressants alter serotonin signaling, mainly by inhibiting the reuptake mechanism that terminates the effect of the released serotonin, and are commonly used in patients with various pain syndromes, including those with visceral pain. In view of their significant impact on central processing, it is not possible to clearly attribute effects to the peripheral changes in serotonin signaling.

**CLINICAL EFFICACY OF SEROTONIN AGONISTS AND ANTAGONISTS**

The 5-HT3 antagonist alosetron has been used successfully in patients with functional bowel disease characterized by abdominal pain and diarrhea.82-85 However, the effect is relatively modest, with a recent meta-analysis showing a small odds ratio (1.8) favoring the active agent over placebo, which translates into a number needed to treat of about 7.86 Other 5-HT3 receptor antagonists, such as ondansetron, play an important role in the treatment of severe nausea and vomiting but do not affect visceral pain.77 Tegaserod, a 5-HT4 agonist, significantly accelerates gastrointestinal transit and alleviates symptoms of constipation, including the associated discomfort and pain.87,88 Using global improvement scores, currently available data suggest a relatively low odds ratio (2.0) favoring tegaserod over placebo, with a number needed to treat of about 7.89 Both agents have been removed from the market in the United States because of safety concerns. Many studies have addressed the impact of antidepressants on visceral pain, with most focusing on gastrointestinal disorders. Even though individual studies have discrepant results, recent meta-analyses suggest improvement in functional gastrointestinal disorders, but not as clearly improvement in pelvic pain.90,91 One large trial examined the effect of amitriptyline in patients with interstitial cystitis without showing benefit over placebo.92 At least for selective serotonin reuptake inhibitors, the improvement was primarily due to changes in global assessment scores rather than pain. Considering the potential impact of psychiatric comorbidity as a confounder, one recent study examined the effect of citalopram in nondepressed patients with irritable bowel syndrome and did not demonstrate any benefit.93 Only one serotonin-norepinephrine reuptake inhibitor, venlafaxine, has been examined for visceral pain and was not found to be superior to placebo.94

**ADVERSE EFFECTS OF SEROTONIN AGONISTS AND ANTAGONISTS**

The most common side effect of alosetron and related agents is constipation, which is reported by 20% to 40% of
patients. Alosetron has been linked to ischemic colitis, a potentially fatal disease, which led to its withdrawal from the market. It is currently available only under a restricted access program with stringent monitoring. Tegaserod has been associated with ischemic events and was similarly removed from the market.

SMOOTH MUSCLE RELAXANTS AND VISCERAL PAIN

Stretch and tension are adequate stimuli for visceral sensation and correspond to distention of a hollow viscus or contraction of the tunica muscularis. Visceral muscle is morphologically and functionally distinct from striated muscle, thus potentially allowing the use of pharmacologic interventions that may not significantly affect striated muscle. Several strategies have emerged or are currently under investigation. Most rely on blockade of muscarinic receptors, the main excitatory signaling mechanism between parasympathetic neurons and visceral smooth muscle. Less commonly used strategies use agonists for α-adrenergic receptors or L-type calcium channel blockers to affect the contractility of visceral smooth muscle. The latter two approaches have largely been used in healthy volunteers, showed only limited efficacy in small studies involving patients with different painful disorders, and carry a significant risk for adverse effects, primarily symptomatic hypotension. Therefore, the discussion of spasmylytic agents will focus on muscarinic receptor antagonists, with the best evidence emerging from studies performed in patients with functional diseases of the gastrointestinal tract.

CLINICAL EFFICACY OF SMOOTH MUSCLE RELAXANTS

Two recently published meta-analyses concluded that when compared with placebo, patients receiving anticholinergic drugs are twice as likely to report an overall benefit, including pain relief. However, many of the patients experienced relatively mild pain at baseline and achieved only moderate pain relief in comparison to placebo.

ADVERSE EFFECTS OF SMOOTH MUSCLE RELAXANTS

About 10% of patients experience largely minor adverse effects, mainly because of effects on the mucous membranes, urinary tract, and eye, such as dry mouth, urinary retention, and accommodation problems. Based on the mechanisms of action, anticholinergic drugs are contraindicated in patients with known glaucoma and should be avoided in patients with micturition problems.

BOTULINUM TOxin AND VISCERAL PAIN

The clinical use of botulinum toxin has expanded significantly beyond its initial target—spastic motor disorders of skeletal muscles. Around 20 years ago it was shown to affect smooth muscle as well and led to symptomatic improvement in patients with achalasia. Because anecdotal evidence has suggested a decrease in pain independent of its effect on muscle activity, botulinum toxin has increasingly been used to treat various pain syndromes, presumably by directly altering peripheral transmitter release from nociceptive afferent nerve terminals. Essentially, all the studies focusing on patients with visceral pain are case series. Frequently, patients have associated impairment of visceral function, such as dysphagia, gastroparesis, or voiding dysfunction.

CLINICAL EFFICACY OF BOTULINUM TOxin

Few studies have focused on pain and systematically examined changes in pain intensity after treatment with botulinum toxin. In patients with various esophageal motility disorders characterized by pain, injection of botulinum toxin into the distal end of the esophagus significantly improved pain scores from severe to mild in about two thirds of patients for about 5 months. In a smaller case series of patients suffering from diffuse esophageal spasm with severe chest pain, endoscopically guided injection of botulinum toxin along the tubular esophagus resulted in nearly complete alleviation of pain for 6 months. Limited results on the effects of this neurotoxin on other areas of the gastrointestinal tract suggest potential benefit in disorders associated with pain. In the urinary tract, botulinum toxin has been used successfully to treat voiding disorders. Although a case series suggested some effect in patients with interstitial cystitis, an idiopathic disorder characterized by pelvic pain, urinary urgency, and increased frequency of micturition, a recently completed randomized controlled trial did not confirm its superiority over placebo.

ADVERSE EFFECTS OF BOTULINUM TOxin

The generally low dosages of locally injected botulinum toxin do not cause systemic side effects. Adverse effects are largely limited to transient pain or infectious complications at the injection site. Injection in close proximity to striated muscle, most notably sphincteric muscle of the bladder or rectum, may lead to transient incontinence.

κ-OPIOIDS AND VISCERAL PAIN

Opioids are potent analgesics for nonvisceral as well as visceral pain. However, µ-opioid receptor agonists commonly cause gastrointestinal side effects such as nausea, vomiting, and constipation. Especially in patients with gastrointestinal disorders, these unwanted effects may become dose limiting. In addition, the rise in opioid use for chronic pain has led to increasing concern about the use of these agents for benign disorders. Because peripheral visceral afferents express κ-opioid receptors, κ-agonists were developed to take advantage of their analgesic properties and the lower likelihood of adverse effects. Animal and acute studies in human volunteers demonstrated increased thresholds to painful visceral stimuli, consistent with a potential analgesic effect. However, central effects with significant dysphoria limit the use of κ-agonists to peripherally acting agents.

CLINICAL EFFICACY OF κ-OPIOID AGONISTS

A single small study reported κ-agonist-induced pain relief in patients with chronic pancreatitis who were refractory to µ-opioid agonists. However, the patients were studied acutely after only a single administration of the agonist. Several randomized controlled trials examined the effects of fedotozine, a κ-opioid agonist, in patients with chronic abdominal pain secondary to functional disorders over a period of at least 6 weeks. Although an overall benefit was reported, the effect was rather small in comparison to placebo. On-demand therapy with asimadoline, a peripherally acting
κ-opioid agonist, did not affect pain severity in patients with irritable bowel syndrome.\textsuperscript{118}

**ADVERSE EFFECTS CAUSED BY K-OPIOID AGONISTS**

Randomized controlled trials did not report a significantly higher incidence of adverse effects after the administration of peripherally acting κ-opioid agonists than after placebo.\textsuperscript{89}

**AGENTS TARGETING THE $\alpha_2\delta$ CALCIUM CHANNEL SUBUNIT**

Voltage-sensitive calcium channels play an important role in neuronal excitability. Gabapentin and pregabalin have been developed as anticonvulsive agents. Because changes in neuronal excitability contribute to peripheral and central sensitization, both agents have been used in patients with chronic visceral pain. In healthy volunteers and patients with irritable bowel syndrome, the agents blunted acute pain triggered by rectal distention.\textsuperscript{119,120}

**CLINICAL EFFICACY OF AGENTS TARGETING THE $\alpha_2\delta$ SUBUNIT**

Despite changes in acute pain sensitivity, pregabalin was not superior to placebo during a 2-week course of treatment in patients with irritable bowel syndrome.\textsuperscript{120} In contrast, a recent study showed improved pain control and decrease opioid use in patients with chronic pancreatitis treated with pregabalin.\textsuperscript{121}

**ADVERSE EFFECTS OF AGENTS TARGETING THE $\alpha_2\delta$ SUBUNIT**

Even though gabapentin and pregabalin were well tolerated without serious adverse events, patients reported problems with cognition and balance, often stating that they felt as though they were drunk.

**SUGGESTED READINGS**

The references for this chapter can be found at www.epertconsult.com.

**CLINICAL IMPLICATIONS**

The improved understanding of normal visceral function and sensation has led to the development of new therapeutic strategies. In the gastrointestinal tract, muscarinic receptor antagonists and serotonin receptor agonists and antagonists alter function and may improve discomfort associated with functional disorders. Antidepressants are commonly used and may lead to some improvement of global symptoms score, likely in part due to their effect on often coexisting psychiatric illnesses. A recent study in patients with chronic pancreatitis suggests some efficacy of pregabalin in visceral pain. Several targeted treatments are currently under development using drugs that interact with purinergic receptors and members of the family transient receptor potential channels (TRPV1 or TRPA1).

Chronic pain in children is an undertreated entity that is commonly ignored. Over the last decade, several studies in the literature have addressed pain in children and its measurement and management. In this chapter we discuss common chronic pain syndromes in children along with their assessment, diagnosis, and management (Box 33.1). Recurrent or persistent pain is seen in 5% to 10% of children. One study demonstrated that 96% of children aged 9 to 13 years experienced some form of acute pain over the previous month, with 78% experiencing headaches, 57% experiencing recurrent pain, and 6% experiencing chronic persistent pain.

### Assessment of Chronic Pain in Children

Assessment of children with chronic pain starts with a biopsychosocial perspective to take into account the multiple factors that can influence the child’s pain experience. Multidimensional models elaborate various biologic, developmental, temperamental, cognitive-behavioral, affective, social, and situational factors that may both shape the child’s pain experience and influence the pathways by which they exert their effects. Each domain may become a target of assessment and intervention. Several developmentally sensitive validated instruments are now available to measure the varied aspects of children’s pain (Table 33.1).

Two standardized interviews for school-age and adolescent children and their parents provide comprehensive yet practical evaluations of the child’s chronic pain—the Children’s Comprehensive Pain Questionnaire (CCPQ), and the Varni-Thompson Pediatric Pain Questionnaire (VTPPQ). These interviews separately assess both the child’s and parents’ experience of the pain problems with open-ended questions, checklists, and quantitative pain-rating scales. Some studies suggest potential limitations of these self-report measures because of cultural or cognitive differences among children. Additionally, the Pain Behavior Observation Method is a 10-minute observational pain behavior measure that can be used in children with chronic pain who may have difficulty with self-report measures because of age or cognitive limitations. Studies have supported the use of electronic versus paper pain diaries in children with chronic pain; electronic diary use was shown to be feasible and resulted in greater compliance and accuracy in diary recording than did traditional paper diaries in children with recurrent pain.

The well-documented comorbidity between pediatric chronic pain and psychiatric disorders, particularly internalizing disorders such as depression and anxiety, obligate the clinician to screen for these disorders. The Children’s Depression Inventory (CDI) is a widely used self-report questionnaire for assessing depression in children 7 to 17 years of age. The Beck Depression Inventory-II can be used with adolescents because some items on the CDI may be less age appropriate for older adolescents. It is important to assess for anxiety symptoms because pain-related disability is associated with anxiety sensitivity, a stable predisposition to fear of anxiety-related sensations, and pain-related avoidance behavior in children as well as adults with chronic pain. The Children’s Anxiety Sensitivity Index (CASI) is the only instrument thus far developed to assess this characteristic in children, and the Pain-Anxiety Symptoms Scale (PASS) was developed for adults to assess fear of pain but has been used in children as young as 8 years. A recent study suggested that the CASI is a better predictor of health-related quality of life than pain intensity in children with chronic pain.

Several well-validated self-report questionnaires assess anxiety in children (see Table 33.1). Two instruments, the Self-Report for Child Anxiety Related Disorders (SCARED) and the Spence Children’s Anxiety Scale (SCAS), include subscales that distinguish among specific anxiety disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV). The Multidimensional Anxiety Scale for Children (MASC) and the Revised Children’s Manifest Anxiety Scale (RCMAS) include subscales that focus on other dimensions of anxiety. These subscales include physical symptoms, social and separation anxiety, and harm avoidance (the MASC) and physiologic symptoms, worry and oversensitivity, and concentration factors (the RCMAS); both also include social desirability items to detect inconsistency or randomness in reporting. The SCAS and SCARED provide both child and parent forms of the instrument, which allows examination of the convergence or lack thereof between the child’s and parent’s assessment of the child’s anxiety symptoms. The State-Trait Anxiety Inventory for Children (STAIC) provides a state version, which measures situation-specific anxiety, and a trait form, which assesses anxiety symptoms that are stable across situations.

Factors that are closely linked with a child’s ability to function with chronic pain, such as perceived stress and coping, can assist in planning behavioral interventions. The Pain Coping Questionnaire (PCQ) and Pain Response Inventory (PRI) and Pain Catastrophizing Scale for Children (PCS-C) assess pain-specific coping strategies. The Response to Stress Questionnaire (RSQ) has been used to assess coping with abdominal pain but also has other versions that target other stressors, such as social stress.
Identification and modification of maladaptive coping responses constitute core elements of cognitive-behavioral approaches for treating pediatric chronic pain. For example, if the child endorses a catastrophizing coping style, which is an established risk factor for poor adaptation to chronic pain, this coping style can become a target of treatment.

The ability to function in tasks of daily living is a critically important outcome measure to assess when treating children and adolescents with chronic pain. Frequently, pain cannot be completely relieved and the child must learn to accept, cope, and adapt to the pain to enable participation in normal developmental activities and tasks, such as going to school, participating in extracurricular activities, and developing and sustaining social relationships. Several measures have been developed to assess the child’s functional abilities, as well as quality of life. For example, the Pediatric Migraine Disability Scale (PedMIDAS) measures headache-related disability in children with chronic pain. This six-question tool assesses school, recreational, and social areas of participation and disability, domains relevant to all children with chronic pain. The Child Activity Limitations Interview (CALI) assesses the impact of recurrent pain on children’s daily activities as a way to identify appropriate targets for treatment. Additionally, the Functional Disability Inventory (FDI) developed to assess illness-related disability in children and adolescents, is a useful tool for evaluating the functional status of pediatric patients with chronic pain, a particularly important concern in children with pain disorders associated with psychological factors and pain-associated disability syndrome. Pain-related disability increases with age and as sex differences emerge in adolescence, with more girls than boys reporting pain-related functional disability.

Quality of life can also be assessed in children and adolescents with chronic pain and as an index of treatment progress, with one study finding that the quality of life of children with recurrent headaches is similar to that of children with rheumatoid arthritis or cancer. The Quality of Life Pain–Youth (QL-PY) was developed to address quality-of-life issues particular to chronic pain. The Child Health Questionnaire, both child (CHQ-CF87) and parent reports (CHQ-50), as well as the PedsQL, are measures that may be used to assess general quality of life in children with chronic pain and have the advantage that the scores obtained on these instruments can be compared with standardized samples of scores obtained by children with other medical illnesses.

Other instruments that may further elucidate the psychological factors contributing to a child’s behavioral adaptation to chronic pain include the Children’s Somatization Inventory (CSI), which measures a child’s propensity to somatization, and the Harter Scales of Perceived Competence, which assess a child’s judgment about his or her capabilities in important domains such as school performance, peer relationships, and athletic abilities. The child’s own judgment of his or her competencies in these domains is useful in understanding other factors that may contribute to the child’s functioning. For example, children with chronic pain who rate themselves as low on social and academic competency may have multiple reasons to avoid returning to school.

Parental or family issues that could impede or support a child’s progress with treatment are also important to assess. The Family Environment Scale (FES) and the Family Adaptation and Cohesion Scales II (FACES II) have been used to assess family characteristics, whereas the Family Crisis-Oriented Personal Evaluation Scale (F-COPES) assesses the family’s problem-solving and coping efforts in relation to a challenging situation, such as having an ill child. At times the parents themselves may require psychiatric treatment to assist them in their efforts to help in their child’s rehabilitation. The Symptom Checklist 90–Revised (SCL-90-R) is a useful screen for parental psychiatric symptoms, and the Medical Outcomes Short-Form 36-Item Health Survey can be used to assess parental adaptive functioning, as well as disabilities.

Scharff and colleagues attempted to identify specific subgroups of pediatric chronic pain patients. Identifying subgroups of adults with chronic pain has proved useful in identifying patients’ coping efforts and determining appropriate psychological interventions. For example, the West Haven–Yale Multidimensional Pain Inventory (WHYMPI) has been used to identify clinical subgroups of adult chronic pain patients—“adaptive copers,” who have good coping and supportive relationships; “dysfunctional copers,” who have poor coping skills and are highly stressed; and the “interpersonally distressed,” who have inadequate social support. These three subgroups have been found in diverse adult populations with chronic pain and are associated with different outcomes in behaviorally based pain treatment programs. Although all three groups were found to benefit from a behavioral intervention, the dysfunctional copers benefited the most, with lower pain scores, decreased impact of the pain on their lives, and decreased depression and negative thoughts. Scharff and colleagues identified similar subgroups in a population of 117 children with various types of chronic pain conditions: a high-functioning group, a disabled and low-functioning group, and a group with family dysfunction. These strongly resemble the subgroups identified by Turk and Rudy in adult chronic pain patients. Although findings from this study were preliminary and need to be interpreted cautiously, such efforts to

distinguish subgroups of children with chronic pain should serve to provide targeted treatments to improve the care of pediatric patients with chronic pain.

Therefore, thorough baseline and ongoing assessment is essential to guide interventions for chronic pain and evaluate the child’s response to treatment. Core elements of assessment include comprehensive evaluation of the child’s pain problem and screens for psychiatric comorbidity and functional status (Box 33.2). More intensive screening of the child’s perceived stress and competencies and the parents’ and family’s functioning adds valuable information to treatment planning, especially in a child with long-standing pain problems that have not responded to previous treatment efforts.

A rehabilitative approach that emphasizes improving the child’s and family’s ability to cope with a chronic condition characterizes the course of most chronic pain treatment programs for children. The focus shifts from the narrow goal of pain reduction, which might be used in the treatment of acute pain, and broadens to decrease pain-related emotional and behavioral disability, thereby increasing the child’s functional status.51,74,75 Psychological pain management methods are directed toward increasing the child’s and family’s understanding of the child’s pain and its treatment, including factors that may reduce or exacerbate the child’s pain, and enhancing cognitive and behavioral coping skills so that pain-related discomfort and disability are reduced. Research on the use of psychological therapies has focused mostly on clinical trials in children with headache.76,77 In a meta-analysis conducted to evaluate the efficacy of behavioral interventions for pediatric chronic pain, Eccleston and coworkers75 concluded that “There is strong evidence that psychological treatment, primarily relaxation and cognitive behavioural therapy, are highly effective in reducing the severity and frequency of chronic pain in children and adolescents.” Additionally, findings by Logan and colleagues suggest that interdisciplinary pediatric pain rehabilitation may facilitate increased willingness to self-manage pain, which is associated with improvements in function and psychological well-being.78

A few promising psychological treatments have also been used for children with disease-related chronic pain, including sickle cell disease,79-81 recurrent abdominal pain,82-85 complex regional pain syndrome (CRPS) type 1,86 musculoskeletal pain,87,88 and juvenile primary fibromyalgia syndrome,89,90 and further support the probable efficacy of cognitive-behavioral approaches to pediatric pain management. Although there is evidence to support the use of single behavioral treatment modalities for the treatment of pediatric chronic pain, such as the use of thermal biofeedback and relaxation for recurrent pediatric headache,91 most treatment programs include a diverse array of techniques that treat chronic pain by modifying children’s cognitive, affective, and sensory experiences of pain, their behavior in response to pain, and environmental and social factors that influence the pain experience. Education about chronic pain and problem solving for improving the child’s functional status is central to the child and family assuming an active role in managing chronic pain. Cognitive techniques are targeted at modifying the child’s thoughts about the pain, in particular, to increase a sense of predictability and control over the pain, to alter memories about painful experiences,92 and to reduce negative cognitions about pain, especially “catastrophizing.”93 Decreasing somatic preoccupation, pain-related rumination,94 and passive coping and learning to accept that the pain may persist95 are also key interventional goals in the psychological management of pain.38

Techniques to alter the sensory aspects of chronic pain include relaxation training, biofeedback, imagery, and hypnosis. Interventions aimed at modifying situational factors that exacerbate chronic pain and disability include contingency or behavioral management methods, modification of activity and rest cycles, and exposure to situations previously avoided because of pain.74,85 Few component analyses have been conducted to determine which psychological therapies may be most essential in the management of pediatric chronic pain, but it is likely that for most chronic pain conditions, a combination of modalities will provide the best opportunity to effect the desired change. Changes in emphasis of various behavioral components may present the opportunity to individualize treatment for the specific child by taking into account developmental, psychological, parental, and family factors, which may provide a way to tailor specific treatment to a child.

There is growing acknowledgment of parents’ crucial role in successful rehabilitation of children with chronic pain, and thus they are increasingly being involved as active partners in their child’s treatment.74,83,96 Parental interactions with their child related to pain and the family characteristics of children with chronic pain that may be associated with the development of maladaptive coping with pain are areas of active research.97,98 Particular types of parental behaviors have been shown to influence a child’s ability to cope with pain. For example, parental attention has been associated with increased symptoms in children with recurrent abdominal pain.100 Walker and colleagues100 found that girls with functional abdominal pain are more vulnerable than boys to the symptom-reinforcing effects of parental attention. Interestingly, although the children with pain rated parental distraction as a helpful strategy, their patients rated distraction as having greater potential for a negative impact on their child than attention. Such findings help guide behavioral interventions for children with chronic pain.
pain and their families because parents’ beliefs in the most effective pain management strategies need to be targeted in any intervention designed to increase the functional abilities of children with chronic pain.

Several methods for the delivery of psychological interventions for recurrent or chronic pain in children have been shown to be effective, including those that involve intensive inpatient or outpatient treatment; those that are self-administered, school based, Internet-based, or CD ROM based, and those that involve minimal clinic contact with home-based practice. The variety of methods for delivery of these interventions offers opportunities to reach a broad population of children with chronic pain, thus increasing the potential to reach many more children than can be treated in specialized pediatric pain treatment centers. Optimally, the child’s school and other caretakers are included in the treatment team to ensure a consistent and comprehensive approach to the child’s pain and disability. For example, if a child’s pain management involves strategies to cope with stress and headache at school, the school nurse can prompt the child to use these strategies rather than defaulting to having the parents pick the child up from school to rest at home (see Brown for a review of school issues related to pediatric pain). Complementary therapies such as massage and acupuncture are increasingly available to children seen in chronic pain clinics, but there is limited literature thus far to document the efficacy of these treatments in pediatric patients.

The complex nature of chronic pain in children creates many challenges in regard to its assessment and treatment, but this same complexity can be exploited to provide the most efficacious methods for pain control and functional rehabilitation. Multidimensional assessment provides the foundation for optimal pain management and functional rehabilitation of chronic pain in children. Psychological interventions include a diverse array of techniques that treat chronic pain by modifying children’s cognitive, affective, and sensory experiences of pain, their behavior in response to pain, and environmental and interactional factors that influence the pain experience. Without addressing the factors that may contribute to pain and pain-related disability, medical treatment of a child’s chronic pain may result in poorer outcomes. Research informed by multidimensional models of pediatric chronic pain can guide investigators in efforts to identify effective pain treatments, as well as the individual children for whom they work best. Finally, the lessons learned about optimal management of pain in children need to be practiced to the fullest extent possible so that the incidence of their suffering and disability may be diminished. For further reviews of psychological interventions for pediatric chronic pain, see McGrath and Holahan, Hillier and McGrath, and Eccleston and coworkers.

**CHRONIC PAIN SYNDROMES**

We briefly discuss the diagnosis and management of some common chronic pain syndromes diagnosed in pediatric patients referred to chronic pain clinics. The introduction of multidisciplinary pediatric pain clinics has allowed children to be seen in a single office visit by a number of consultants who are able to provide service for the child and develop a comprehensive pain management plan. Our clinic includes anesthesiologist specialized in pain management, a child psychologist with a special interest in pain, a physical therapist, a complementary medicine practitioner (including message therapy and acupuncture therapy), and a specialist in biofeedback. This comprehensive approach reduces the need for multiple visits and exposes our patients to a multi-modal therapeutic approach.

Common pain syndromes in children include CRPS type 1, headache, abdominal pain, chest wall pain, back pain, pelvic pain, and cancer-related pain. We address each of these conditions with a specific emphasis on accepted current therapy.

**COMPLEX REGIONAL PAIN SYNDROME TYPE 1**

CRPS 1, or reflex sympathetic dystrophy (RSD) as it was originally called, is a complex syndrome consisting of pain, allodynia, hyperalgesia, and possible loss of function. The International Association for the Study of Pain (IASP) has defined CRPS 1 as “A continuous pain in a portion of an extremity after trauma, which may include fracture but does not involve major nerve lesions and is associated with sympathetic hyperactivity.” CRPS 1 is a common reason for referral to a pediatric pain clinic. It is seen more commonly in the lower extremity and most of the children involved are female, many of whom have endured minor trauma before the development of chronic pain. Though reported in a 2½-year-old girl, it is generally seen in children older than 9 years and more frequently in girls 11 to 13 years of age. Early recognition and management are the major factors in improving outcome and preventing resistant CRPS. Management by an experienced multidisciplinary team is recommended. Because psychosocial factors play an important role, psychological evaluation and cognitive-behavioral treatment should be provided in an expeditious manner.

The mechanisms that generate neuropathic pain (NP) are varied and complex. Injuries to peripheral nerves may involve crush, transection, compression, demyelination, axonal degeneration, inflammation, ischemia, or other processes. The primary loci of increased irritability following peripheral nerve injury may be at several levels in the nervous system, including axonal sprouts or neuroma, the dorsal root ganglia, the dorsal horn of the spinal cord, or sites more rostral in the central nervous system. Central neural causes and peripheral small-fiber neuropathy have been implicated in the mechanisms leading to NP. NP rarely keeps the subject from harm because it involves the erroneous generation of impulses.

**EVALUATION OF NEUROPATHIC PAIN**

**History**

A detailed history of the nature of the injury, the type and duration of the pain, relieving and aggravating factors, and dependence on medications is mandatory before evaluation.

**Physical Evaluation**

A thorough and systematic neurologic examination should be performed. Complete evaluation of motor, sensory, cerebellar, cranial nerve, reflex, cognitive, and emotional...
functioning is important. A concerted effort must be made to rule out a rare but possible malignancy or central degenerative disorder.

Sympathetically mediated pain is often diagnosed by clinical and diagnostic criteria based on responses to sympathetic blocks. However, the diagnosis of sympathetically mediated pain cannot be based on responses to sympathetic blocks alone.

The strength of the extremity should be evaluated on several occasions. It is important to compare it with the strength in the contralateral extremity because CRPS 1 can occur in both extremities at the same time.

Allodynia is excruciating pain that can be produced by innocuous stimuli such as stroking (e.g., stroking the skin with a feather). This is very characteristic of NP. Tactile allodynia in the absence of skin problems is a classic diagnostic criterion for NP.

Hyperalgesia is an increased sensitivity to pain. Hyperalgesia to cold is seen more frequently than hyperalgesia to warmth. The distribution is not generally restricted to particular dermatomes, as in an adult, and commonly occurs along a glove-and-stocking distribution.

Nerve conduction studies may provide some insight into the location and type of nerve injury. However, the use of invasive electromyography may not be acceptable to children.

Quantitative sensory testing (QST) with thermal and vibration sensations and thermal pain detection thresholds in the affected limbs can be compared with data from normal healthy children. The patient’s rating of pain and quality of pain can be assessed. Mechanical static allodynia and dynamic allodynia can be measured. Quantitative thermal and vibration detection thresholds can be measured. Although this involves cumbersome equipment, bedside QST may have a greater role in the diagnosis of CRPS 1 in children and adolescents.

Bone scans may be helpful in the diagnosis of CRPS 1. Although there are not enough data on their diagnostic accuracy in children, they are nevertheless performed in children and adolescents with CRPS 1. A decrease in isotope uptake is noticed with CRPS 1.

**Box 33.3** International Association for the Study of Pain Diagnostic Criteria for Complex Regional Pain Syndrome

1. Presence of an initiating noxious event or cause of immobilization
2. Continuous pain, allodynia, or hyperalgesia in which the pain is disproportionate to any known inciting event
3. Evidence at some time of edema, changes in blood flow, or abnormal sudomotor activity in the region of pain
4. Diagnosis excluded by the existence of other conditions that would otherwise account for the degree of pain and dysfunction

**Diagnosis**

Diagnosis of CRPS 1 in children is usually based on symptoms and signs (Box 33.3). The characteristics of the pain and sensory, motor, and sudomotor changes may vary among patients; also, differences between NP and nociceptive pain can be noted (Table 33.2). A test with phentolamine has been used to confirm the diagnosis and to predict the response to sympathetic blockade. Bone scans may offer some information about CRPS 1. Disturbed vascular scintigraphy with increased pooling in the initial phase and hyperfixation on bone scintigraphy may denote the presence of CRPS 1. The IASP criterion for CRPS 1 is applicable to children and adolescents (see Box 33.3). Classic signs and symptoms of the various stages of CRPS 1 are presented in Table 33.1.

**TREATMENT OF NEUROPATHIC PAIN**

Management of NP (Box 33.4) can be frustrating for the caregiver, as well as the patient. No single therapy can uniformly provide relief to these patients. Management depends largely on the response to various clinical measures. Titration of medications is limited by the presence of side effects and complications. One of the primary goals is to return the child to a functional state and to school. Definitive resolution of the pain is not always possible. Most management techniques have been extrapolated from work done in adult patients. It is imperative to build trust with the patient and the parents. Family dynamics are important.
because the added burden of familial disharmony or parental abuse can worsen the symptoms. There seems to be a greater propensity for enmeshment in these families. The algorithm shown in Figure 33.1 is used by our pain clinic.129

**Psychological and Behavioral Therapy**

Behavioral measures are extremely useful in the management of NP. Family therapy often helps family members cope with the situation.130 We generally advocate consultation with a medical psychologist during the initial visit to the pain clinic. Several techniques, including biofeedback, visual guided imagery, and structured counseling, have been shown to assist in the development of adequate coping skills.131 Participation in a day program for acute psychological intervention has been valuable for some of our patients, specifically those with significant psychiatric co-illness. See earlier for more detailed explanations of various psychological interventions.

**Physical Therapy**

Physical therapy is geared toward adequate functional ability of the child. Transcutaneous electrical nerve stimulation (TENS) is widely used, and its efficacy has been studied in adults as well as children; therapeutic benefits with TENS in children with RSD have been reported by Kesler and colleagues.132 We use TENS extensively in our practice, along with physical therapy, which consists of both active and passive physical modalities. The physical therapy program is geared toward individual patients, and the goal is to allow the child to participate in as many activities as possible. It may be necessary to have input from a pediatric physical therapist or occupational therapist for adequate management. Other commonly used modalities include desensitization, warm and cold baths, massage therapy, and heat therapy. Such modalities, when used in conjunction with active physical modalities, can help ameliorate the pain symptoms.133

CRPS, complex regional pain syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs; TENS, transcutaneous electrical nerve stimulation.

**Box 33.4 Management of Neuropathic Pain**

**Figure 33.1 Algorithm for the management of chronic regional pain syndrome type 1.** IVRA, intravenous regional anesthesia; SNRIs, serotonin norepinephrine reuptake inhibitors; TCAs, tricyclic antidepressants; TENS, transcutaneous electrical nerve stimulation.
Tricyclic Antidepressants. Adults are frequently prescribed tricyclic antidepressants (TCAs) for the management of NP.134 Despite the lack of adequately controlled studies in pediatric patients, TCAs are widely prescribed for several forms of NP.135 Because amitriptyline may cause sedation, it is our practice to use nortriptyline, which appears to have less sedative and fewer anticholinergic side effects. Thorough examination of the cardiovascular system is necessary before instituting TCA treatment because of associated tachydysrhythmia and other conduction abnormalities of the heart, particularly prolonged QT syndrome.136,137

Anticonvulsants. Anticonvulsant medications have been used for several years to manage NP.138 Although carbamazepine and oxcarbazepine have been used extensively to treat NP,139-143 the introduction of gabapentin and pregabalin has revolutionized the world of pain medicine.140-143 Despite the lack of controlled trials in children to demonstrate the efficacy of either drug, both of these voltage-gated calcium channel blockers have been used in our clinic with promising results.144 More controlled trials need to be conducted to better determine the dosing and efficacy of this class of drugs in children with CRPS 1. An important side effect that we have noted in our clinic setting is the potential for increased somnolence, as well as the potential for weight gain in children taking pregabalin. This is important to consider, especially when treating adolescent girls, who happen to be the majority of this cohort.

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors. Despite the lack of proven efficacy of the use of selective serotonin reuptake inhibitors in the management of pain in children and adolescents, they are occasionally used to treat psychological comorbidity, including depression associated with pain.145 More recently, serotonin-norepinephrine reuptake inhibitors have been introduced and used successfully to treat NP, especially in patients with psychological comorbidity.146

Opioids. Opioids can be helpful in the management of NP, especially for cancer-related NP (see later). Arner has shown that several types of NP are resistant to the effects of opioids.127 Opioids should be titrated in a graded fashion to optimize the effect. Sedation is a side effect that may be desirable, especially in cancer-related NP, and in some cases it may need to be antagonized with the addition of amphetamines.147 For children with non–cancer-related NP, non-opioid-based techniques are generally exhausted before starting opioids.

Systemic Vasodilators. Several patients with RSD have benefited from the use of vasodilators such as prazosin, nifedipine, and phenoxybenzamine. However, overwhelming adverse effects of orthostatic hypotension often offset the efficacy of this therapy.

Regional Anesthesia and Sympathetic Blocks. A common treatment of these syndromes is to interrupt the apparent pathologic reflexes by performing sympathetic blocks (Box 33.5). Regional anesthesia, though used often in adults for the diagnosis and management of CRPS, is generally introduced in children after pharmacological and cognitive-behavioral management has been exhausted.148

In severe cases, regional anesthesia is used to introduce a physical therapy regimen. In this section we discuss the different regional techniques that are used in children for the management of CRPS.

Central neuraxial blockade is used in children with severe pain to facilitate the introduction of physical therapy. An indwelling epidural catheter is placed in the lumbar or cervical area and infused with a low-concentration local anesthetic solution, which allows better cooperation from the patient and the parents to introduce a physical therapy regimen.23 In addition, intrathecal analgesia has been reported to be an effective method for treating refractory CRPS 1 in children.149,150

Bier block has been used for mild to moderate cases of CRPS 1 as a primary modality for providing analgesia and sympathetic blockade.127 Although a myriad of substances have been used to provide a Bier block, a local anesthetic in combination with either an α2-agonist or an NSAID appears to produce better results. In our case series of children who received intravenous regional anesthesia with lidocaine and ketorolac, we demonstrated a marked improvement in symptoms and the ability to perform physical therapy.129 Peripheral nerve blocks are used to facilitate physical therapy while providing a sympathetic block and have become more plausible, especially with the use of ultrasound guidance.148 Serial peripheral nerve blocks may be performed. With serial blocks, the patient’s pain relief often outlasts the duration of conduction blockade, which may be due to reduced central sensitization, as well as interruption of the circuit established between the nociceptor, central nervous system, and motor unit.151 Concomitant corticosteroid administration may contribute to this effect via anti-inflammatory action and by suppressing ectopic discharge in neural membranes.152 We have noted these effects in our practice. The majority of our patients with NP who have undergone serial peripheral nerve blocks experience pain relief that increases in duration with each block.

Continuous peripheral nerve blocks (CPNBs) have been reported to be effective in both controlling pain and facilitating physical therapy in children with CRPS.155 Despite such reports, limited data exist regarding the feasibility, safety, and efficacy of CPNBs in children.154 After perineural catheter placement, a dilute solution of local anesthetic is infused with the view of providing analgesia while allowing physical activity. The catheter is left in place for 4 to 5 days; this can be done on an inpatient basis, or the patient may be sent home with a portable infusion device. We prefer sciatic nerve

catheter placement for the lower extremities (see Fig. 33.2) and interscalene or infraclavicular brachial plexus catheters for the upper extremities. Concurrent physical therapy is indicated to improve range of motion and function. We institute physical therapy at the time of provision of a nerve block to enhance the patient’s experience with therapy.

**Sympathetic blockade** is used in children after exhausting the aforementioned techniques. A stellate ganglion block may be performed under ultrasound guidance for upper extremity CRPS (see Fig. 33.3), and a lumbar sympathetic block is performed under fluoroscopic guidance for lower extremity CRPS.\(^{155}\) A crossover trial of fluoroscopically guided lumbar sympathetic blocks demonstrated a decrease in allodynia and pain intensity when compared with intravenous injection of lidocaine in adolescents with CRPS.\(^{156}\)

**Neuromodulation** via spinal cord stimulation, though commonly performed in adults for refractory cases of CRPS, is very rarely used in the pediatric setting.\(^{157,158}\) Spinal cord stimulation has been reported to achieve favorable outcomes in adolescents with therapy-resistant CRPS.\(^{159}\) The use of peripheral nerve stimulators, however, is gaining ground in the pediatric setting and may benefit children with refractory CRPS.

**PROGNOSIS OF NEUROPATHIC PAIN**

Varni and colleagues\(^{160}\) reported uniform improvement in their series of patients who endured a prolonged course of physical therapy and inpatient rehabilitation. Ashwal and associates\(^{161}\) concluded that the prognosis of childhood CRPS is more favorable than that of adult CRPS. NP can be puzzling and frustrating and requires a strong alliance with the family and the patient. A multidisciplinary algorithmic management approach involving the use of available techniques can be helpful. The use of physical therapy and psychological management must be stressed while managing these patients.

**HEADACHES IN CHILDREN**

Headaches are a common finding in children and adolescents. Few physicians discussed headaches in children until 1873, when William Henry Day, a British pediatrician, devoted a chapter to the subject of headaches in his book *Essays on Diseases in Children*.\(^{162}\) In 1967, Freidman published the data available in *Headaches in Children*.\(^{163}\) These books provided an impetus to the many subsequent papers dealing with headaches in children. Many child care providers do not believe that children have an appreciable number of headaches. In a study of 9000 children in Sweden, Bille\(^{164}\) reported migraine headaches in 3.9% of children younger than 12 years and a 6.8% incidence of nonmigrainous headaches daily. This translates to a greater number of school days lost from absenteeism because of the debilitating nature of the headaches. A more recent study by Bille\(^{165}\) demonstrated that almost 40% of these children with headaches in childhood progress to a headache-free state in adulthood. A 2010 survey of middle schools in the Chicago area demonstrated the presence of headaches in a large percentage of all schoolchildren.\(^{166}\)

Most headaches in children are linked to either organic or nonorganic causes and may be deemed acute or chronic based on the duration of the headaches. Chronic daily headache is classified as headaches that occur at least 15 times monthly for a period of 3 months and can last for more than 4 hours daily.\(^{167}\)

**EVALUATION OF HEADACHE**

A thorough history and physical examination help determine the nature of the headache. Specific questions about neurologic symptoms such as ataxia, lethargy, seizures, or visual impairment should be asked. Other medical conditions such as hypertension, sinusitis, and emotional disturbances must

---

**Figure 33.2** Sciatic nerve catheter for the management of complex regional pain syndrome type 1.

**Figure 33.3** Image of ultrasound-guided stellate ganglion blockade.
be evaluated. Physical examination, including a thorough neurologic examination and blood pressure measurement, is mandated for children with headaches. Neuroimaging may be required and a lumbar puncture might be advised in some cases. Benign intracranial hypertension or idiopathic intracranial hypertension is a constellation of symptoms and signs that includes headaches, diplopia, tinnitus, and eye pain. These conditions usually have normal imaging results. Although a diagnostic lumbar puncture may be needed in some settings, patients with chronic daily headaches may be prone to post–lumbar puncture headaches.

**PATHOPHYSIOLOGY OF HEADACHE**

A headache is modulated by extracranial as well as intracranial structures (Box 33.6).

**CLASSIFICATION OF HEADACHE**

Classification of headaches is based on the presumed location of the abnormality, its origin, its pathophysiology, or the symptom complex that the patient has (Box 33.7).

**EVALUATION OF HEADACHE**

Comorbid symptoms are associated with headaches. The most common comorbidity is sleep deprivation. Delayed sleep is a frequent disorder seen in children with headaches. Many also have symptoms of dizziness, which may be associated with postural hypotension and tachycardia (postural orthostatic tachycardia syndrome). Orthostatic hypotension should be treated by increasing fluid intake, and in some cases, a β-blocker may be needed. A history of a new-onset severe headache, pain that awakens a child from sleep, headaches associated with straining, changes in chronic headache patterns, or the presence of a headache accompanied by nausea or vomiting suggests a more pathologic origin of the headache and must be carefully evaluated (Box 33.8).

It is imperative to evaluate any relevant neuroimaging studies before the patient’s appointment in the pain clinic.

After establishing that the headaches are not secondary to any intracranial pathology, the following information is obtained:

1. Neurologic status, including a complete neurologic examination.
2. Physical status of the patient (i.e., is the patient actively mobile?).
3. Does the headache prevent the child from performing normal activities (e.g., interacting with others, participating in sports)?
4. Is there a history of school absenteeism?
5. What is the child’s interaction with the parents and siblings at home?
6. Are there any factors that relieve the headache?
7. Has the child been taking any medications for pain? Has there been any improvement at all in the clinical characteristics of the pain?
8. Are any postural changes associated with the headaches? Is there diurnal variation in the headaches?
9. The family history is crucial in these children; a family history of migraine is suggestive of childhood migraine.

After careful evaluation and classification of the type of headache, treatment is initiated in stepwise fashion. We use the algorithm shown in Figure 33.4 for the management of headaches.

Patients with migraine headaches are frequently managed by neurologists and are referred to the pain clinic only in refractory cases. We have intervened by providing peripheral nerve blocks for headaches. A trigeminal nerve block for frontal headaches and occipital nerve blocks for persistent occipital pain have been shown to be effective in children.

A tension-type headache is perhaps the most common type of headache that we see in our pain clinic. These patients frequently complain of debilitating frontotemporal or frontoparietal headaches. The headache results from contraction of the temporalis muscle and tension on the scalp muscles. Management of tension-type headaches includes the use of relaxation techniques, as well as biofeedback. These patients frequently benefit from the routine use of nonsteroidal agents. In addition, caffeine has been described as an effective adjuvant to nonsteroidal drugs in treating childhood headaches.

Children occasionally have persistent neuropathic headaches. This commonly occurs in those who have undergone ventriculoperitoneal shunt revision or surgical decompression for a Chiari malformation. After cognitive-behavioral therapy we have attempted to use serial peripheral nerve blocks in these patients. This includes trigeminal nerve blocks for frontal headaches and occipital nerve blocks for occipital headaches. An ultrasound-guided approach to the occipital nerve allows easy access to the C2 nerve root, thereby providing a more robust blockade than can be achieved with a peripheral subcutaneous injection. Local anesthetic is injected with or without a small dose of steroid to provide analgesia.

**ABDOMINAL PAIN IN CHILDREN**

Abdominal pain is a frequently encountered problem in infants, children, and adolescents. When evaluating abdominal pain, it is imperative that all organic causes be eliminated. Functional abdominal pain (FAP) is defined as pain unrelated to an identifiable organic gastrointestinal disorder. Once a diagnosis of FAP is established, cognitive-behavioral therapy along with family-centered therapy has proved effective. Several authors have described an affective component of FAP. Furthermore, Walker and associates suggested that children with FAP are at increased risk for the development of chronic pain in adulthood. This may be due to mechanisms linked to heightened central sensitization. Amitriptyline has been described as an effective treatment of FAP in children, although a randomized prospective trial demonstrated no significant difference between control and amitriptyline.

We demonstrated the efficacy of serial nerve blocks in children with abdominal pain, particularly those in whom NP develops after abdominal surgery. The use of serially performed ultrasound-guided rectus sheath blocks or transversus abdominis plane blocks has decreased abdominal pain in our cohort. By blocking the thoracolumbar nerve roots, complete analgesia is provided to the anterior abdominal wall (see Fig. 33.5).

Ilioinguinal neuralgia following hernia repair is an underreported cause of abdominal pain in older children and adolescents and is probably secondary to major dissection during surgery. TENS may be helpful and peripheral nerve blocks can be used to manage pain. Serial ultrasound-guided ilioinguinal nerve blocks have been demonstrated to be effective. A perineural catheter may be left in place in severe cases.
CHEST PAIN IN CHILDREN

Chest pain is a common symptom in older children and adolescents. A study conducted in Belgium reported a greater preponderance in males. Most children encountered in the emergency department complain of chest tightness with pain located lateral to the sternum. In a study of 96 patients with a mean age of 13 years, 37% were noted to have idiopathic chest pain. A major life event, such as a family divorce or death of a relative, was a significant factor predisposing to chest pain in more than 30% of these children.

CAUSES OF CHEST PAIN

The most common causes of chest pain include chest wall pain (64.5%) and cardiac (5%), respiratory (13%), gastrointestinal (3%), psychological (9%), and traumatic causes (5%). After cardiac causes are ruled out with an electrocardiogram and a careful physical examination, other causes of chest pain should be considered. Each has similar initial symptoms, although the diagnostic workup may be different, depending on the physical findings (Table 33.4).

CHEST WALL PAIN

This is often seen in teenagers and is manifested as acute pain along the costal margin. The most common chest wall pain is secondary to costochondritis. The diagnosis is made by eliciting pain along the costochondral margin with deep pressure. Other chest wall pain syndromes include Tietze’s syndrome and slipping rib cage syndrome. Management usually consists of the use of NSAIDs. We have seen several patients with slipping rib cage syndrome who have not had relief despite surgical resection of the slipping rib. We use cognitive-behavioral therapy, as well as alternative therapies, including acupuncture and massage therapy, for these children. In addition, we have successfully placed intercostal nerve blocks under ultrasound guidance and achieved good relief in children with severe, recurring chest wall pain. Serial blocks are performed with adequate resources available for biofeedback and massage therapy to allay any pain-associated anxiety.

PULMONARY CAUSES

The most common respiratory emergencies manifested as acute chest wall pain occur in children with acute asthma attacks, who may have primarily chest pain without actual respiratory embarrassment. Other common causes include bronchial pneumonia and respiratory illnesses, including severe lower respiratory tract illnesses. Management includes treating the respiratory illness with antibiotics or anticholinergics and inhaled bronchodilators.

CARDIAC CAUSES

Cardiac causes of chest pain are probably the most compelling reasons for a good diagnostic workup. The most common cardiac causes of chest pain include mitral valve prolapse and the presence of dysrhythmias. Workup may include echocardiography, electrocardiography, and in some cases, Holter monitoring for diagnosis. It is important to address the pain in an expeditious manner.

ABDOMINAL CAUSES

Gastroesophageal reflux is the most common abdominal cause of continued chest pain in children. In addition, the presence of eosinophilic esophagitis should be ruled out by upper endoscopy because it can usually be treated.

PSYCHOGENIC CAUSES

Usually, there is a family history of intercurrent cardiac illness, including a recent myocardial infarction in an older family member or possibly the death of a family member from cardiac causes that can lead to chest wall pain. In most cases, adequate family therapy should be offered. With the increasing diagnostic methodologies available, the diagnosis is far more accurate in these children than several decades ago.

BACK PAIN

Back pain is a common problem in adults and is now becoming a significant health issue in children. With high-impact sports that involve a greater degree of stress on the
back muscles, such as gymnastics, children seem to have a higher degree of injuries to their back. Common back problems include spondylolysis, spondylolisthesis, disk degeneration, disk herniation, tumors of the spinal cord, and other diseases, including sickle cell disease. Classic symptoms of herniation may be seen, including radicular symptoms. Management in children is usually conservative with an emphasis on exercise for the back. We have found that a small segment of these children may require a lumbar epidural steroid injection. Alternative medicine, including massage therapy and acupuncture, is used extensively for the management of children and adolescents with back pain. These therapies are especially effective when the pain has a myofascial component.

PELVIC PAIN

Pelvic pain is often reported in female adolescents. A thorough history has to be obtained, including a history of sexual activity. Children with a history of sexual abuse have a greater preponderance of chronic pelvic pain. Though not common, a subpopulation of these adolescent girls have a history of endometriosis. This could lead to severe pelvic pain and may need to be treated more aggressively than the occasional pelvic pain. Alteration of the ovulatory cycles with birth control pills, as well as the use of strong NSAIDs, should be implemented in these patients. We have had success with the use of active massage therapy and physical therapy as adjuncts for the management of these patients.

CANCER-RELATED PAIN

Cancer remains the second leading cause of death in children. Cancer is diagnosed in more than 12,000 children annually, and 2200 children die each year of this disease. Pain is a common symptom during different phases of cancer treatment. The incidence of cancer-related pain in children at the time of diagnosis is estimated to be 75%, with ongoing pain affecting 50%. However, the incidence of pain at the terminal phase of disease is likely to be higher than 89%. Cancer pain in children is due to several reasons: (1) cancer-related pain (e.g., solid tumor or bony metastatic tumors), (2) pain caused by treatment (e.g., mucositis or surgical pain), and (3) NP secondary to tumor invasion or surgery. Pain caused by treatment and procedural pain are cited as the most frequent types of pain experienced by children with cancer.

Management of pediatric cancer-related pain must be individualized, and caregivers must be empathetic to family needs and concerns. Although more than most pain complaints can be managed by implementation of the World Health Organization (WHO) cancer pain ladder paradigm, a significant number of children may require additional therapies or techniques for pain management because of escalating or intractable pain. Only allopathic techniques are discussed in this section. The pediatric doses for most medications are off-label recommendations; dosing is based on the current pediatric clinical literature.

ORAL MEDICATIONS

Most pain management is achieved with oral maintenance dosing. Around-the-clock scheduling is supplemented with as-needed analgesic doses for breakthrough pain. Oral techniques include sublingual and transmucosal applications for breakthrough and procedural pain.

Sublingual application of morphine is as effective as intravenous morphine for pediatric postoperative pain. Because sublingual administration avoids hepatic first-pass dosing, it is comparable to intravenous administration. Sublingual morphine may be a suitable alternative to intravenous morphine for pain control in children with cancer-related pain if enteral tolerance or intravenous access is limited. Sublingual buprenorphine, 5 to 7 µg/kg per dose, has demonstrated similar analgesic efficacy as intravenous morphine, 150 µg/kg. Oxycodone concentrate prepared as 20 mg/mL is appropriate for sublingual application, but small changes in volume can mean large changes in dose. When using this concentrated formulation, an increment of 0.1 mL (from 0.2 to 0.3 mL) constitutes a 50% increase in dose; an additional 0.1-mL increase (from 0.2 to 0.4 mL) represents a 100% increase or doubling of the dose administered. Thus, prescribing dosing increments that are less than 5 mg may result in variation in the actual amount of oxycodone concentrate delivered. Oxycodone concentrate is not recommended for use in small children.

Intravenous preparations administered by the transmucosal route have been tried with some success. Oral administration of the intravenous formulation of fentanyl can achieve a pharmacokinetic distribution similar to that of oral transmucosal fentanyl citrate (OTFC) lozenges, but there is much interpatient variability. OTFC lozenges have been used for breakthrough pain and procedural pain in children. Oral mucositis pain treated with 200-µg OTFC lozenges is tolerated but ineffective in adult cancer patients.

The effective oral dosage range for postoperative pain management is 10 to 15 µg/kg for buccal application. Schechter and colleagues found 15 to 20 µg/kg of OTFC to be effective for pediatric procedural pain, but a third of the children experienced vomiting. Transmucosal oxycodone, 200 µg/kg, provides relief similar to 10 µg/kg of OTFC for procedure-related pain.

Tablets designed for buccal delivery aim to enhance bioavailability and drug uptake and speed the onset of pain relief. Hepatic first-pass effects are avoided. Studies on fentanyl effervescent buccal tablets have revealed pain relief onset times of 10 to 15 minutes. The efficacy of the system is dependent on pH because higher plasma levels are achieved at a lower pH. Another benefit of the technique is its discrete nature since the tablets are held between the cheek and gum without telltale evidence of drug intake. The buccal tablet is designed for faster onset than with oral or transmucosal delivery, so it is particularly useful in the management of breakthrough pain and may be helpful in cases of anticipated incident pain or potentially noxious activity. This formulation may be an alternative route of administration for those with an inability to swallow medications because of dysphagia or a history of pill aversion.

INTEGUMENTARY APPLICATIONS

Transdermal Delivery Systems

Transdermal delivery systems of analgesics and adjuvants can be effective for chronic pain. The ideal characteristics of a transdermal delivery system include low molecular weight,
lipophilicity, high potency, and reliable patch adhesion.\(^{211}\) The drug’s solubility in the adhesive, its diffusion coefficient, and its permeability coefficient also play major roles in the time to steady-state release into the skin.\(^{212}\) Release rates of the agent are dependent on the drug concentration and type of matrix used. A steady-state skin flux is required to yield consistent rates of drug release at zero-order kinetics. Several transdermal systems are available for opioids, \(\alpha_2\)-agonists, and anesthetics.\(^{213}\)

**Fentanyl.** Transdermal fentanyl was approved for use in children in 2002.\(^{213,214}\) A prospective study has cited improvement in pain and quality of life in children 2 to 16 years of age who had established opioid requirements for cancer and chronic noncancer pain.\(^{214}\) In pediatric oncology studies, 75% to 90% have reported that transdermal fentanyl therapy is “good” or “very good” for the relief of cancer-related pain. These findings suggest that transdermal fentanyl is effective and acceptable to children and their families.\(^{214,215}\)

**Buprenorphine.** Transdermal buprenorphine has been used for the treatment of nociceptive pain and NP. Buprenorphine is a long-acting partial \(\mu\)-opioid agonist with antagonist action at \(\kappa\)-opioid and \(\delta\)-opioid receptors. Reversal of respiratory depression and sedation from this mixed agonist-antagonist is difficult to achieve with naloxone.\(^{216,217}\) Patients with previous opioid use have experienced up to a 30% dose reduction in analgesic requirements. Pediatric tolerance is associated with marked ventilatory reduction with buprenorphine in comparison to morphine and would warrant close observation for the initial 24 hours of use.\(^{218}\)

**Clonidine.** Transdermal application of clonidine has been the most studied mode of delivery of \(\alpha_2\)-agonists. Transdermal clonidine is well studied in adults, but it is a difficult-to-use modality for the management of acute or chronic pain. Although neuraxial clonidine has a place in cancer and chronic pain management, transdermal clonidine has limited evidence of analgesic efficacy or opioid sparing.\(^{219}\) However, transdermal application does appear to increase the release of enkephalin-like substances and may therefore be an agent enhancer in balanced analgesia techniques.\(^{220}\)

**Lidoderm Patch**

The 5% lidocaine patch is a topical peripheral analgesic that has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of post-herpetic neuralgia.\(^{221}\) It has been used for nociceptive pain and NP in noncancer patients. This technique may be of use for malignancy-induced peripheral nerve disease. Unlike other transdermal delivery systems, which work by systemic uptake, the lidocaine contained in the patch penetrates the skin to act locally on damaged or dysfunctional nerves and soft tissue under the skin.\(^{221}\) Each 10- \(\times\) 14-cm 5% lidocaine patch contains 700 mg of lidocaine in an aqueous base. It should be applied to intact skin only because of the risk for possible systemic uptake. The patch is applied directly on or beside the area of pain. Patches can be cut before removal of the release liner to fit the targeted area. The recommended use is a 12-hour-on, 12-hour-off dosing schedule. It should be used with caution in patients taking oral local anesthetic antiarrhythmic drugs, such as mexiletine, to prevent additive effects. Patients sensitive to amide local anesthetics, such as bupivacaine or ropivacaine, should not use the lidocaine patch. The 5% lidocaine patch has not been studied in children.

**Topical Local Anesthetic**

**Eutectic Mixture of Local Anesthetics.** Four percent tetracaine gel and a eutectic mixture of local anesthetics (EMLA)—lidocaine and prilocaine—as a cream or patch have proved effective in relieving pain in children undergoing cancer-related procedures.\(^{222,223}\) Studies in children 3 to 21 years of age have shown these commercial preparations to be beneficial in diminishing the pain associated with lumbar puncture, venipuncture, and central port accessing.\(^{224}\) These preparations should not be used in premature infants because of the risk for local anesthetic toxicity. Plasma concentrations of lidocaine and prilocaine were well below the toxic level for each agent. Moderate plasma lidocaine levels (4.5 to 7.5 \(\mu\)g/mL) may cause restlessness, dizziness, blurred vision, or tremors. At high levels (>7.5 \(\mu\)g/mL), lidocaine can produce generalized tonic-clonic seizures.\(^{225}\) Buccal application of EMLA has not led to local anesthetic toxicity. A study in 12 subjects showed peak concentrations at 40 minutes for lidocaine and prilocaine; the maximum concentration measured in any subject was 418 ng/mL for lidocaine and 223 ng/mL for prilocaine, each below toxic plasma levels.\(^{226}\) Methemoglobinemia from prilocaine has been reported with the application of EMLA onto newly regenerated postburn or abraded skin.\(^{227}\) An occlusive dressing was also used in both cases. Methemoglobin levels below 3% are nontoxic, but skin cyanosis may occur. Levels above 3% can be associated with agitation and levels higher than 50% result in coma, seizures, arrhythmias, and acidosis.\(^{228}\) Adverse effects of EMLA include transient skin blanching, erythema, urticaria, allergic contact dermatitis, irritant contact dermatitis, hyperpigmentation, and purpura.

**Liposome-Encapsulated Lidocaine.** Another option for topical pain control before venipuncture is 4% liposomal lidocaine (L-M-X4), an over-the-counter topical local anesthetic that poses no risk for methemoglobinemia because it does not contain prilocaine. Both 4% tetracaine gel and 4% liposomal lidocaine are effective within 30 minutes of application.

**Compounding Topicals**

Creams and gels applied topically to the skin target the primary site of pain and discomfort. Pluronic lecithin organogel (PLO) is a poloxamer used for topical delivery that has a bioavailability of 10% to 60%.\(^{229}\) The advantage of using topical medications is that a high concentration of the drug is deposited exactly where it is needed, and purportedly little drug is taken up systemically. This would reduce or eliminate the usual side effects of these medications when taken orally. With a prescription, compounding pharmacies can locally prepare selected agents into topical preparations not currently available on the open market. However, variation in concentration and sterility and lack of FDA regulatory control require that caution be used with these agents. Death has resulted from the use of PLO preparations.\(^{229}\) Commonly compounded agents for topical application include NSAIDs (e.g., aspirin, ketoprofen), membrane stabilizers (e.g.,
oral management is not practical but long-term opioid require-
site of delivery every 72 hours.232 Patient-controlled analgesia
in adults and tolerated for up to 7 days, with rotation of the

(e.g., leukemia).234 It has been proposed that hyperalgesia
or nerve roots at the neuraxis are more likely to require mas-
pounded by extension of the neoplasm to peripheral nerves
factory pain control. Children with solid tumor disease com-
cancer-related pain; however, only 60% of adults achieve satis-
designed to provide adequate analgesia for most adults with
The WHO has advocated a three-step ladder approach
in situ for chemotherapy or nutrition. Because of limited
access, coadministration of analgesics with parenteral nutri-
tion solutions are not advised. Delivery of the analgesic
drug at a Y site in the central catheter system is best.

Subcutaneous Infusions
Subcutaneous infusions are considered equivalent to intrave-
nous infusions once a plasma steady state is achieved. Up to
5 mL/hr can be absorbed by subcutaneous infusion, thus mak-
ing this route of delivery feasible for pediatric cancer pain
management.251 This technique should be considered when
oral management is not practical but long-term opioid require-
ments have been substantiated. Success of this technique is
dependent on patient selection, ongoing home health care
support, and choice of analgesic drug. Highly concentrated
solutions are well tolerated and allow lower infusion rates.
Opioid concentrations of up to 30 mg/mL have been used
in adults and tolerated for up to 7 days, with rotation of the
site of delivery every 72 hours.232 Patient-controlled analgesia
(PCa) can be delivered by subcutaneous infusion if intrave-
nous access is not possible. Access via small-caliber needles,
such as a 27-gauge butterfly needle, or access with as large as
a 22-gauge tunneled intravenous catheter can be maintained
in situ for the infusion. Combined techniques of subcutane-
ous and intravenous infusion may be indicated when venous
access is limited but titration of individual agents is needed.

Intravenous Infusions
Outpatient use of intravenous opioids and adjuvants is
indicated for gastroenteric intolerance, escalating pain
inadequately controlled with adjusted oral medications, or
intolerable side effects from oral agents. Intravenous access
via peripheral catheters or central ports and catheters is often
used in situ for chemotherapy or nutrition. Because of limited
access, coadministration of analgesics with parenteral nutri-
tion should be considered to limit interruption of access and
control the risk for infection. Trissel and coworkers233 stud-
ed the compatibility of parenteral nutrition solutions with
selected drugs during simulated Y-site administration. They
reported that parenteral nutrition solutions are compatible
with many agents, including opioids, for 4 hours at 23° C.
Morphine, fentanyl, hydromorphone, and oxymorphone are
compatible via a filter with total parenteral nutrition. Despite
visual compatibility testing, admixtures of analgesics into
nutritive solutions are not advised. Delivery of the analgesic
drug at a Y site in the central catheter system is best.

Neuraxial Delivery System
The WHO has advocated a three-step ladder approach
designed to provide adequate analgesia for most adults with
cancer-related pain; however, only 60% of adults achieve satis-
factory pain control. Children with solid tumor disease com-
pounded by extension of the neoplasm to peripheral nerves
or nerve roots at the neuraxis are more likely to require mas-
sive opioid doses than are children with nonsolid tumors
(e.g., leukemia).234 It has been proposed that hyperalgesia
and NP are associated with reduced opioid antinociception
and contribute to the massive dose requirements. Systemic
morphine doses as high as 518 mg/kg/hr have been cited
in the pediatric literature.235 The use of neuraxial (epidural
and intrathecal) analgesia is indicated for the management
of cancer pain when other routes are impractical or yield
intolerable side effects. Retrospective reviews of adult and
pediatric populations suggest that neuraxial (epidural or
intrathecal) infection is a rare occurrence. A review by Straf-
ford and colleagues296 revealed no serious complications in
1620 general pediatric subjects who underwent short-term
epidural catheterization. Bacterial colonization of caudal
and lumbar epidural catheters in children has been studied
prospectively. Kost-Byerly and associates237 found a 35% col-
oration rate of epidural catheters and an 11% occurrence
of local inflammatory changes when catheters remained in
situ for up to 5 days (mean duration, 3 days). No clinical evi-
dence of epidural abscess was found, but no reports in the
literature have identified the risk factors for epidural infec-
tion.65,238 Fine and coworkers239 noted that epidural infec-
tion is rare in adult immunocompromised cancer patients.

Long-standing epidural analgesia is effective and safe for
the spectrum of cancer-related pain, as well as for terminally
ill patients, but proper management of infection risk and
strict catheter care are imperative. Tunneling of epidural
catheters is done to decrease the likelihood of infection,
 improve catheter stability, and aid patient mobility during
prolonged administration of neuraxial analgesia. One case
 report noted a 15-year-old child who received 5 months of
effective analgesia until his disease-related demise.240 A percutaneously inserted tunneled catheter connected to an
externalized pump is a feasible technique for prolonged
care (Figs. 33.6 to 33.9). Use of a 0.2-µm filter, regular chang-
ing of the pump tubing, and weekly or biweekly dressing site

Figure 33.6 Positioning for epidural placement in a child.

Figure 33.7 Percutaneous placement of an epidural.
Care performed with sterile technique may decrease the risk for infection. In a retrospective pediatric study of 25 children, the externalized catheters remained in place for up to 240 days without the occurrence of an epidural abscess or meningitis. The duration of tunneled catheter use by region was 22 days for thoracic (3 catheters), 240 days for lumbar (12 catheters), and 42 days for caudal (10 catheters).

Tunneled epidural catheters placed in patients with cancer and coexisting NP may have a higher likelihood of infection. Patients with non–cancer-related NP appear to have a higher rate of neuraxial infection than do patients with chronic noncancer pain. Hayek and colleagues reviewed 260 accounts of tunneled epidural use in 218 adult patients with NP or nociceptive pain. Because of superficial infection or suspected infection, 34 catheters were removed; 33 of those removed were in the NP group. In addition, 24 patients had infections in the epidural space confirmed by positive catheter tip cultures or epidural fluid lavage; 23 of these patients were in the NP group. The duration of catheter use was not ruled out as a contributing factor because those with NP had their catheters indwelling for a significantly longer time (28 days) than did those in the somatic pain group (16.5 days).

The risks and benefits of tunneled epidural analgesia in patients with cancer and coexisting NP should be weighed closely. It is recommended that totally implanted systems be considered for patients with NP. The signs and symptoms of epidural infection include fever, escalating back pain, back or neck ache, magnetic resonance imaging evidence of inflammation, and an elevated sedimentation rate, C-reactive protein level, and white blood cell count. Superficial infection may include local tenderness, erythema, subcutaneous phlegmon, and exudates at the exit site. The presence of an epidural abscess is confirmed by aspiration of exudates, an epidurogram with dye loculation at the catheter tip or retrograde flow, positive culture of the catheter tip, or positive

Figure 33.8 A, The epidural catheter is threaded and the second needle is tunneled to exit the initial (first needle) entry site. This is performed before removal of the first needle to avoid shearing of the catheter. B, The second needle acts as a trocar. This step can be repeated for a longer tunneled section that can be brought to the anterior. C, The first needle is removed and the catheter is threaded in retrograde fashion into the tip of the second needle and exits the hub. D, The second needle is then withdrawn.

Figure 33.9 The externalized catheter can be connected to a balloon-type pump or patient-controlled analgesia apparatus.
culture of epidural lavage material. \textsuperscript{243} Removal of the epidural catheter is indicated in those with temperatures of 39\degree C or higher and if any of the aforementioned signs and symptoms are present. \textsuperscript{237} Superficial infections are treated with a 7- to 14-day course of antibiotics. Epidural abscess management includes 6 weeks or more of intravenous antibiotics with or without neurosurgical drainage of the epidural abscess. \textsuperscript{237,243}

Analgesia via the neuraxial route is associated with less sedation and fewer adverse effects because significantly smaller doses of opioids are used. Spinal opioids provide selective pain blockade without sympathetic nervous system blockade. \textsuperscript{244} The more hydrophilic or hydrophobic opioids have limited uptake in epidural fat and its vasculature and yield greater rostral spread in cerebrospinal fluid (CSF) than do hydrophobic lipophilic opioids such as fentanyl. Intrathecal opioids bypass the bloodstream and have direct CSF spread. The onset of action of intrathecal morphine is 15 to 45 minutes. \textsuperscript{244} Delayed respiratory depression is a concern with spinal opioids. Gregory and coworkers\textsuperscript{245} noted that peak morphine levels in the medulla coincided with peak ventilatory depression 6 hours after lumbar intrathecal injection. Nichols and colleagues\textsuperscript{246} injected 0.020 mg/kg of morphine into the intrathecal space at the L4-5 interspace; this showed the greatest depressed ventilatory response to carbon dioxide at 6 hours that persisted for up to 18 hours, and infants 4 to 12 months of age responded in similar fashion to children 2 to 15 years old. Other side effects do not appear to be dose dependent and include nausea, vomiting, pruritus, and urinary retention. However, side effects are worse with intrathecal than with epidural opioids.\textsuperscript{247} The incidence of nausea and vomiting in cancer patients is lower when repeated epidural dosing is used.\textsuperscript{247}

The more commonly used adjuvants to improve pain and decrease opioid requirements include local anesthetics and \(\alpha_2\)-agonists. The literature has consistently documented appreciable pain control when clonidine is administered by the intravenous and neuraxial routes as an adjuvant to opioid or local anesthetics.\textsuperscript{248} The benefits of clonidine as an adjuvant include the following: (1) reduction in the amount of opioid required for analgesia and thus a probable decrease in side effects because of opioids; (2) titrated sedation and anxiolysis without additive respiratory depression when given in combination with opioids; and (3) vaso-dilation and improved circulation of the cerebral, coronary, and visceral vascular beds.\textsuperscript{248}

Continuous intravenous infusion of clonidine has been cited as a safe adjuvant for control of pain in adult and pediatric populations, but the question of long-term impact on neurobehavioral function has been raised. The amount of opioid required by patients experiencing procedural pain was found to be reduced by 30\%. Hemodynamic stability was maintained within normal limits because patients experienced less than a 10\% change in mean blood pressure. Clonidine has the further advantage of producing sedation associated with only small reductions in minute ventilation and has no effect on hypercapnic or hypoxic respiratory drive.\textsuperscript{249,250}

**CHAPTER 33 — PEDIATRIC CHRONIC PAIN MANAGEMENT**

There has recently been a surge in treatment modalities for pain, and treatment of children is now part of a cure-oriented and technology-based health care system. Recently, with the involvement of facilities such as hospices, the care of terminally ill children has been based on the same philosophy as that for adults.\textsuperscript{251,252} Pain can be a significant problem in children who require terminal care. When some children with a life-threatening illness have a significant setback, there may be no firm criteria to stop treatment and direct palliative care.

Alternative novel methods for providing analgesia have been used by our pain service for children who do not have intravenous access. Nebulized opioids\textsuperscript{253} or transdermal delivery systems have been used to offset pain in children with intractable pain. Adverse effects associated with the long-term use of opioids include tolerance and withdrawal. Careful rotation of opioids, along with the judicious use of other adjuvants such as N-methyl-D-aspartate (NMDA) receptor antagonists, should be considered in the care of children and adolescents.

Several approaches to pain management can be taken depending on the state of the patient, involvement of the disease process, and general state of the caregivers. PCA has been widely used in our institution for homebound patients with terminal cancer. Smaller, more user-friendly pumps have been devised for easy programming and less frequent changing. In patients who do not have venous access, we recommend the use of subcutaneous PCA. Other drugs are useful for terminally ill children. NSAIDs and steroids are particularly helpful in the management of bone pain from metastasis. Carbamazepine, gabapentin, pregabalin, and TCAs are useful for the management of NP. Hypnosis, biofeedback, and distraction techniques can be used effectively in children who are not heavily sedated.

A child’s view of death is very different from that of an adult. There is a consistent progression of the conceptual aspects of death as children grow older. A school-age child finally understands the permanence of death. Home care may be useful for the family to cope with the grief and sorrow. It also allows other siblings to spend some time with the loved one. A home care coordinator should be available for the management of any adverse conditions. Knowing the family helps the coordinator understand the goals of the family. One basic tenet of hospice care is to enable the patient to lead a full life, of the best quality, for whatever time is remaining. Cooperation between the family and caregiver should allow the child to die with as much dignity as possible. It is the responsibility of the home coordinator to provide the caregivers with enough information about the management of pain.

Targeted and titrated delivery of antinociception is becoming a reality as more receptor-specific agents are devised. More pediatric studies are needed to substantiate the use of the agents and techniques discussed for the management of cancer-related pain in children and adolescents. Regardless of how creative advancements in pain management may become, patient safety must be first. Novel applications of older agents have broadened the armamentarium of pediatric anesthesiologists and pain management specialists.

**CONCLUSION**

Chronic pain in children is an under-recognized entity. Early diagnosis and intervention are helpful in ensuring adequate
recovery. A dedicated cognitive-behavioral therapy program is a helpful adjunct to medical management and physical therapy. Complementary therapy, including massage, acupuncture, and biofeedback, can be used to reduce pain and decrease the need for additional pain medication. Interventional techniques, including serial nerve blocks, can be helpful in refractory cases. A dedicated pain treatment center facilitates adequate and early management of pain in children to ensure rapid recovery to normal function. Future research in the paradigms for managing chronic pain in children needs to be conducted to shape treatment strategies and develop novel approaches to caring for this challenging group of patients.

**KEY POINTS**

- Assessment of pain in children involves a multidisciplinary approach specifically tailored to the biomedical, psychological, and social elements of each patient and family.
- Psychological interventions can treat pain effectively by modifying the child’s cognitive, affective, and sensory experiences of pain; behavior in response to pain; and environmental and interactional factors that influence the pain experience.
- Management of pediatric complex regional pain syndrome includes physical therapy, pharmacological therapy, regional and sympathetic blockade, neuro-modulation, and psychological interventions.
- Headaches in children should be evaluated carefully to determine their cause before initiating treatment.
- Management of headache includes pharmacological therapy, cognitive-behavioral therapy, peripheral nerve blocks, and complementary therapy.
- Functional abdominal pain is best treated with cognitive-behavioral therapy, antidepressants, and serial rectus sheath or transversus abdominis plane blocks.
- Noncardiac chest wall pain may be treated with nonsteroidal anti-inflammatory drugs, cognitive-behavioral therapy, and complementary techniques, including acupuncture and message therapy. Nerve blocks may be used in refractory cases.
- Common causes of pediatric back pain include spondylosis, spondylolisthesis, disk degeneration, disk herniation, tumors of the spinal cord, and other diseases, including sickle cell disease.
- Management of pediatric cancer-related pain is individualized and based on family needs and concerns.
- Pain can pose a significant problem in children who require terminal care. Approaches to pain management are based on the state of the patient, involvement of the disease process, and general state of the caregivers.

INTRODUCTION

The population is aging, with demographic shifts resulting in a significant increase in the proportion of adults 65 years and older. The rising prevalence of many long-term conditions, of which pain is a frequent symptom, is strongly associated with advancing age. Persistent pain, which exists beyond the expected healing time, often has no identifiable physical cause and is reported by around 50% of community-dwelling older adults and up to 80% of nursing home residents. In addition to increasing age, factors associated with the development of persistent pain include sex, with women being more likely than men to report persistent pain; low income; and mental health conditions such as depression and anxiety. Obesity is a leading risk factor for development of the painful condition osteoarthritis, which affects as many as half of all older adults. Cancer-related pain is also prevalent in older adults, with cancer being the second leading cause of death in this population. Research indicates that advancing age is a strong risk factor for undertreatment of cancer-related pain. In contrast, acute pain, a sign of injury or disease, is often treatable or even curable. Unrelieved persistent pain in later life has many debilitating consequences, including psychological distress, social isolation, impaired sleep quality, physical disability, and increased risk for falls, as well as loss of independence.

Optimizing pain management is important, but in older adults this process can be complex. Consideration of an older patient’s functional capacity is essential when formulating a management plan. Cognitive deficits are common in later life and must be considered, especially in relation to the patient’s ability to reliably report pain. The presence of obstacles to the identification, assessment, and management of pain in older adults underscores the importance of paying extra attention when providing pain care to older patients. This chapter provides the reader with an overview of current thinking regarding the assessment and management of persistent pain in older adults and describes challenges that health care providers may encounter when delivering pain care to older patients.

PHYSIOLOGIC FUNCTION AND AGING

Anatomic and physiologic changes are considered a normal part of the aging process. Such changes are progressive, but concomitant injury or disease can rapidly worsen the health status of older individuals. Age-related changes in both pharmacokinetics (alteration of absorption, distribution, metabolism, and excretion of drugs) and pharmacodynamics (drug-related adverse side effects) necessitate a modified approach to pain management in older patients. Renal impairment is quite common and leads to increased half-lives of medications that are excreted by the kidneys. In addition, hepatic function can decline and thereby reduce arterial hepatic blood flow and increase the elimination time for hepatically metabolized drugs. Reductions in dose strength and the frequency of analgesic dosing are necessary to decrease the risk for toxicity. Older age is also associated with a change in the volume of distribution. Total body fat increases and total body water decreases, which translates into higher peak plasma concentrations for water-soluble drugs and prolonged half-lives for lipid-soluble drugs.

Both the peripheral and central nervous systems are affected by aging. There is a reduction in β-endorphin content and γ-aminobutyric acid (GABA) synthesis in the lateral thalamus and a reduced concentration of GABA and serotonin receptors. Speed of processing noxious stimuli and both C- and Aδ-fiber function also decrease with age, which can lead to corresponding reductions in older adults’ ability to sense and respond to "first or initial pain." As a result, older adults may have greater susceptibility to burns and other injuries such as lacerations because they are not as likely to sense the initial pain and do not respond (e.g., removing the hand) as quickly as younger adults.

ASSESSING PAIN IN OLDER ADULTS

Although accurate assessment of pain is the critical first step in the pain management process, this step can challenge even seasoned clinicians. The presence of sensory and cognitive deficits, older patients’ beliefs that pain is a natural part of the aging process, patient (or caregiver) misconceptions about the meaning of pain, and language and cultural issues can all operate as barriers to effective assessment. Barriers to assessment also occur at the provider level. For example, the belief that pain is an expected part of the aging process can lead to underassessment of pain. Inadequate provider training is likewise a commonly endorsed barrier to effective pain assessment. Furthermore, older adults typically have multiple symptoms and medical conditions, which leave health care providers little time to address pain in the context of a busy office visit. The implications of these barriers are described in subsequent sections of this
chapter. Recognizing these challenges and addressing them are important first steps in the assessment and management of pain in older adults.

Older patients should be asked routinely about pain at each visit, but because many older adults will not admit to experiencing “pain,” they should also be queried about the presence of ache, discomfort, or burning sensations. The following section outlines age-appropriate assessment tools for use with both cognitively intact and cognitively impaired older adults.

**ASSESSMENT TOOLS**

A wide range of assessment tools are available for use in older adults, many of which have been well validated (Box 34.1). Unidimensional pain scales (e.g., those that assess pain intensity only) are feasible for use in the context of a busy clinical encounter. Examples include the verbal pain descriptor (none, mild, moderate, or severe) and numerical rating scales (0 to 5 or 0 to 10), the Pain Thermometer, and the Faces Pain Scale, all of which have been validated for use in older populations, including individuals with mild to moderate cognitive impairment.18 However, it is important to remember Melzack’s famous quote: “To describe pain solely in terms of intensity is like specifying the visual world only in terms of light flux, without regard to pattern, color, texture and the many other dimensions of the visual experience.”21 Using instruments that capture the multidimensional experience of pain, including its impact on function, is therefore strongly encouraged. In terms of multidimensional measures, the Brief Pain Inventory22 and Geriatric Pain Measure23 are both appropriate for use in geriatric pain populations. The McGill Pain Questionnaire (MPQ) is another useful measure of pain quality that provides a list of 78 descriptors of pain from which the user can pick words that can later be summed to yield a sensory, effective, and evaluative overall pain score.21 This well-validated measure has been translated into many languages, thus making it particularly appropriate for cross-cultural use. A short-form of the MPQ is also available. The Short-Form MPQ (SF-MPQ) correlates well with the original MPQ and is more practical for use in the clinical setting.24

**PHARMACOLOGIC MANAGEMENT OF PERSISTENT PAIN IN OLDER PATIENTS**

Analgesic medications constitute the primary treatment used by physicians when managing older adults with persistent pain,30 and it is the most commonly reported method used by older persons with a persistent pain condition.31 For example, in one study of older black and non-Hispanic white adults with osteoarthritis, more than 80% of both groups reported regular use of prescription and over-the-counter (OTC) pain medications.31 Barriers to effective pharmacologic management of pain in older adults are diverse and include age-related physiologic changes (described earlier), which often dictates altering the dose and frequency of analgesic administration. Most older adults with a persistent pain disorder have multiple chronic conditions such as diabetes, hypertension, and osteoporosis, and they must be taken into account when formulating a treatment plan. Many older adults experience polypharmacy (defined as the use of multiple medications, with five or more being a typical threshold criterion), which frequently complicates the pharmacologic management of pain.32 Various patient sociodemographic factors can also operate as barriers. Although adequate social support enhances adherence to medication,33 many older adults live alone with limited social support. In addition, many older adults cannot afford the high cost of certain pain medications. Furthermore, substantial numbers of older adults lack the necessary skills to read and process basic health

care information, including understanding instructions on pill bottles, information present on patient handouts, and clinicians’ instructions about the side effects of medications. Low health literacy can lead to problems with medication adherence, such as taking too much or too little pain medication.

In older adults with persistent pain, commonly prescribed analgesic agents include nonopioids, opioids, and adjuvant therapies (Box 34.2). Issues related to the safety and efficacy of these three analgesic classes are summarized briefly in the following sections.

**NONOPIOIDS**

Acetaminophen is the most commonly prescribed analgesic for the treatment of mild to moderate persistent pain in older adults because of its low cost and overall safety profile. One meta-analysis found that up to 4 g of acetaminophen daily was modestly effective in reducing pain in comparison to placebo, with a standardized mean difference of −0.13 (95% confidence interval [CI] = −0.22 to −0.04). With respect to safety, acetaminophen toxicity is the leading cause of acute liver failure in the United States. Unintentional overdose remains the major cause of acetaminophen-induced hepatotoxicity, and the vast majority of affected individuals report having taken acetaminophen to treat pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) continue to be one of the most commonly prescribed and consumed analgesic agents, particularly as OTC products. One meta-analysis examining the efficacy of oral NSAIDs reported an effect size of 0.29 (95% CI = 0.22 to 0.35) for pain reduction. Although oral NSAIDs are widely considered to be more effective pain relievers than acetaminophen, NSAID use has significant limitations in the form of renal, gastrointestinal (GI), and cardiovascular toxicity, particularly in older patients. When compared with younger patients, older patients are at increased risk of experiencing GI complications in the form of peptic ulcer disease and GI bleeding. Use of either cyclooxygenase-2 (COX-2)-selective inhibitor NSAIDs (e.g., celecoxib) or nonselective NSAIDs is associated with increased risk for myocardial infarction, stroke, and mortality. These safety concerns led the American Geriatrics Society to generate an updated pain management guideline that recommends the use of nonselective or selective NSAIDs in highly selected cases only and with “extreme caution.” Given the risks associated with oral NSAID use, increasing attention has focused on the development and testing of topical NSAIDs. Two topical NSAIDs have been approved for use by the U.S. Food and Drug Administration (both are diclofenac preparations), and a number of trials testing other topical NSAID formulations are currently under way. Although no long-term studies have been published, preliminary evidence suggests that topical NSAIDs produce fewer side effects and are better tolerated than oral NSAIDs. The COX-2 inhibitors do not appear to be more efficacious than nonselective NSAIDs, and there are no data that they are better tolerated. The promise of reducing GI toxicity is also still questionable.

**OPIOIDS**

The short-term efficacy of opioids has been established in older adults for conditions such as osteoarthritis and painful neuropathies. In one meta-analysis, positive effect sizes were demonstrated for reductions in pain (effect size = −0.56, P < 0.001) and physical disability (effect size = −0.43, P < 0.001). However, the studies included in the meta-analysis were short-term (most lasted 8 weeks or less), and most excluded older adults with comorbidity, thus raising questions about the long-term efficacy and safety of opioids in typical older patients (i.e., those with multiple chronic conditions and taking multiple prescription medications). Though well accepted as a means of treating both acute and cancer pain, opioid analgesics remain controversial in the treatment of persistent non–cancer-related pain. Solomon and colleagues used Medicare claims data to examine the safety of selective and nonselective NSAIDs versus opioids for nonmalignant pain. Patients receiving selective NSAIDs or opioids experienced more adverse cardiovascular outcomes than did nonselective NSAID users. Although both nonselective and selective NSAID users had similar risk for fractures, opioid users were found to have a significantly increased risk for fractures, adverse events requiring hospitalization, and all-cause mortality. Study limitations included concerns about an inability to control for certain confounders (e.g., OTC analgesic use, functional status, cognitive deficits) and an inability to quantify the risk associated with distinct patterns of analgesic use. Despite these limitations, the findings provide strong support for additional studies to quantify both the risks and the benefits of opioid use (vs. other types of analgesics) when treating persistent pain disorders in older adults.

**ADJUVANT AGENTS**

Commonly administered adjuvants include both antidepressants and anticonvulsants, and they are typically prescribed to treat neuropathic pain. Tricyclic antidepressants such as nortriptyline and desipramine are effective for the treatment of diabetic neuropathy and post-herpetic neuralgia. Although the use of low doses can mitigate the occurrence of side effects, many older adults experience treatment-limiting anticholinergic side effects in the form of dry mouth, urinary retention, and constipation, as well as increased risk for falls. Duloxetine, a selective serotonin-norepinephrine reuptake inhibitor (SSNRI), has also been shown to be effective in the treatment of diabetic neuropathy and to have a superior safety profile relative to the tricyclic antidepressants. Venlafaxine, also an SSNRI, has been shown to be effective

in lowering pain levels in patients with painful diabetic neuropathy. Nausea is a commonly reported side effect with both SSRI agents. Anticonvulsants (pregabalin and gabapentin) may be useful in treating neuropathic pain disorders in older adults. However, side effects in the form of sedation, confusion, and peripheral edema can limit the use of these medications in older patients.

PRACTICE RECOMMENDATIONS

For many classes of pain-relieving medications, older patients have been shown to have increased analgesic sensitivity. However, it is important to remember that older adults constitute a highly heterogeneous group, so dosing guidelines need to be based on careful consideration of a patient’s pain, its impact on functional status, and the patient’s comorbid conditions and other factors (e.g., polypharmacy and sociodemographic and health literacy issues). There are currently no geriatric-specific dosing guidelines. Since advancing age is associated with a greater incidence of treatment side effects, the adage “start low and go slow” is a reasonable rule of thumb when initiating a trial of an analgesic in older patients. This does not mean that one should “start low and stay low,” which can contribute to undertreatment. Sustained-release analgesic preparations are recommended for continuous pain, along with the use of short-acting agents to treat pain flares and breakthrough pain. Although long-acting agents are more convenient (and probably associated with greater adherence), there is no evidence that they provide better pain relief.

If treatment goals are not being met and the patient is tolerating the therapy, advancing the dose is reasonable before prescribing another therapy.

NONPHARMACOLOGIC AND SELF-MANAGEMENT APPROACHES TO MANAGING PERSISTENT PAIN

A range of nonpharmacologic pain management (NPM) modalities are available and should be considered when managing pain in older patients. Strategies popular among older adults include exercise, the application of heat or cold, and nutritional supplements. The American Geriatrics Society guideline recommends NPM as an adjunctive treatment to pharmacologic management. The guideline specifically advises practitioners to consider recommending exercise, cognitive-behavioral therapy (CBT), and patient education for long-term pain management. Complementary and alternative approaches such as massage, transcutaneous electrical nerve stimulation, or acupuncture may be initiated on a trial basis to find strategies that offer short-term relief in the event of pain flare-ups. Fear of pain can result in avoidance of movement and consequentially reduced physical function, which exacerbates the pain experience. With regular moderate exercise, older adults can increase physical function, slow physical deterioration, and improve joint range of motion. Prescribed exercise should be individualized, be supervised for those with either severe pain or significant physical disability, and include flexibility, strength, and endurance exercises. Poor coping skills and negative beliefs about pain and its management make managing persistent pain difficult regardless of patient age. CBT is a psychological therapy that aims to promote and reinforce self-management and positive health behavior and pain beliefs. CBT is recommended for older adults with persistent pain disorders and can be provided as a structured, professionally led program that can be delivered on an individual or group basis, face to face or online. However, the limited number of providers skilled in delivering CBT may restrict the availability of this particular therapy.

Most older adults express a willingness to try new strategies and voice preference for self-delivered strategies that promote independence and control. An increasing number of papers on the management of persistent pain in older adults have been published, and there is increasing awareness that self-management of persistent pain is a viable strategy for older populations. The American Geriatrics Society guideline recommends encouraging older patients to locate information about self-help strategies and participate in pain education to increase awareness of pain treatments and skills important in pain management, such as goal setting. Pain self-management is a patient-centered process that involves the acquisition, practice, and execution of skills needed to respond to and control pain and its associated symptoms. Successful and optimized pain management requires that older patients be confident and able to manage the everyday symptoms and consequences of pain. To achieve this, older patients must adopt responsibility for managing their pain, along with support from others. Identifying older patients who are already effective self-managers and those who would benefit from additional support remains a difficult area, however. Self-efficacy, or confidence in one’s ability to self-manage pain, is an important psychological predictor of an individual’s capability for effective self-management and can be assessed in the clinical setting. Other factors, such as pain beliefs, attitudes, and motivation, also influence participation in self-management. For older patients who require additional support, a variety of materials and interventions are available, including professional or lay-led group courses (delivered in person or online), educational resources (i.e., workbooks, leaflets, and CDs), and self-help groups. The efficacy of self-management programs for older adults that specifically focus on generalized management of persistent pain remains controversial, with some reviews suggesting little patient benefit. Conversely, disease-specific programs, such as those developed for arthritis, have demonstrated more consistent benefit, including moderate reductions in pain and enhanced psychological well-being. Decisions on how best to support older patients’ self-management will largely be determined by what is available and accessible to the patient locally, but to the extent possible, older patients should be encouraged to choose between available formats and select individual strategies that best meet their needs.

Older patients’ use of NPM and self-management strategies varies extensively, and barriers include a lack of advice and support from their primary care providers, affordability of and access to certain strategies, and the pain management attitudes of professionals, older patients, and their caregivers. It is important that clinicians discuss NPM and self-help strategies with older patients. These strategies can improve quality of life and reduce pain and the associated impact of pain on daily life through the adoption of
positive pain behavior and coping responses. Although many strategies may appear harmless, unknown risks may exist. For example, some dietary supplements or herbal remedies may pose a risk to older patients when taken with particular pharmacologic agents. It is therefore imperative that clinicians ascertain the full extent of their older patients’ pain and pain management experiences and consider cultural, lifestyle, and socioeconomic factors that may influence these experiences. This must be done in a manner that identifies the use of risky NPM strategies that have the potential to cause harm but still encourages patients to play an active role in the management of their pain.

OTHER IMPORTANT BARRIERS TO SUCCESSFUL PAIN MANAGEMENT IN OLDER PATIENTS

PATIENT AND PROVIDER BELIEFS AND ATTITUDES ABOUT AGING AND PAIN

Certain beliefs that older patients and providers have about pain and pain treatments may negatively influence their expectations, behavior, and decisions regarding treatment recommendations (at the provider level) and engagement or adherence (at the patient level). As noted, many older individuals believe that pain is a natural part of getting older. Previous studies have also demonstrated that some older adults believe that pain only gets worse over time, whereas others believe that treatment of pain is not likely to provide any meaningful benefit. Beliefs such as these can lead to stoicism or acceptance of the status quo. Although relatively little research has examined whether these beliefs are associated with specific health behaviors, it is likely that such beliefs can negatively affect an older patient’s willingness to seek treatment or adhere to a recommended treatment plan. Indeed, one study found that participants who endorsed the belief that nothing can be done for one’s arthritis were significantly less likely to have a regular physician. This finding suggests that beliefs about persistent pain can negatively affect an older patient’s treatment-seeking behavior. Previous research has also shown that some older adults endorse beliefs about pain medications that may decrease their willingness to engage in or adhere to pharmacologic interventions. For example, some older adults use pain medications sparingly because of a fear of addiction or dependence. Older patients’ caregivers, often a spouse or an adult child, can also voice fears about the possibility of addiction in older patients. Finally, some older adults believe that the use of pain medication invariably results in harmful side effects. Older adults with pain who endorse this belief report minimizing medication use except when the pain is “very bad.”

From the perspective of health care providers, practitioners may also approach pain as though it were an inevitable symptom associated with the aging process and give older patients advice such as “what do you expect, you’re just getting older.” Other research has documented that health care providers are often reluctant to prescribe opioid medications for older patients with non–cancer-related pain because of fear of causing patient harm. Other provider barriers include the absence of objective methods of determining whether a patient is experiencing pain and fear of contributing to addiction or dependence. Although clinicians should remain vigilant about the possibility of misuse or abuse of opioid agents in all patients irrespective of age, it is important to note that advancing age is associated with a significantly decreased risk for opioid misuse or abuse. Indeed, some authors suggest that underuse of opioids in older populations constitutes a bigger problem.

SENSORY IMPAIRMENT

Sensory impairment is common in older adults and can have a negative impact on the management of pain. As many as 30% of older adults experience visual impairments in the form of cataracts, macular degeneration, and diabetic retinopathy, which can make reading prescription labels or participating in recommended exercise programs difficult. Use of good lighting in patient examination rooms, asking older patients to wear eyeglasses to appointments, and providing reading material in large font can help mitigate the negative impact of poor vision on pain care. Hearing impairments are also common. As many as 40% of adults 75 years and older experience hearing problems as a result of conductive or sensorineural hearing loss (or both). Hearing problems can make it hard to communicate a treatment plan during a clinical encounter (e.g., discussing the risks and benefits of a given analgesic). Use of handheld amplifiers, speaking slowly while facing older patients directly to allow lip reading, and providing written instructions can help decrease the negative impact of hearing loss when managing pain in older adults with hearing deficits.

COGNITIVE IMPAIRMENT

Pain in older patients with cognitive impairment is common, under-recognized, and undertreated. Cognitively impaired older patients have been shown to receive significantly less opioid and nonopioid analgesia than cognitively intact older adults. Numerous barriers exist to providing appropriate analgesia to this group, both at the patient level and at the provider level. Cognitively impaired older patients have been shown to under-report pain. Communication is a major challenge to both assessing and managing pain in this patient population. Short-term memory impairment can alter the interpretation of pain and the response to treatment modalities and thereby potentially lead to increased doses of analgesics and associated side effects. Manifestation of pain in cognitively impaired older patients can also vary, from behavioral disturbances such as lethargy and physical aggression to more expected reactions such as groaning and grimacing.

For health care providers, a diagnosis of cognitive impairment creates additional challenges to assessing pain in older adults. Studies have documented a failure to assess for pain and provider lack of trust in actual reports of pain by this vulnerable population. Provider fear of precipitating medication-induced adverse effects and exacerbating underlying clinical conditions also leads to undertreatment. General principles for pharmacologic management of pain in cognitively impaired older patients include a collaborative assessment of pain; administration of around-the-clock analgesics; frequent reassessment of the verbal, behavioral,
and functional responses to treatment; and timely titration of analgesics. Reviewing side effect profiles of the pharmacologic agents, starting with low doses, and initiating a prophylactic bowel regimen with opioid use are equally important strategies.

In addition to pharmacologic management, nonpharmacologic therapies should be instituted concurrently, including physical techniques, such as repositioning; use of heat and cold, massage, transcutaneous electrical stimulation, and therapeutic touch, as well as behavioral modifications such as distraction, relaxation, and guided imagery. Research evaluating their use in the cognitively impaired population is limited; however, based on their efficacy in cognitively intact older adults, their general use can be inferred in this population. Choosing the appropriate complementary therapy should be individualized inasmuch as the level of cognitive impairment may limit the use of certain interventions, particularly behavioral modifications. Sensory techniques such as music and art therapy represent emerging approaches in NPM that are being piloted in older adults with cognitive impairment.

As a framework to help providers conceptualize older patients’ culturally informed views about illness and pain, several models are useful, including the “health belief model” and the “explanatory model” (EM). The health belief model focuses on individual patients’ views about their health, as well as barriers to and facilitators of illness behavior. The EM hails from medical anthropology. The EM approach highlights the different views of health and illness held by older patients and providers because all individuals possess their own EM, which includes a person’s views about health and behavior. An approach using an EM places more emphasis on cultural and social factors than the health belief model does. Treatment is more likely to be appropriate when a patient’s EM accords with that of the provider, but providers can take steps to understand the content of a patient’s EM. Since EMs are socially and culturally grounded, a person’s EM can change over time for a number of reasons, including migration or other experiences through the course of life. Within a pain management context, finding out about a patient’s EM would mean asking open questions about the patient’s views on the origins and cause of the pain, the meaning and impact of the pain, and the patient’s views about appropriate treatment and treatment goals. Attempts to systematize the elicitation of patients’ EMs have not provided a single “recipe” of questions because appropriate questions will depend on the context and goals of the health care encounter. However, when assessing and managing pain, it is important to understand that highlighting these general areas by an EM approach may be critical in achieving shared decisions and acceptable pain care.

Although language and ethnicity are not synonymous, some older members of ethnic minorities may need additional help in communicating or the services of interpreters (“translators”) within health care. Recent and older immigrants may find health care challenging if they do not achieve competence in the dominant language and may rely on family or friends as means of accessing health care. The presence of an interpreter may influence a consultation, not only because of the accuracy of language translation but also because of social roles in the health care interaction, which may be influenced by age, sex, and position in a social hierarchy. Interpreters are invaluable in assisting health care providers to work with patients to facilitate effective, acceptable care. Building good relationships with interpreters may help health care providers in this context.

**PROVIDING PAIN CARE TO OLDER PATIENTS WHO BELONG TO AN ETHNIC MINORITY GROUP**

Pain assessment and management take place in increasingly multiethnic settings. Pain specialists may find themselves providing pain care to recent immigrants or long-standing minority groups or may work in societies that are not their “own.” Appreciating cultural diversity in older patients’ pain beliefs and behavior can help in providing appropriate and acceptable pain care.

Older adults who are members of ethnic minorities face particular barriers to adequate pain management. Older members of some ethnic minority groups have a higher prevalence of certain forms of persistent pain, may be less inclined to seek help for their pain, and are less likely to receive adequate intervention. Reasons for the established disparities in pain management are complex but include socioeconomic disadvantage, discriminatory health care systems, and pain beliefs and behavior. Beliefs and behavior are further affected by factors such as acculturation, time since migration and sex. Socioeconomic disadvantage and broader discriminatory systems are not easily addressed by providers. However, in their clinical practice, providers are well positioned to improve pain assessment and management for members of ethnic minority groups.

Cultural variation in how patients understand and communicate their pain has been well documented. A classic study by Zborowski suggested that members of American ethnic groups (i.e., Italian, Jewish, Irish, and “Old American”) exhibit different emotional responses to pain and have varying attitudes to pain medication. More recent research continues to draw similar conclusions about diverse ethnic groups. Although such work highlights differences, it is important not to use reports of diversity as a basis for stereotyping members of different ethnic groups in practice. Stereotyping has the potential to obscure individual variation and to foster discriminatory practices.

**KEY POINTS**

- A wide range of validated tools are available to assess pain in older adults, including those with cognitive impairment.
- A multidimensional approach to pain management is imperative, just as in younger patients.
- Providers need to be aware of and work to address barriers that often occur in assessing and managing pain in this age group, such as physical and cognitive impairment and social and cultural issues.
- The full range of available pharmacologic and nonpharmacologic pain management approaches should be considered.
KEY POINTS—cont’d

• Although increased analgesic sensitivity occurs with advancing age, older adults constitute a highly heterogeneous group, so dosing guidelines need to be based on a careful consideration of an older patient’s pain, its impact on functional status, and the patient’s comorbid conditions and other factors (e.g., polypharmacy).
• Providers are strongly encouraged to support older patients’ efforts to become active participants in their own care.

Almost all women will experience pain during pregnancy. Common musculoskeletal conditions can cause severe pain in an otherwise uncomplicated pregnancy. Some women will enter pregnancy with preexisting painful disorders, and management of the ongoing pain and painful exacerbations can be challenging. This chapter reviews the common painful musculoskeletal conditions of pregnancy and an approach to the management of chronic pain during pregnancy and in breastfeeding mothers.

USE OF MEDICATIONS DURING PREGNANCY

Medical management of pregnant patients should begin with attempts to minimize the use of all medications and use nonpharmacologic therapies whenever possible. When opting for drug therapy, the clinician must consider any potential for harm to the mother, the fetus, and the course of the pregnancy. The degree of protein binding and lipid solubility of the medication, the speed of maternal metabolism, and molecular weight all affect placental transfer of medications from mother to fetus. With the exception of large polar molecules (such as heparin and insulin), as well as ionized molecules (glycopyrrolate), almost all medications will reach the fetus to some degree.

Approximately 3% of newborns will have a significant congenital malformation. Only 25% of fetal malformations have a known genetic cause, and just 2% to 3% have a clear environmental link, such as maternal medication exposure during organogenesis. One of the major limitations in evaluating any medication’s potential for causing harm to a developing human fetus is the degree of species specificity for congenital defects. A classic example of such specificity is the drug thalidomide; nonprimate studies revealed no teratogenic effects, but severe limb deformities occurred in human offspring when thalidomide was prescribed during pregnancy.

The most critical period for minimizing maternal drug exposure is during early development, from conception through the 10th menstrual week of pregnancy (the 10th week following the start of the last menstrual cycle). Drug exposure before organogenesis (prior to the fourth menstrual week) usually causes an all-or-none effect—the embryo either does not survive or develops without abnormalities. Drug effects later in pregnancy typically lead to single- or multiple-organ involvement, developmental syndromes, or intrauterine growth retardation. Certain medications may not influence fetal organ development directly but have the potential to influence the physiology of pregnancy adversely. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) may delay the onset of labor, decrease amniotic fluid volume, or place a newborn at risk for pulmonary hypertension or renal injury.

The U.S. Food and Drug Administration (FDA) has developed a five-category labeling system for all approved drugs in the United States (Table 35.1). This labeling system rates the potential risk for teratogenic or embryotoxic effects based on available scientific and clinical evidence. It is important to note that the FDA classification system has been revised to address neonatal influences other than teratogenicity. For example, ibuprofen is associated with decreased amniotic fluid and constriction of the ductus arteriosus. In fact, many NSAIDs used to be class B before 30 weeks and class D after 30 weeks. More recently, this has changed to class C before 30 weeks and class D thereafter. Because few medications have undergone large-scale testing during human pregnancy, most are category C, which indicates incomplete knowledge of the potential for benefit and harm with drug therapy. More specifically, our present knowledge about the adverse effects of uncontrolled pain, as well as the risks associated with administering medications during pregnancy, remains incomplete, and the physician is left to weigh the risks against the benefits of instituting pharmacologic therapy for each individual.

USE OF MEDICATIONS IN BREAST-FEEDING MOTHERS

The same physicochemical properties that facilitate transplacental drug transfer affect drug accumulation in breast milk. High lipid solubility, low molecular weight, minimal protein binding, and the un-ionized state all facilitate excretion of medications into breast milk. The neonatal dose of most medications obtained through breastfeeding is 1% to 2% of the maternal dose. Even with minimal exposure via breast milk, neonatal drug allergy and slower infant drug metabolism must be considered. Only small amounts of colostrum are excreted during the first few postpartum days; thus, early breastfeeding poses little risk to an infant whose mother received medications during delivery.

Most breast milk is synthesized and excreted during and immediately following breastfeeding. Taking medications after breastfeeding or when the infant has the longest interval between feedings and avoidance of long-acting medications will minimize drug transfer via breast milk. However, effective treatment of chronic pain often necessitates the
use of long-acting medications, particularly long-acting opioids. To aid physicians in drug selection and to provide advice to lactating mothers, the American Academy of Pediatrics has categorized medications in relation to the safety of ingestion by breastfeeding mothers (Table 35.2). Although many common pain medications are listed as category 3 (compatible with breastfeeding), psychotropic medications, which are used frequently for the treatment of chronic pain, are category 2, for which the effects are unknown and caution is urged.

### MEDICATIONS COMMONLY USED FOR PAIN MANAGEMENT

#### NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs have both analgesic and anti-inflammatory properties and are commonly used for musculoskeletal pain. Although the exact mechanism of action is uncertain, NSAIDs decrease pain by acting as nonselective inhibitors of cyclooxygenase and thereby inhibiting prostaglandin synthesis. During pregnancy, prostaglandins modulate many key processes, including stimulating uterine activity, maintaining patency of the fetal ductus arteriosus (essential for adequate in utero blood flow), and promoting fetal urine production (which contributes to the level of amniotic fluid in the second and third trimesters). As expected, alteration of prostaglandin metabolism then has varied effects on the pregnancy, depending on the timing and duration of use. For example, short-term use of indomethacin in the second trimester is effective for the treatment of pain caused by degenerating fibroids; use for long periods (more than 48 hours) in the third trimester has been associated with narrowing of the ductus arteriosus and oligohydramnios. To complicate this picture further, aspirin, the prototypical NSAID, is used in a therapeutic manner in low doses (80 to 160 mg/day) to decrease the incidence of pregnancy complications in certain high-risk groups but is associated with premature narrowing of the ductus arteriosus at higher doses. Therefore, NSAID use in pregnancy must be carefully planned to achieve the proposed benefit and avoid fetal risk. In general, if NSAID use is indicated, the duration should be short (less than 48 hours) in the absence of monitoring of fetal ductus flow and amniotic fluid volume. All NSAID use for pain should be discontinued by 34 weeks’ gestation to prevent pulmonary hypertension in the newborn.

NSAIDs are among the most frequently used drugs during the first trimester of pregnancy. Over-the-counter use of these medications is very common in this population. With their use so common, many women may not realize that there is a potential for deleterious effects on them or their developing fetuses. Furthermore, as the age of first-time

FDA, U.S. Food and Drug Administration.
mothers increases, more women are likely to take NSAIDs for conditions such as joint and musculoskeletal pain. The effects of fetal exposure to NSAIDs in the third trimester are well documented, and they are associated with premature narrowing of the ductus arteriosus, which can lead to pulmonary hypertension in the newborn. However, there is controversy regarding the risk associated with maternal exposure and other congenital anomalies.18

There is no role for the routine use of NSAIDs for pain other than that related to rheumatologic disease or uterine fibroids. In the largest published series of NSAID use during pregnancy to date, Ostensen and Ostensen19 detailed a series of 88 women with rheumatic disease and compared the outcomes of 45 who received NSAID therapy during pregnancy with the outcomes of 43 who were not treated during pregnancy. The most common agents used were naproxen (23/45) and ibuprofen (8/45). NSAIDs were most frequently used during the first and second trimesters because many patients stopped therapy once pregnancy was recognized; many of the rheumatic conditions remitted later in pregnancy. They found no significant differences in pregnancy outcome (duration of pregnancy and labor, vaginal delivery rate, maternal bleeding requiring transfusion, or incidence of congenital anomalies) or the health status of offspring at long-term follow-up (ranging from 6 months to 14 years). The authors concluded that NSAID therapy limited to periods of active rheumatic disease until weeks 34 to 36 did not adversely affect the neonate.19 It is of note, however, that women with rheumatic disease have poor pregnancy outcomes in general, so these outcome data should not be applied to the general obstetric population.

More recently, Ofori and colleagues18 published a case-control study of the risk for congenital anomalies in pregnant users of NSAIDs. Using a population-based pregnancy registry from 1997 to 2003 in Quebec, they identified 93 births with congenital anomalies in 1056 women (8.8%) who filled prescriptions for NSAIDs in the first trimester of pregnancy versus 2478 in 35,331 (7%) women who did not. They concluded that there may be a greater risk of NSAID users having children with congenital anomalies, particularly those related to cardiac septal closure.

Despite the physiologic effects of NSAIDs, the results of the Collaborative Perinatal Project suggested that first-trimester exposure to aspirin does not pose appreciable teratogenic risk,20 nor does ibuprofen or naproxen, the most commonly used NSAIDs. Patients who conceive while taking NSAIDs can be reassured that this will not impair the outcome of the pregnancy. However, NSAIDs can interfere with implantation and placental circulation. In a population-based cohort study, the risk for miscarriage was 1.8 (95% confidence interval [CI] = 1.0 to 3.2) with any NSAID use and increased to 8.1 (95% CI = 2.8 to 23.4) if used for more than 1 week around the time of conception.21

Aspirin has well-known platelet-inhibiting properties and, theoretically, may increase the risk for peripartum hemorrhage. Neonatal platelet function is inhibited for up to 5 days after delivery in aspirin-treated mothers.22 Although low-dose aspirin therapy (60 to 80 mg/day) has not been associated with maternal or neonatal complications, higher doses appear to increase the risk for intracranial hemorrhage in neonates born before 35 weeks’ gestation.13 Low-dose aspirin has been used to improve pregnancy outcomes in women with both preeclampsia and antiphospholipid antibodies.23 However, as with other NSAIDs, aspirin crosses the placenta. Even though it has not been implicated in causing congenital abnormalities, it has been associated with an increased risk for vascular disruptions, particularly gastrochisis.21,24 Data from two retrospective meta-analyses suggest that there may be a twofold to threefold increased risk for gastrochisis with aspirin exposure.24,25 However, reassuring data from more than 30,000 women enrolled in randomized, controlled trials of low-dose aspirin versus placebo have not shown any significant risk for intraventricular hemorrhage, other neonatal bleeding, or poor pregnancy outcomes.25

Ketorolac is an NSAID available for oral and parenteral administration. According to the manufacturer’s prescribing information, ketorolac did not cause birth defects in the offspring of pregnant rabbits. However, ketorolac administration during labor did lead to dystocia in rodents. Ketorolac shares the platelet-inhibiting properties of other NSAIDs. Although ketorolac has not undergone evaluation for its effects on the fetal ductus arteriosus or renal vasculature, it is likely to have effects similar to those of other NSAIDs. Until more information is available, it may be prudent to choose the more extensively studied NSAIDs for use during pregnancy.

Based on our clinical experience and a review of the available literature, we have formulated guidelines for the use of NSAIDs during pregnancy (Box 35.1). NSAID use in pregnancy must be planned carefully to achieve benefit and avoid fetal risk. In general, if NSAID use is indicated, the duration should be short (48 hours) in the absence of monitoring of fetal ductus flow and amniotic fluid volume. Chronic use of NSAIDs should be avoided in pregnancy, especially in the third trimester. Before the 24th week of pregnancy, NSAIDs should be used with caution. It is preferable to use both low-dose and short-half-life NSAIDs.

Because of the antiplatelet properties of NSAIDs, many anesthesiologists are concerned about the risk for epidural hematoma formation as a result of epidural catheter placement. To date, there are no outcome studies on which to base recommendations. There is no evidence that low-dose aspirin therapy or the use of other NSAIDs increases the risk for epidural hematoma formation following spinal or epidural placement. As part of our routine history and physical examination of parturients, we screen for any evidence of bleeding diathesis or easy bruising and, in their absence, proceed with epidural placement without further laboratory testing. This practice is consistent with the guidelines published by the American Society of Regional Anesthesia.

In breastfeeding women, salicylate transport into breast milk is limited by its highly ionized state and high degree of protein binding. Caution should still be exercised if more than occasional or short-term aspirin use is contemplated during lactation because neonates have very slow elimination of salicylates. High-dose aspirin can lead to rashes, platelet abnormalities, and bleeding in nursing infants. The American Academy of Pediatrics considers diclofenac, flunixin, ibuprofen, indomethacin, naproxen, ketorolac, piroxicam, and tolmetin to be compatible with breastfeeding. Both ibuprofen and naproxen are also minimally transported into breast milk and are considered compatible with breastfeeding; these agents are generally better tolerated than indomethacin. Little information is available on the safety of maternal ketorolac use during lactation. One study found that ketorolac concentrations ranged from 1% to 4% of maternal serum levels in breast milk. Analysis of breast milk in 10 women given ketorolac, 10 mg orally every 6 hours for 4 days, resulted in clinically insignificant levels that the nursing infant would be exposed to. Taking into account the bioavailability of ketorolac after oral administration, this would probably result in neonatal blood levels between 0.16% and 0.40% of the maternal dose. The American Academy of Pediatrics considers ketorolac to be compatible with breastfeeding.

Acetaminophen is a analgesic and antipyretic drug used frequently by pregnant women. It provides similar analgesia without the anti-inflammatory effects seen with NSAIDs. Acetaminophen has no known teratogenic properties, does not inhibit prostaglandin synthesis or platelet function, and is hepatotoxic only in extreme overdosage. As with most drugs, there are no controlled studies in pregnant women in the first trimester. In animal studies, acetaminophen has not demonstrated fetal risk. Data obtained from 88,142 patients in the Danish National Birth Cohort (1996 to 2003) who had information on acetaminophen use during the first trimester of pregnancy indicated that ingestion of acetaminophen during pregnancy is not related to an overall increased prevalence of congenital abnormalities or to an increased prevalence of the most frequent abnormalities. If persistent pain demands use of a mild analgesic during pregnancy, acetaminophen appears to be a safe and effective first-choice agent. Acetaminophen does enter breast milk, although maximal neonatal ingestion would be less than 2% of a maternal dose. Acetaminophen is considered compatible with breastfeeding.

**OPIOID ANALGESICS**

Many women of childbearing age are prescribed opioids for the management of intermittent or continual pain. In the United States, more than half of pregnancies are unplanned, which can lead to fetal medication exposure before a woman knows that she is pregnant. Much of our present knowledge about the effects of chronic opioid exposure during pregnancy is derived from the study of opioid-abusing patients. Chronic opioid use in pregnancy is associated with low birth weight and decreased head circumference, although the contribution of comorbid conditions, including polysubstance abuse and smoking, is not clear. Enrollment and compliance with methadone therapy for opioid dependence improve birth weight and prolong gestation, thus supporting the role of therapy during gestation.

Until recently there was no evidence to suggest a relationship between exposure to any of the opioid agonists or agonist-antagonists during pregnancy and large categories of major

---

**Box 35.1 Guidelines for Use of NSAIDs during Pregnancy**

- Consider nonpharmacologic management or acetaminophen use first.
- Consider use of a mild opioid or opioid-acetaminophen combination analgesic.
- Continue aspirin or other NSAID if the symptoms cannot be controlled nonpharmacologically or with acetaminophen alone.
- Institute close fetal monitoring during the second trimester. If high doses of NSAIDs are required, periodic fetal ultrasound, including fetal echocardiography, should be used to monitor amniotic fluid volume and patency of the ductus arteriosus.
- Discontinue NSAID use after weeks 34 to 36 to reduce the risk for peripartum bleeding, neonatal hemorrhage, and persistent fetal circulation.

NSAID, nonsteroidal anti-inflammatory drug.
or minor malformations. The Collaborative Perinatal Project monitored 50,282 mother-child pairs and studied exposure to codeine, propoxyphene, hydrocodone, meperidine, methadone, morphine, and oxycodone. Only codeine was found to have an association with malformation (respiratory), but this has not been confirmed by other studies. No evidence was found for either agent to suggest a relationship to large categories of major or minor malformations. In spring 2011, a study by Broussard and colleagues used data gathered from the National Birth Defects Prevention Study (1997 to 2005), which consisted of an ongoing multisite, population-based, case-control study of more than 30 types of major structural birth defects. They reported that opioid treatment from 1 month before pregnancy through the first trimester was associated with a greater risk for conoventricular septal defects, atrioventricular septal defects, hypoplastic left heart syndrome, spina bifida, and gastrochisis. Codeine and hydrocodone represented 69% of all reported exposures. However, these results should be interpreted with caution because some sample sizes were borderline and further investigation is necessary. It is important to understand that the increased relative risk for a rare birth defect with exposure to medications usually translates into only a modest absolute increase in risk above baseline. All opioid analogues are now teratogenic risk category C when used for a short time. It is critical that health care providers weigh the risks and benefits when prescribing opioids to pregnant women or to those of childbearing age.

It is important to note that all opioid medications are risk category D when used for long periods during pregnancy. This increased risk warning is due to the potential for neonatal opioid dependence when mothers are treated with opioid medications for prolonged periods during pregnancy. Abrupt cessation of opioids by an opioid-dependent patient late in pregnancy can precipitate fetal withdrawal in utero, which is characterized by fetal tachycardia and fetal death. Therefore, pregnant women who are opioid dependent, regardless of whether use is prescription or illicit, should not undergo acute withdrawal late in pregnancy without careful fetal monitoring. The general recommendation is to offer continuation of narcotic medication (for prescription use) or opioid substitution therapy such as methadone or buprenorphine plus entry into treatment programs for women using illicit drugs. Additional benefits of treatment programs include improved prenatal care, higher birth weight, and reduction of infectious risk to the neonate.

Neonates exposed to opioid medications in utero can develop dependence and manifest withdrawal symptoms in the first few days of life, known as neonatal abstinence syndrome (NAS). Although NAS is characterized by irritability and increased tone in mild cases, severe neonatal withdrawal is associated with poor feeding and seizures. NAS occurs in 30% to 90% of infants exposed to heroin, methadone, or buprenorphine in utero when mothers are treated for illicit opioid use. Patients requiring methadone for the treatment of chronic pain tend to require lower doses of methadone, and their infants have a lower incidence of NAS, approximately 11%. Most infants who undergo narcotic withdrawal are symptomatic by 48 hours postpartum, but there are reports of withdrawal symptoms beginning 7 to 14 days postpartum. Neonates with prenatal exposure to opioids for long periods may require very slow weaning (as slow as a 10% reduction every third day) to prevent withdrawal symptoms. The American Academy of Pediatrics considers methadone to be compatible with breastfeeding.

Recognition of infants at risk for NAS and institution of appropriate supportive and medical therapy typically result in little short-term consequence to the infant. The long-term effects of in utero opioid exposure are unknown. Chasnoff considered the environmental and socioeconomic factors that influence child development and concluded that no definite data demonstrate long-term developmental sequelae from in utero opioid exposure.

Buprenorphine, a partial μ-opioid agonist and κ-opioid antagonist, is currently used for office-based treatment of opioid dependence but is increasing in use for the treatment of chronic pain. Obstetricians and anesthesiologists will therefore encounter patients treated with buprenorphine with increasing frequency. This drug’s low intrinsic receptor efficacy results in a ceiling effect and diminished risk for overdose when compared with methadone. Although methadone has been used for more than 40 years for the treatment of opioid dependence, buprenorphine has recently been advocated as first-line therapy. The literature reporting use of buprenorphine in pregnancy remains limited, but buprenorphine has been found to be superior to methadone in reducing signs of withdrawal in newborns, thus requiring less medication and hospitalization time for the babies. In a randomized, double-blind trial comparing 175 women and infants treated with methadone versus buprenorphine, infants who had prenatal exposure to buprenorphine required significantly less morphine for treatment of NAS, a significantly shorter period of NAS treatment, and significantly shorter hospitalization than did those with prenatal exposure to methadone. However, there was no difference in the number of neonates requiring NAS treatment, in peak NAS scores, in head circumference, or in any other neonatal or maternal outcome. In buprenorphine-maintained patients, though, acute pain can be difficult to treat because of the partial antagonist activity at the μ receptor. Whereas treatment of opioid dependence requires only once-daily dosing, opioid-dependent patients with mild pain who are receiving buprenorphine may attain analgesia simply by splitting the same daily dose into intervals of every 6 hours.

According to the drug manufacturer’s insert, buprenorphine is not recommended during breastfeeding; however, it appears to be safe. Because of low levels in breast milk, as well as poor oral bioavailability in infants, an infant is exposed to about 1% to 1.4% of the maternal weight-adjusted dose. Breast milk–induced addiction appears to be unlikely, and there is no reason to time breastfeeding to avoid peak levels of buprenorphine. The amount of buprenorphine in milk may not be sufficient to prevent neonatal withdrawal, and treatment of the infant may be required.

Fentanyl is one of the most common parenteral opioid analgesics administered during the perioperative period. As with all opioid analgesics, administration of fentanyl to the mother immediately before delivery may lead to respiratory depression in the newborn. Maternal administration of fentanyl or other opioids may also cause loss of the normal variability in fetal heart rate. Loss of fetal heart rate variability can signal fetal hypoxemia, so administration of opioids during labor may deprive obstetric caregivers of a useful tool for assessing fetal well-being.
Meperidine undergoes extensive hepatic metabolism to normeperidine, which has a long elimination half-life (18 hours). Repeated dosing can lead to accumulation, especially in patients with renal insufficiency. Normeperidine causes excitation of the central nervous system manifested as tremors, myoclonus, and generalized seizures. Significant accumulation of normeperidine is unlikely in a parturient who receives single or infrequent doses; however, meperidine offers no advantages over other parenteral opioids.

Although mixed agonist-antagonist opioid analgesic agents are widely used to provide analgesia during labor, they do not appear to offer any advantage over pure opioid agonists. In a blinded randomized comparison of meperidine and nalbuphine during labor, the two agents appeared to provide comparable analgesic effects, as well as similar neonatal Apgar and neurobehavioral scores. Use of nalbuphine or pentazocine during pregnancy can lead to NAS. Nalbuphine may also cause a sinusoidal fetal heart rate pattern after maternal administration, thereby complicating fetal assessment.

Low-affinity opioid agonists, such as tramadol (Ultram), are being used with increasing frequency, in part because of a perceived lessening of the abuse and addiction potential. There is no evidence that acute use of tramadol for labor analgesia has any advantages over more traditional opioids. According to the manufacturer’s prescribing information, no drug-related teratogenic effects were observed in the progeny of rats treated orally with combination tramadol and acetaminophen at 1.6 times the maximum human daily dose. However, at this dose embryo and fetal toxicity consisted of decreased fetal weight and increased supernumerary ribs. Tramadol administered intramuscularly to mothers in labor reaches the neonate almost freely, thus confirming a high degree of placental permeability. The neonate already possesses the complete hepatic capacity for metabolism of tramadol into its active metabolite, but renal elimination of the active tramadol metabolite M1 is delayed, in line with the slow maturation process of renal function in neonates. Neonates born to women who are chronically taking tramadol during pregnancy carry a risk for withdrawal. No studies have compared the relative rate of NAS with tramadol versus other opioid analgesics. Breastfeeding is of unknown risk when the mother is taking tramadol.

Postoperative analgesia for most pregnant women undergoing nonobstetric surgery can be provided readily with narcotic analgesics (Tables 35.3 and 35.4). Fentanyl, morphine, and hydromorphone are all safe and effective alternatives when a potent opioid is needed for parenteral administration. There are a range of safe and effective oral analgesics—fentanyl or epidural delivery of hydrocodone is a good alternative; for moderate pain, oxycodone alone or in combination with hydrocodone is effective; and more severe pain may require morphine or hydromorphone, both of which are available for oral administration.

Narcotic analgesics can also be administered into the intrathecal or epidural compartments to provide postoperative analgesia. Such neuraxial administration of hydrophilic agents (e.g., morphine) greatly reduces the total postoperative opioid requirements while providing excellent analgesia. Spinal or epidural delivery of opioids can be used to minimize

---
maternal plasma concentrations, thereby reducing placental transfer to the fetus or exposure of breastfeeding infants. Opioids are excreted into breast milk. Pharmacokinetic analysis has demonstrated that breast milk concentrations of codeine and morphine are equal to or somewhat higher than maternal plasma concentrations. Use of meperidine by breastfeeding mothers via patient-controlled analgesia (PCA) has resulted in significantly greater neurobehavioral depression of the breastfeeding newborn than seen with equianalgesic doses of morphine. After absorption from the infant’s gastrointestinal tract, opioids contained in ingested breast milk undergo significant first-pass hepatic metabolism. Morphine undergoes glucuronidation to inactive metabolites, whereas meperidine undergoes N-demethylation to the active metabolite normeperidine. The half-life of normeperidine is markedly prolonged in newborns, so regular breastfeeding leads to accumulation and the resultant risk for neurobehavioral depression and seizures. The American Academy of Pediatrics considers the use of many opioid analgesics, including codeine, fentanyl, methadone, morphine, and propoxyphene, to be compatible with breastfeeding. There are insufficient data to determine the safety of buprenorphine with breastfeeding; however, excretion of buprenorphine into breast milk is minimal.

LOCAL ANESTHETICS

Few studies have focused on the potential teratogenicity of local anesthetics. Lidocaine and bupivacaine do not appear to pose significant developmental risk to the fetus. In the Collaborative Perinatal Project, only mepivacaine was found to have any suggestion of teratogenicity; however, the number of patient exposures was inadequate to draw conclusions. Animal studies have found that continuous exposure to lidocaine throughout pregnancy does not cause congenital anomalies but may decrease neonatal birth weight. Continuous exposure to local anesthetics is unusual but might be seen with the frequent use of local anesthetic patches or creams, which are used for post-herpetic neuralgia and other neuropathic pain states.

Neither lidocaine nor bupivacaine appears in measurable quantities in breast milk after epidural local anesthetic administration during labor. Intravenous infusion of high doses (2 to 4 mg/min) of lidocaine for suppression of cardiac arrhythmias has led to minimal levels in breast milk. Based on these observations, continuous epidural infusion of dilute local anesthetic solutions for postoperative analgesia should result in only small quantities of drug actually reaching the fetus. The American Academy of Pediatrics considers local anesthetics to be safe for use in nursing mothers.

Mexiletine is an orally active antiarrhythmic agent with structural and pharmacologic properties similar to those of lidocaine. This agent has shown promise in the treatment of neuropathic pain. Mexiletine is lipid soluble and crosses the placenta freely. There are no controlled studies in humans of mexiletine use during pregnancy. However, studies in rats, mice, and rabbits involving doses of up to four times the maximum daily dose in humans have demonstrated an increased risk for fetal resorption but not teratogenicity.

Mexiletine appears to be concentrated in breast milk, but based on expected breast milk concentrations and average daily intake of breast milk, the infant would receive only a small fraction of the usual pediatric maintenance dose of mexiletene. Mexiletine is rated risk category C by the FDA, and its use should be undertaken cautiously during pregnancy. The American Academy of Pediatrics considers the use of mexiletine to be compatible with breastfeeding.

STEROIDS

Corticosteroids may be used commonly in pregnant patients with autoimmune disease, as well as in those with premature rupture of membranes. There is variability in placental metabolism and transplacental passage of steroids, depending on the preparation. Most corticosteroids cross the placenta, although prednisone and prednisolone are inactivated by the placenta, whereas dexamethasone and betamethasone do not undergo significant metabolism. Fetal serum concentrations of prednisone are less than 10% of maternal levels. In 145 patients exposed to corticosteroids during their first trimester of pregnancy, no increase in malformations was seen. The use of corticosteroids during a limited trial of epidural steroid therapy in a pregnant patient probably poses minimal fetal risk (see further discussion later in this chapter).

In a mother who is breastfeeding, less than 1% of a maternal prednisone dose appears in the nursing infant over the next 3 days. This amount of steroid exposure is unlikely to affect infants’ endogenous cortisol secretion.

BENZODIAZEPINES

Benzodiazepines are among the most frequently prescribed of all drugs and are often used as anxiolytic agents, for the treatment of insomnia, and as skeletal muscle relaxants in patients with chronic pain. First-trimester exposure to benzodiazepines may be associated with an increased risk for congenital malformations. Diazepam may be associated with cleft lip or cleft palate, as well as with congenital inguinal hernia. However, epidemiologic evidence has not confirmed the association of diazepam with cleft abnormalities; the incidence of cleft lip and palate remained stable after the introduction and widespread use of diazepam.

Epidemiologic studies have confirmed the association of diazepam use during pregnancy with congenital inguinal hernia. Benzodiazepine use immediately before delivery also increases the risk for fetal hypothermia, hyperbilirubinemia, and respiratory depression.

Two other benzodiazepines have been evaluated for teratogenicity. Chlordiazepoxide has been reported to produce a fourfold increase in congenital anomalies, including spastic diplegia, duodenal atresia, and congenital heart disease. However, a study of more than 200,000 Michigan Medicaid recipients did not support these earlier findings. Instead, this study found a high co-prevalence of alcohol and illicit drug use in patients receiving benzodiazepines. Benzodiazepine use alone did not appear to be a risk factor for congenital anomalies. Oxazepam use during pregnancy has also been associated with congenital anomalies, including a syndrome of dysmorphic facial features and central nervous system defects. In addition to the risk for teratogenesis, neonates who are exposed to benzodiazepines in utero may experience withdrawal symptoms immediately after birth.
In a breastfeeding mother, diazepam and its metabolite desmethyldiazepam can be detected in the infant’s serum for up to 10 days after a single maternal dose. This is due to the slower metabolism in neonates than in adults. Clinically, infants who are nursing from mothers receiving diazepam may exhibit sedation and poor feeding. It appears most prudent to avoid any use of benzodiazepines during organogenesis, near the time of delivery, and during lactation.

**ANTIDEPRESSANTS**

Antidepressants are often used for the management of migraine headaches, as well as for analgesic and antidepressant purposes in chronic pain states. Although they are an effective therapy in nonpregnant patients, the most commonly used medications of this class are FDA category C or D. Selective serotonin reuptake inhibitors (SSRIs) have become the mainstay for the treatment of depression and are widely prescribed. As with most medications, increased use has been associated with increased reports of adverse effects in pregnancy and the neonate. Though initially thought to be safe in early pregnancy, unpublished epidemiologic reports from GlaxoSmithKline have raised concern that paroxetine, one of the most widely prescribed antidepressants, may be associated with an increase in malformations, particularly cardiovascular malformations, when used in the first trimester. This recent retrospective epidemiologic study of 3881 pregnant women exposed to paroxetine or other antidepressants during the first trimester suggested that paroxetine has an increased risk for overall major congenital malformations relative to other antidepressants (odds ratio [OR] = 2.20; 95% CI = 1.34 to 3.63). The risk for cardiovascular malformations was also increased with the use of paroxetine versus other antidepressants (OR = 2.08; 95% CI = 1.03 to 4.23); 10 of the 14 infants with cardiovascular malformations had ventricular septal defects. In addition, use late in pregnancy has recently become a concern, with reports of NAS, including jitteriness or seizures and pulmonary hypertension, occurring in the newborn. These data initiated a re-evaluation of the risks and benefits of SSRIs during pregnancy and raised the FDA risk category from B to C. It is important to note that although the relative risk for adverse outcomes has increased, the incidence of malformations (1% to 3%) and pulmonary hypertension (0.5% to 1%) remains low, whereas the presence of severe depression in pregnant women is high (15%). As with all medications, the risk associated with no medication must be carefully weighed against the risk related to treatment; there are many women who will need to keep taking their antidepressant throughout pregnancy, and the low incidence of adverse outcomes remains reassuring.

Although tricyclic antidepressants have had a more limited role in the treatment of depression, they can be of benefit in patients with chronic pain. Amitriptyline, nortriptyline, and imipramine are all rated risk category D by the FDA. Desipramine and all other conventional antidepressant medications are category C. Amitriptyline is teratogenic in hamsters (encephaloceles) and rats (skeletal defects). Imipramine has been associated with several congenital defects in rabbits, but not in rats, mice, or monkeys. Although there have been case reports of human neonatal limb deformities after maternal use of amitriptyline and imipramine, large human population studies have not revealed an association with any congenital malformation, with the possible exception of cardiovascular defects after maternal imipramine use. There have been no reports linking maternal desipramine use with congenital defects. Withdrawal syndromes have been reported in newborns born to mothers taking nortriptyline, imipramine, and desipramine, with symptoms including irritability, colic, tachypnea, and urinary retention. Amitriptyline, nortriptyline, and desipramine are all excreted into human milk. Pharmacokinetic modeling has suggested that infants are exposed to about 1% of the maternal dose. In a critical review of the literature regarding the use of antidepressants during breastfeeding, Wisner and colleagues concluded that amitriptyline, nortriptyline, desipramine, clomipramine, and sertraline are not found in quantifiable amounts in nurslings and reported no adverse effects; they recommended use of these agents as the antidepressants of choice for breastfeeding women. Fluoxetine is also excreted into human milk and has a milk-to-plasma ratio of about 0.3. No controlled studies are available to guide fluoxetine therapy during lactation; however, colic and high infant serum levels have been reported. Maternal doxepin use has also been associated with elevated plasma levels of the metabolite N-desmethyldoxepin and respiratory depression in a nursing infant. The American Academy of Pediatrics considers all antidepressants to have unknown risk during lactation.

Duloxetine, a selective serotonin-norepinephrine reuptake inhibitor (SSNRI), is representative of a new class of drug that combines inhibition of serotonin and norepinephrine reuptake. Duloxetine is efficacious for depression and neuropathic pain and may have particular efficacy for diabetic neuropathy. Duloxetine is FDA pregnancy category C, a class indicating potential risks and benefits. Neonates born to mothers receiving SSRI or SSNRI drugs may have a withdrawal reaction, as discussed earlier. Although the relative risks and benefits of breastfeeding when a woman is receiving duloxetine have not been fully evaluated, the manufacturer advises against its use during breastfeeding.

**ANTICONVULSANTS**

A number of anticonvulsant medications are used in chronic pain management. However, most data on the risk for major malformation in fetuses of mothers taking anticonvulsants are derived from the treatment of epilepsy. Although epilepsy itself is not associated with an increased risk for congenital malformations, some theoretical risk may exist. Nonetheless, data from anticonvulsant use in epileptic women are used to assess the risk associated with the same medications when used for pain conditions. Recently, the American Academy of Neurology and the American Epilepsy Society subcommittee undertook a systematic review of the evidence for teratogenic potential and perinatal outcomes in pregnant women taking antiepileptic medication. The review found that exposure to valproic acid, especially in the first trimester, contributes to neural tube defects, facial clefts, and possibly hypospadias. They also found that neonates of women taking anticonvulsants were also more likely to be small for gestational age and have
The use of gabapentin during lactation. There is a possible dose relationship for the development of congenital malformations when valproic acid is taken during the first trimester. Though not consistent throughout all the studies, a dose of valproic acid greater than 1000 mg daily may be associated with the greatest risk for malformations.

In the same review, carbamazepine was associated with an increased risk for cleft palate, but this was not confirmed by another study focusing specifically on carbamazepine and using the EUROCAT (European Surveillance of Congenital Anomalies) database. Although this study did not find an association between carbamazepine and clefts, it did find an association with spina bifida.

Data suggest that topiramate (Topamax) increases the risk for cleft lip and cleft palate in babies born to women who use the medication during pregnancy. Its use has also been linked to low birth weight. The FDA has recently changed its pregnancy category from C to D.

Gabapentin is a new anticonvulsant that is being used for the treatment of neuropathic pain syndromes. Little information exists about the safety of gabapentin in pregnant women, and thus far, the Gabapentin Registry Study has not shown an increased risk for adverse maternal and fetal events. In their prescribing information, the manufacturer has reported a series of nine women who received gabapentin during their pregnancies. Four women elected termination of their pregnancy, four had normal outcomes, and one neonate had pyloric stenosis and an inguinal hernia. Insufficient data exist to counsel patients regarding the fetal risk associated with gabapentin use during pregnancy.

A drug similar to gabapentin is pregabalin, which combines anticonvulsant activity and affinity for the γ-aminobutyric acid receptor. The main applications of pregabalin are for the treatment of pain associated with diabetic neuropathy and post-herpetic neuralgia. Pregabalin is listed as FDA pregnancy risk category C, but the risk during breastfeeding is unknown.

Patients contemplating childbearing who are taking anticonvulsants should have their pharmacologic therapy critically evaluated. Those taking anticonvulsants for neuropathic pain should strongly consider discontinuation during pregnancy, particularly during the first trimester. Consultation with a perinatologist is recommended if continued use of anticonvulsants during pregnancy is being contemplated. Frequent monitoring of serum anticonvulsant levels and folate supplementation should be initiated, and maternal α-fetoprotein screening may be considered to detect fetal neural tube defects.

The use of anticonvulsants during lactation does not seem to be harmful to infants. Phenytoin, carbamazepine, and valproic acid appear in small amounts in breast milk, but no adverse effects have been noted. No data exist on the use of gabapentin during lactation.

ERGOT ALKALOIDS

Ergotamine can have significant therapeutic efficacy for the episodic treatment of migraine headaches. However, even low doses of ergotamine are associated with significant teratogenic risk, and higher doses have caused uterine contractions and spontaneous abortion. During lactation, ergot alkaloids are associated with neonatal convulsions and severe gastrointestinal disturbances. Occasionally, methylergonovine is administered systemically to treat uterine atony and maternal hemorrhage immediately after delivery. This brief exposure is not a contraindication to breastfeeding.

CAFFEINE

Caffeine is a methylxanthine often used in combination with analgesics for the management of vascular headaches. It is readily absorbed from the gastrointestinal tract and crosses the placenta such that concentrations in the fetus are similar to maternal plasma levels. Early studies of caffeine ingestion during pregnancy suggested an increased risk for intrauterine growth retardation, fetal demise, and premature labor, but more recent studies do not. Although the data against caffeine use in pregnancy are not strongly compelling, most obstetricians recommend that pregnant women limit caffeine intake to less than 300 mg/day. To date, there is no evidence for birth defects related to caffeine.

Caffeine use is also associated with certain cardiovascular changes. Ingestion of modest doses of caffeine (100 mg/m², a dose similar to that found in two cups of brewed coffee) by caffeine-naïve subjects produces modest cardiovascular changes in the mother and fetus, including increased maternal heart rate and mean arterial pressure, increased peak aortic flow velocity, and decreased fetal heart rate. The modest decrease in fetal heart rate and increased frequency of fetal heart rate accelerations may confound the interpretation of fetal heart tracings. Caffeine ingestion is also associated with an increased incidence of tachyarrhythmia in the newborn, including supraventricular tachyarrhythmia, atrial flutter, and premature atrial contractions. Many over-the-counter analgesic formulations contain caffeine (typically in amounts of 30 to 65 mg per dose), and use of these preparations must be considered when determining total caffeine exposure.

Moderate ingestion of caffeine during lactation (up to two cups of coffee per day) does not appear to affect the infant. Breast milk usually contains less than 1% of the maternal dose of caffeine, with peak breast milk caffeine levels appearing 1 hour after maternal ingestion. Excessive caffeine use may cause increased wakefulness and irritability in the infant.

SUMATRIPTAN

Sumatriptan is a selective serotonin agonist that has achieved widespread use because of its efficacy in the treatment of migraine headaches. It has been associated with fetal malformations in rabbits, but not in rats. Limited data in humans have not demonstrated any strong teratogenic effects. Sumatriptan is advantageous in the treatment of migraine headaches in pregnancy because it does not share uterine contractile properties with ergotamine and would probably not have abortifacient effects. Beginning in January 1996, Glaxo Wellcome established a registry to prospectively evaluate the risk associated with sumatriptan use during pregnancy. The accumulated evidence from the Sumatriptan Pregnancy Registry and other studies...
suggests that this drug is a safe therapeutic option for the treatment of migraine attacks in pregnant women. Sumatriptan is labeled risk category C by the FDA.

A minimal amount of sumatriptan is excreted into breast milk, and it is considered safe for breastfeeding. The use of sumatriptan during lactation has not been well studied. One study of a single 6-mg subcutaneous dose of sumatriptan given to lactating women found total breast milk sumatriptan level to be only 0.24% of the maternal dose. Because sumatriptan is poorly absorbed from the infant’s gastrointestinal tract, only 14% of the drug ingested by the fetus would be bioavailable. Even this minor exposure could be largely avoided by expressing and discarding all milk for 8 hours after injection.\(^{114}\)

**β-BLOCKERS**

Propranolol and other β-blockers are used for chronic prophylaxis against migraine and nonmigraine vascular headaches. Most of the studies on β-blocker use during pregnancy involve women being treated for hypertension, as opposed to migraine prophylaxis, and hypertension itself may increase the risk for small-for-gestational-age fetuses.\(^{115}\) A 2009 Cochrane review looking at β-blocker use for mild to moderate hypertension during pregnancy found that the effect of β-blockers on perinatal outcome is unclear.\(^{116}\) There is no evidence that propranolol is teratogenic. Fetal effects noted with maternal consumption of propranolol include decreased weight, potentially because of a modest decrease in maternal cardiac output with consequent diminished placental perfusion.\(^{117}\) Patients should be aware that fetal toxicity can result in complications, including intrauterine growth retardation, hypoglycemia, bradycardia, and respiratory depression.\(^{117}\) Longer-acting agents should lead to less fluctuation in both maternal and fetal blood concentrations and perhaps less fluctuation in the drug’s effects on fetal heart rate. The FDA rates all β-blockers as class C with the exception of atenolol, which is rated class D.

In a lactating mother, propranolol doses of up to 240 mg/day appear to have minimal neonatal effects. The average neonatal exposure at this maternal dose is less than 1% of the therapeutic dose.\(^{118}\) Atenolol is concentrated in breast milk but still results in subtherapeutic levels in the infant.\(^{119}\)

**EVALUATION AND TREATMENT OF PAIN DURING PREGNANCY**

We have been asked to consult on numerous patients with uncontrolled pain during the course of pregnancy. Frequently, severe pain was arising from an extreme form of one of the more common musculoskeletal pain syndromes of pregnancy. Thus, a working knowledge of the painful musculoskeletal conditions that occur during pregnancy is essential. We also discuss evaluation of back pain and migraine headaches during pregnancy because these are among the most common problems encountered in practice. Although sickle cell pain crisis is less common, it provides a good example of the approach to managing chronic recurrent pain during the course of pregnancy.
HIP PAIN

Two relatively rare conditions, osteonecrosis and transient osteoporosis of the hip, both occur with somewhat greater frequency during pregnancy. Although the exact cause is not known, high levels of estrogen and progesterone in the maternal circulation and increased interosseous pressure may contribute to the development of osteonecrosis. Transient osteoporosis of the hip is a rare disorder characterized by pain and limitation of motion of the hip and osteopenia of the femoral head. Both conditions are associated with hip pain during the third trimester, which may be sudden or gradual in onset. Osteoporosis is easily identified, with plain radiography demonstrating osteopenia of the femoral head and preservation of the joint space. Osteonecrosis is best evaluated with magnetic resonance imaging (MRI), which will demonstrate changes before they appear on plain radiographs. Both conditions are managed symptomatically during pregnancy. Limited weight bearing is essential with transient osteoporosis of the hip to avoid fracture of the femoral neck.

PELVIC GIRDLE PAIN

CAUSATIVE FACTORS AND CLINICAL FEATURES

Pelvic girdle pain is a clinical syndrome consisting of pain localized to the posterior iliac crest and gluteal fold over the anterior and posterior elements of the bony pelvis. The syndrome has been called by many other terms, including symphysis pubis dysfunction, pelvic joint insufficiency, pelvic girdle relaxation, and posterior pelvic pain. This pain entity is distinct from pregnancy-related low back pain. The etiology of pelvic girdle pain remains unclear but is probably multifactorial with mechanical, hormonal, and genetic influences. Mechanical factors relate to separation of the pubic symphysis during pregnancy. Hormonal changes include elevated levels of progesterone and relaxin. Genetic influence is based on the epidemiologic finding of an increased prevalence in first-degree relatives.

BACK PAIN

CAUSATIVE FACTORS AND CLINICAL FEATURES

Pregnancy-related low back pain is characterized by pain in the lumbar region. Fifty percent of women will experience low back pain during their pregnancy, and it is commonly looked on as a normal part of pregnancy. In a third of pregnant women, back pain is a severe problem that compromises normal everyday activity. The pain resembles the low back pain of the nonpregnant state and is often described as dull and aching in nature. There can be a limitation in range of motion of the lumbar spine, and the pain is exacerbated by both forward flexion and palpation of the erector spinae muscles.

As with pelvic girdle pain, the etiology of pregnancy-related low back pain is probably multifactorial. The lumbar lordosis becomes markedly accentuated during pregnancy to balance the anterior weight of the womb and may represent a mechanical cause of the pain. Endocrine changes
during pregnancy may also play a role in the development of back pain. Relaxin, a polypeptide secreted by the corpus luteum, softens the ligaments around the pelvic joints and cervix to allow accommodation of the developing fetus and facilitate vaginal delivery. This laxity may cause pain by allowing an exaggerated range of motion.\textsuperscript{131}

The onset of low back pain is usually around the 18th week of pregnancy, with peak intensity occurring between the 24th and 36th weeks.\textsuperscript{129} However, the pain can start as early as the first trimester or as late as 3 weeks postpartum. Sixteen percent of women with pregnancy-related back pain report persistent pain 6 years later, thus suggesting that pregnancy is a risk factor for persistent low back pain.\textsuperscript{132} Although radicular symptoms often accompany low back pain during pregnancy, herniated nucleus pulposus has an incidence of only 1 in 10,000.\textsuperscript{133} Pregnant women do not have an increased prevalence of lumbar disk abnormalities.\textsuperscript{134} Direct pressure of the fetus on the lumbosacral nerves or lumbar plexus has been postulated as the cause of radicular symptoms.

\section*{EVALUATION OF PATIENTS WITH BACK AND PELVIC GIRDLE PAIN}

Evaluation of pregnant patients with low back pain and pelvic girdle pain must begin with a thorough history and physical examination.\textsuperscript{135} The aim is to exclude other causes of pain because obstetric complications (preterm labor, abruption, degeneration of uterine fibroids, round ligament pain, and chorioamnionitis) may also be manifested as low back pain.\textsuperscript{136,137} Urologic disorders, including hydronephrosis, pyelonephritis, and renal calculi, may likewise result in low back discomfort.\textsuperscript{138} Major morphologic changes occur in the collecting system of pregnant women, including dilation of the calices, renal pelvis, and ureters\textsuperscript{139} (Fig. 35.3). The physical examination should include complete back and neurologic evaluations. Particular attention should be directed toward the pelvis and sacroiliac joints during the examination. Posterior pelvic pain (sacroiliac dysfunction) can often be distinguished from other causes of low back pain based on the physical examination (Figs. 35.4 and 35.5 and Table 35.5; also see Box 35.2). A positive straight-leg raise test (typical low back pain with or without radiation to the ipsilateral lower extremity) during physical examination...
is consistent with sacroiliac subluxation or a herniated nucleus pulposus. Unilateral loss of knee or ankle reflex or the presence of a sensory or motor deficit is suggestive of lumbar nerve root compression.

X-ray imaging techniques such as computed tomography (CT) are not ideal in pregnancy. However, pregnancy is not an absolute contraindication to radiographic evaluation. Radiation exposure during pregnancy leads to concerns about resultant congenital anomalies, mental retardation, and increased risk for subsequent cancers. No detectable growth or mental abnormalities have been associated with fetal exposure to less than 10 rads; the dose received during pregnancy remains controversial. The American College of Obstetricians and Gynecologists recommends specific muscular conditioning exercises to promote good posture and prevent low back pain during pregnancy.

MRI has revolutionized diagnostic imaging during pregnancy; it has proved to be effective and reliable in the diagnosis of many structural abnormalities. Although MRI appears to be safe during pregnancy, no long-term studies have examined the safety of fetal exposure to intense magnetic fields during gestation. Schwartz presented a thorough and insightful review of neurodiagnostic imaging of pregnant patients. Practical guidelines for the use of radiographic studies in the evaluation of pregnant patients are given in Box 35.3.

Electromyography and nerve conduction studies (collectively referred to as EMG) serve as good screening tests in a patient with a new onset of low back pain accompanied by sensory or motor symptoms. When the clinical findings are confusing, EMG can aid in differentiating peripheral nerve lesions, polyneuropathies, and plexopathies from single radiculopathies. However, false-negative results on EMG are common, especially in the case of a herniated nucleus pulposus causing compression of a single nerve root.

PREVENTION AND TREATMENT

Few of the commonly used strategies to prevent low back pain during pregnancy are universally effective. Patients who were instructed in basic lifting techniques experienced significantly less backache than did a control group who did not receive similar instruction. Aerobic exercise can be prescribed safely throughout pregnancy; however, maintenance of good physical conditioning may not alter the incidence of back pain during pregnancy. Nonetheless, the American College of Obstetricians and Gynecologists recommends specific muscular conditioning exercises to promote good posture and prevent low back pain during pregnancy.

Treatment of pregnancy-related low back and pelvic girdle pain begins with education on the common causes of pain during pregnancy. Back care classes that focus on anatomy, ergonomics, correct posture, and relaxation techniques are available. If the pain remains poorly controlled, referral to a physical therapist for instruction in body mechanics and low back exercises may be beneficial. In a recent Cochrane review of the treatment of low back pain, pregnancy-specific exercise programs, physiotherapy, and acupuncture added to the usual prenatal care appeared to reduce back pain more than just the usual prenatal care. When compared with each other, acupuncture may be more effective than physiotherapy. Participation in water gymnastics programs also reduced the number of back pain–related work absences.

Although the incidence of herniated nucleus pulposus during pregnancy is low, radicular symptoms are common and often accompany sacroiliac subluxation and myofascial pain syndromes. Use of epidural steroids outside pregnancy remains controversial. The strongest evidence for efficacy of epidural steroids appears to be in patients with symptoms attributable to acute disk pathology. Although the risk to the fetus following a single epidural dose of...
a corticosteroid appears to be low, it is our opinion that epidural steroids should be reserved for parturients with a new onset of signs (e.g., unilateral loss of deep tendon reflex, sensorimotor change in a dermatomal distribution) and symptoms consistent with lumbar nerve root compression. In such patients, we believe that it is reasonable to proceed with epidural steroid treatment before obtaining imaging studies. Resolution of the radicular symptoms after epidural steroid treatment may well obviate the need for imaging studies.

Guided local anesthetic injection into the sacroiliac joint or pubic symphysis can have diagnostic and therapeutic value. As mentioned previously, most clinicians wish to limit exposure to ionizing radiation during pregnancy. Surface ultrasound can be used to aid entry into the sacroiliac joint. Relief after an intra-articular injection is indicative only of intra-articular pathology. Extra-articular pathologies contributing to pelvic girdle pain such as strain of the superficial long sacroiliac joint ligament are unlikely to improve after an intra-articular injection.

Treatment options during pregnancy are limited by the presence of and potential hazard to the fetus. After delivery, the majority of women do have improvement in their symptoms within a few months. Nonpharmacologic treatment modalities used during pregnancy include physical therapy with pelvic tilt exercises, rotational manipulation of the sacroiliac joint, water gymnastics, transcutaneous electrical nerve stimulation (TENS), and acupuncture. With use of a TENS unit during pregnancy, there is a theoretical concern about inadvertent induction of labor through the use of certain acupuncture points, as well as fetal cardiac conduction disturbances with passage of current through the fetal heart. Limited data suggest that TENS is safe during pregnancy. A recent Cochrane review on the use of TENS for treatment of pain during labor found no deleterious effects on the mother or fetus. Given the theoretical concerns, one recommendation for the use of TENS during pregnancy is to keep the current density low and avoid certain acupuncture points.

### MIGRAINE HEADACHE DURING PREGNANCY

#### CAUSATIVE FACTORS AND CLINICAL FEATURES

The clinician is often confronted with the occurrence of headache during pregnancy because recurring headaches most commonly take place during the childbearing years. Migraine can be a disabling disorder and is more prevalent in women than men, which is thought to be due in part to the influence of female sex hormones. Migraine headaches vary with female reproductive events, including menarche, menstruation, oral contraceptives, pregnancy, and menopause. Eighty percent of female migraineurs report an onset of migraine from the age of 10 to 39 years, thus suggesting that sex hormones do play a significant role in pathogenesis. They typically improve in the first trimester of pregnancy, when there is a sudden and sustained increase in estradiol levels. In fact, 50% to 80% of patients who suffer from migraines experience a significant reduction in frequency or total cessation of migraine attacks during pregnancy. However, women with headaches persisting into the second trimester are less likely to improve thereafter.

Migraine headaches rarely begin during pregnancy, but if they do, they typically occur during the first trimester. Many clinicians believe that headaches initially occurring during pregnancy should generate a thorough search for potentially serious causes. One report of nine women with migraine-like headaches during pregnancy found that four were severely thrombocytopenic, two met the criteria for preeclampsia, and one had a threatened abortion. The literature is replete with reports of intracranial pathology that mimicked migraines during pregnancy, including strokes, pseudotumor cerebri, tumors, aneurysms, arteriovenous malformations, and cerebral venous thrombosis. Metabolic causes of headache during pregnancy include illicit drug use (most notably cocaine), antiphospholipid antibody syndrome, and choriocarcinoma.
EVALUATION

Patients with their first severe headache during pregnancy should be evaluated aggressively. Only when secondary causes of headache in pregnancy, including head trauma, cerebral venous thrombosis, preeclampsia, intracranial or subarachnoid hemorrhage, ischemic stroke, vasculitis, and dehydration, have been ruled out should primary headache be diagnosed in pregnant women. The first step is a detailed history and neurologic examination. Focal neurologic abnormalities, papilledema, and seizures in the setting of headache warrant further investigation. Diagnostic suggested tests for new-onset headache during pregnancy include urinalysis, blood chemistries, hematologic studies, liver function tests, and coagulation studies.® Brain imaging is also an important component of the workup. MRI without gadolinium enhancement is safe in all trimesters and should be the modality of choice during pregnancy.® In a patient with a sudden onset of the “worst headache of my life,” subarachnoid hemorrhage should be ruled out.® If CT of the brain is negative for hemorrhage, a lumbar puncture should be performed and the spinal fluid evaluated for subarachnoid blood. Progressively worsening headaches in the setting of sudden weight gain should suggest preeclampsia or pseudotumor cerebri. The triad of elevated blood pressure, proteinuria, and peripheral edema points toward preeclampsia; hyperreflexia and elevated serum uric acid are also found in patients with preeclampsia.

TREATMENT AND PREVENTION

In pregnant women with a history of migraines before pregnancy and normal neurologic findings, the therapeutic challenge is to achieve control of the headaches while minimizing risk to the fetus. Nonpharmacologic techniques, including relaxation, biofeedback, and elimination of certain foods, often suffice for treatment. Marcus and colleagues demonstrated a significant reduction in headache that continued throughout pregnancy and at the 1-year follow-up when a combination of relaxation training, thermal biofeedback, and physical therapy exercises was used.

If pharmacologic therapy appears to be warranted, acetaminophen with or without caffeine is safe and effective.® A drawback with acetaminophen is the potential for medication overuse and rebound headache, which could lead to the development of chronic daily headaches. Ibuprofen and naproxen are the most commonly used NSAIDs for abortive management of migraines; however, they are risk category C before 30 weeks and risk category D in the third trimester. The short-term use of mild opioid analgesics such as hydrocodone, alone or in combination with acetaminophen, also appears to carry little risk (see Table 35.3). When oral analgesics prove ineffective, hospital admission and administration of parenteral opioids may be required (see Table 35.4).

Until more information is available on the safety of sumatriptan during pregnancy, it should be used only after other strategies have failed. Triptans are the most used abortive agents in nonpregnant patients, but they are rarely used during pregnancy. There are pregnancy registries for both sumatriptan and naratriptan to track pregnancy outcomes after exposure to these medications. At this time there does not seem to be an increased incidence of teratogenicity or adverse pregnancy outcomes with use in the first trimester. Ergot preparations should be avoided during pregnancy and lactation. They are known to cause prolonged and markedly increased uterine tone and impaired placental flow leading to fetal distress or spontaneous abortion.

A history of three to four incapacitating headaches per month warrants consideration of prophylactic therapy.® If the frequency of the headache or headaches is less than three to four per month but they are severe and unmanageable with acute therapies, prophylactic therapy should be considered to prevent dehydration of the mother, which could cause fetal distress. Daily oral propranolol or atenolol is a reasonable choice, although patients should understand that their use is associated with small-for-gestational-age infants.® Longer-acting agents should lead to less fluctuation in maternal and fetal blood concentrations and perhaps less fluctuation in drug effects on the fetal heart rate. Based on this theoretical advantage, we prefer to use long-acting agents (e.g., atenolol or sustained-release propranolol). Although antidepressants are effective as prophylactic therapy in nonpregnant patients, the most commonly used medications in this class (imipramine, amitriptyline, and nortriptyline) are all FDA category D. The SSRIs are category B or C and can be used with caution, especially if comorbid depression is present. There are very limited data, which has led most physicians to avoid these medications. Limited anecdotal experience with calcium channel blockers (verapamil, nifedipine, and diltiazem are all FDA class C) or minidose aspirin (80 mg/day) suggests that they may be effective prophylactic agents during pregnancy.®

MIGRAINE AND LACTATION

Postpartum headaches are common and can occur in 30% to 40% of all women.® Most take place in the first week, and about 50% of those who experience relief of their migraine during pregnancy have recurrence a short time after delivery. This phenomenon may be secondary to the rapid ovarian withdrawal of progesterone and estradiol. Lactation can inhibit ovulatory cycles during the puerperium and is characterized by increased levels of prolactin and low levels of estradiol. In mothers of bottle-fed infants, the hormonal cycle is restored rapidly, which may contribute to it being a main risk factor for postnatal recurrence of migraine.®

PAIN IN PREGNANT PATIENTS WITH SICKLE CELL DISEASE

CAUSATIVE FACTORS AND CLINICAL FEATURES

Sickle cell disease is an inherited multisystem disorder. The presence of abnormal hemoglobin in red blood cells leads to the cardinal features of the disease, namely, chronic hemolytic anemia and recurrent painful episodes. Vaso-occlusive crisis is the most common maternal complication noted in parturients with sickle cell hemoglobinopathies.® The vaso-occlusive crises follow a characteristic pattern of recurrent sudden attacks of pain, usually involving the abdomen, chest, vertebrae, and extremities. One prospective study has demonstrated that the clinical course of women with sickle cell disease is not adversely affected by their pregnancy as measured by the rate of painful episodes over a 100-day period.® The rate was constant before, during, and after the first and subsequent pregnancies. Painful episodes occurred at some time during the course of 50% of pregnancies.
Most crises during pregnancy are vaso-occlusive and often precipitated by urinary tract infection, preeclampsia or eclampsia, thrombophlebitis, or pneumonia. Clinically, the individual will describe pain in the bones or joints but may also perceive the soft tissues as being affected. Visceral pain is also common and may be related to events in the liver or spleen. Painful episodes can be variable in severity and duration, with most episodes lasting from 3 to 5 days.167

EVALUATION
Because laboratory evaluation is nonspecific, the diagnosis of vaso-occlusive crisis begins with exclusion of other causes of the painful episode, particularly occult infection.165 Complete assessment and acute management of sickle cell crises in pregnancy have been reviewed by Martin and coworkers.168

TREATMENT
Management of vaso-occlusive crisis during pregnancy is primarily supportive and symptomatic. A 2009 Cochrane review of interventions for treating a sickle cell crisis during pregnancy attempted to assess the effectiveness and safety of commonly used treatment regimens, including red cell transfusion, oxygen therapy, intravenous hydration, analgesic drugs, and steroids; there are no randomized clinical trials on this topic, in part because pregnant women tend to be excluded from clinical trials.169 Most clinicians begin management with aggressive hydration to increase intravascular volume and decrease blood viscosity.168 Supplemental oxygen is essential in patients with hypoxemia. Partial exchange transfusions to reduce polymerized hemoglobin S remain an integral part of the management of sickle cell disease; prophylactic transfusion may reduce the incidence of severe sickling complications during pregnancy.171

Education about how pregnancy interacts with sickle cell disease can help reduce depression or anxiety and often decreases the pain that the patient is experiencing. Biofeedback has been shown to reduce the pain of sickle cell crises and the number of days that analgesics are taken.172 Physical therapy techniques (e.g., exercise, splinting, local application of heat) can also be helpful.173 TENS may be helpful when the pain is isolated to a limited region.174

The severity of the pain dictates the pharmacologic approach to managing sickle cell pain. Although nonopioid analgesics may suffice, oral or parenteral opioids are often required (see Tables 35.3 and 35.4). Acetaminophen remains the nonopioid analgesic of choice during pregnancy. Although NSAIDs can be useful adjuncts, particularly for controlling bone pain, they should be used cautiously during pregnancy. Oral analgesic combinations containing acetaminophen and hydrocodone or another opioid with weak to moderate potency can be added for more severe pain.

In a hospitalized patient with severe sickle cell pain, potent opioid analgesics administered intravenously may be necessary to control the pain adequately (see Table 35.4). Morphine sulfate is well tolerated and effective for control of severe sickle cell pain; fentanyl and hydromorphone provide reasonable alternatives for patients who cannot tolerate morphine. Administration of morphine via a PCA device allows patients a sense of control over their illness. Weisman and Schechter176 noted that significantly higher doses of opioids may be necessary for control of the pain of vaso-occlusive crisis than for control of postoperative pain. In our practice we aggressively treat individuals with severe sickle cell pain with potent opioids administered via PCA (most often using morphine). As the pain of vaso-occlusive crisis begins to resolve, patients are transitioned to a long-acting oral opioid (such as sustained-release morphine). This approach allows earlier ambulation and hospital discharge. All opioids are then tapered over the following 7 to 10 days.

The use of regional anesthesia has not been formally studied in sickle cell disease. There are case reports describing epidural analgesia for the treatment of sickle cell crisis during pregnancy in parturients with pain localized to the trunk or lower extremities.177,178 This technique offers the theoretical advantage of increased microvascular blood flow while providing pain relief without opioids.

ACUTE PAIN IN OPIOID-DEPENDENT PATIENTS
Acute pain in pregnant patients is most often encountered during labor and delivery. Both pain control and withdrawal symptoms are mediated through the µ-opioid receptor. Therefore, narcotic pain medication requires availability of the µ-opioid receptor, which in opioid-dependent patients is also occupied by opioid agonist therapy for dependence. No randomized or controlled studies are available to determine whether anesthetic needs differ in opioid-dependent and control patients. One descriptive study found that 24% of opioid-dependent women had difficulty with labor analgesia and 74% had difficulty with postcesarean analgesia.179 These statistics may overestimate the difficulty in pain control because it was not clear that treatment of opioid dependence was adequate before the treatment of acute pain. When opioid dependence is untreated and combined with acute pain, opioid needs reflect the combined therapies rather than treatment of pain alone. Although no randomized clinical trials have been performed, we have found that epidural analgesia with a standard dose of local anesthetic and low-dose opioid (e.g., 0.625% bupivacaine with fentanyl, 2 µg/mL) provides adequate intrapartum analgesia.

Intrathecal or epidural analgesia using only opioids may not be effective in reducing the need for systemic narcotics. Sustained administration of µ-opioid agonists by any route can induce both opioid tolerance and abnormal pain that is similar to neuropathic pain.180 Though previously attributed to pharmacologic tolerance, patients maintained on methadone may experience opioid-induced hyperalgesia, a paradoxical effect mediated in part by the neurotransmitter N-methyl-D-aspartate and possibly by the novel neuropeptide dynorphin.181 Interestingly, dynorphin may be an important mediator of chronic neuropathic pain, a common complaint in opioid-dependent patients.

No trials have investigated opioid use and pain control after vaginal or abdominal delivery in opioid-tolerant patients. Recently published guidelines for the treatment of acute pain in patients maintained on methadone or buprenorphine provide a reasonable approach until more data are available.54 Patients maintained on methadone for opioid dependence should have their methadone continued at the same dose in addition to standard-dose opiates as needed for acute pain. Use of nonopioid analgesics should
be included, but additional opioid medication should not be withheld. This additional short-acting opioid medication can be discontinued gradually as clinically indicated. If patients are unable to tolerate oral medication, methadone can be administered intramuscularly or subcutaneously in two to four divided doses.

Patients maintained on buprenorphine pose a more difficult dilemma in the postoperative period. As a combined opioid agonist-antagonist, continued administration of buprenorphine can block the µ-mediated analgesic effect of additional short-acting opioids. It is of note that although nonpregnant patients receive a combination of buprenorphine and naloxone, monotherapy with buprenorphine is prescribed during pregnancy to avoid naloxone exposure by the neonate. Pain control options, in addition to non-opioid analgesics, include the following: (1) adding short-acting opioids with the realization that larger doses may be needed; (2) dividing the daily dose of buprenorphine into 6-hour intervals, which can take advantage of the short-term analgesic effect of buprenorphine; and (3) discontinuing buprenorphine and initiating methadone at 30 mg/day, with increasing titration in 5- to 10-mg intervals daily to alleviate withdrawal symptoms. In this way, short-acting opioids can be used for pain and methadone can be used to prevent withdrawal, with less direct antagonism at the µ-opioid receptor. This approach is best attempted with the help of an addiction specialist because restarting the buprenorphine after the acute pain has resolved can precipitate withdrawal symptoms. In general, buprenorphine should be restarted only when patients have mild withdrawal symptoms (not before) to prevent antagonistic effects at the µ-opioid receptor.

CONCLUSION

Many physicians find themselves apprehensive about treating pain in pregnant patients. Evaluation and treatment are limited by the relative contraindication of radiography in the workup and the risks associated with pharmacologic therapy during pregnancy. Nonetheless, familiarity with common pain problems, as well as the maternal and fetal risks associated with pain medications, can allow the pain physician help women achieve a more comfortable pregnancy. A single health care provider should be designated to coordinate the specialist evaluations and incorporate their suggestions into a single integrated plan of care.

KEY POINTS—cont’d

- Medical management of pregnant patients should begin with attempts to minimize the use of all medications and use nonpharmacologic therapies whenever possible.
- The most critical period for minimizing maternal drug exposure is during early development, from conception through the 10th menstrual week of pregnancy.
- Most breast milk is synthesized and excreted during and immediately following breastfeeding. Taking medications after breastfeeding or when the infant has

Derivatives from the opium plant have been described as analgesics and used for pain control since 3500 BC. It was not until 1806 that a pure opioid substance was isolated. This substance was called “morphine,” named after the Greek god Morpheus. Since that time the opium plant has yielded other derivatives, and synthetic analogues of morphine have been produced for medicinal use. The use of opioid medications in the United States has fluctuated because of a variety of factors, including but not limited to production, availability, governmental regulation, and physician and societal attitudes. Over the last 20 years the prescribing pattern of opioids has escalated significantly for a number of reasons. The increased trend in prescription writing has been accompanied by a concordant rise in the incidence of diversion and abuse, as well as an increase in the incidence of complications, including overdose and death. Over the past decade, evidence for a sustained benefit of opioids in alleviating chronic pain has remained weak and inadequate, although evidence of risk associated with use of the drugs has clearly escalated. This change in which evidence of the efficacy of opioids has not changed whereas risk has increased should have a significant impact on treatment decisions based on risk-benefit analysis. The goal of this chapter is to review clinically relevant aspects of selected opioids, including side effects and pharmacology, and review current consensus on rational opioid prescribing.

**GENERAL CONSIDERATIONS OF OPIOID ADMINISTRATION**

**OPIOID RECEPTORS**

Multiple systems are involved in the modulation of pain perception, including the endogenous opioid system. The natural endogenous opioids include the endogenous peptides—β-endorphins, enkephalins, and dynorphins. Since the discovery of opioid receptors in the central nervous system (CNS) in 1973, the body of literature describing their function and location has grown immensely.2,3 Opioid receptors have integral roles in the endogenous antinoceptive system and, accordingly, are located throughout the central and peripheral nervous systems. The best described opioid receptors are labeled mu (µ), kappa (κ), and delta (δ) and are prominently located in the CNS, particularly in the dorsal horn of the spinal cord, as well as on dorsal root ganglia and peripheral nerves.5,6 The three opioid receptors identified, µ, κ, and δ, belong to a superfamily of guanine (G) protein–coupled receptors located at presynaptic and postsynaptic sites in the CNS and peripheral tissues.7

The µ-opioid receptor modulates input from mechanical, chemical, and thermal stimuli at the supraspinal level. The κ receptor is similar to the µ receptor in that it influences thermal nociception but, in addition, it also modulates chemical visceral pain. The δ receptor influences mechanical and inflammatory pain.8 An opioid agonist such as morphine binds with an opioid receptor to produce analgesia, as well as undesired side effects, such as respiratory depression and constipation, largely via interaction with the µ receptor. In a study using knockout mice that lacked the µ receptor, it was found that they have no response to morphine with respect to analgesia, respiratory depression, constipation, or physical dependence.9

**DISTRIBUTION, METABOLISM, AND EXCRETION**

The amount of opioid required to produce analgesia has significant interindividual variability. Factors responsible for this variability include opioid receptor individuality, as well as variations in opioid absorption and clearance. Such individual variability requires careful titration of an opioid to the desired response. The onset, duration, and intensity of analgesia depend on the delivery of drug to the target and on the length of time that the receptor is occupied. The number of receptors occupied and the length of time that the opioid activates its target receptor depend on the perfusion, plasma concentration, pH, and permeability coefficient of the drug.10

The metabolic pathway for each opioid is based on the molecular variables of the specific opioid. Opioids with hydroxyl groups, such as morphine and hydromorphone, undergo hepatic metabolism via uridine diphosphate glucuronosyltransferase (UGT) enzymes. UGT adds a glucuronic acid moiety to form glucuronide metabolites (hydromorphone 3-glucuronide [H3G], morphine 6-glucuronide [M6G], and morphine 3-glucuronide [M3G]). These metabolites are then excreted through the kidneys. Patients with renal impairment are particularly prone to deleterious effects from metabolite accumulation.11

The cytochrome P-450 (CYP) system contains two polymorphic isoforms that metabolize certain opioids. The first CYP isoform, responsible for the biotransformation of codeine, oxycodone, and hydrocodone, is 2D6. It is estimated that up to 10% of white individuals lack this enzyme, thus making them “poor metabolizers” of certain opioids and providing another cause for the high interindividual variability seen in patients treated with opioids.11 The 3A4 isoform of the CYP
system is involved in the biotransformation of fentanyl and methadone to their inactive forms. Because some other drugs also interact with 3A4 isoenzymes, the metabolism of methadone and fentanyl can be problematically decelerated or accelerated. For example, macrolide antibiotics inhibit the enzyme, which decreases the clearance of methadone and fentanyl, whereas anticonvulsants such as phenytoin induce the activation of this enzyme system and increase the clearance of methadone and fentanyl. Excretion of most opioid metabolites is via the kidneys, but some of the glucuronide conjugates are excreted in bile, and methadone is excreted primarily in feces.

The study of pharmacogenomic polymorphisms is important in understanding the interindividual variability in analgesic effects. Opioid-related therapies have a multiplicity of genetic factors that influence the metabolism and clearance of specified opioids. As we look to the future, the use of regulator-approved pharmacogenomic assays may be advantageous in identifying many of these variant alleles. Understanding pharmacogenomic polymorphisms will most assuredly play a role in the everyday clinical decision making for management of acute and chronic pain. As safety and patient care benefit from detailed knowledge of specified polymorphisms, this science will most likely be incorporated into the standard of care for physicians.

ADMINISTRATION

Multiple routes of administration are one of the many clinically useful characteristics of opioids. Administration can range from intrathecal, intravenous, or oral to rectal, sublingual, buccal, intranasal, or transdermal. Depending on the clinical situation, one route may be more advantageous than another. For example, a patient who requires continuous opioid delivery but is unable to take medications orally may benefit from a transdermal delivery system, such as is currently available in a transdermal patch containing fentanyl. Fentanyl is also available as a rapid-onset transmucosal delivery product. Neuraxial routes of opioid delivery are widely used in perioperative and postoperative care, as well as for terminally ill patients.

The goal of effective opioid therapy for chronic pain is to provide sustained analgesia over regular intervals. This requires consideration of a number of factors, including knowledge of equianalgesic dosages between opioids and the pharmacologic properties and side effects of specific opioid agents. Pain in opioid-tolerant patients is particularly challenging because typical dosages for opioid-naïve patients do not apply and exact opioid requirements may require careful titration.

Whether fixed dosing is better than as-needed (PRN) dosing is controversial, with each method having advantages in particular situations. With fixed dosing there is consistent opioid delivery, which can theoretically reach steady-state levels. Presumably, this avoids the peak-and-trough effect that can be associated with on-demand dosing and may prevent the delays in delivery that can occur with on-demand schedules. One problem for opioid-naïve patients who receive fixed doses of opioids that have longer half-lives is that they may experience excessive side effects or toxicity because of the difficulty in predicting the exact opioid requirement and potential accumulation. For example, morphine may take less than 24 hours to reach steady-state levels, whereas methadone can take up to 1 week. When there is a need to assess a patient’s analgesia threshold, PRN dosing of an opioid with a short half-life may be used, or conservative fixed dosing of opioids that have a short half-life, supplemented by PRN “rescue” dosing, may be used.

Analgesic therapy with long-acting opioids (LAOs) offers convenient dose intervals that can attain safe, effective, steady-state levels. Several controlled-release opioids are available, including morphine (MS Contin, Oramorph SR, Kadian), oxycodone (OxyContin), fentanyl (Duragesic patch), and oxymorphone. Methadone can be used as an LAO, but it poses specific issues and concerns for clinicians distinct from those of other opioids (see later discussion). Methadone has a faster onset and longer analgesic effect than many other opioids do and may be ideal in some situations. However, these effects may also limit its use. Methadone is not specifically formulated for sustained release like other LAOs, which essentially release a short-acting opioid (SAO) throughout the drug’s passage through the gastrointestinal (GI) tract. Methadone simply has an intrinsically longer plasma half-life than other typical opioids do, such as hydromorphone (Dilaudid) and morphine, and can therefore be advantageous in patients with GI motility issues such as short gut syndrome.

Although sustained- and immediate-release opioid preparations have made the oral route a practical option, some cancer patients are unable to tolerate oral delivery. In such cases, transdermal, buccal, rectal, intravenous, or subcutaneous infusions are often a practical alternative option. With infusion, the first-pass effect is eliminated, thereby potentially offering some advantages. When compared with the oral route, there may be faster onset of analgesia with uncomplicated access. When compared with the intramuscular route, administration is often less painful and may be safer in patients with bleeding disorders or reduced muscle mass.

ADVERSE EFFECTS

The most commonly encountered side effects associated with opioids include constipation, nausea, vomiting, sedation, urinary retention, pruritus, and respiratory depression. Any of these side effects can significantly limit therapy, but tolerance to them usually ensues shortly after initiation of opioids. However, constipation is a major exception because it does not resolve with the prolonged use of opioids. Particular attention should be given to older adults and patients with hepatic or renal insufficiency. Tolerance and physical dependency are also commonly associated with opioid therapy. These are pharmacologic properties related to opioids that are frequently misinterpreted as indicators of addiction. Addiction is also a potential risk associated with opioid use (see later discussion). Physicians should anticipate any or all of these adverse effects, remain vigilant throughout therapy, and monitor patients closely, particularly when initiating therapy and escalating opioid doses.

CONSTIPATION

The most common side effect of opioid administration is constipation, and unfortunately, tolerance to it does not generally develop. Constipation can cause significant discomfort, nausea, and emesis. The underlying mechanism
of opioid-induced constipation is thought to be decreased gastric motility related to opioid binding to highly concentrated opioid receptors located in the antrum of the stomach and the proximal part of the small bowel. There is limited evidence that certain opioids at equianalgesic doses produce more or less constipation than others. Because the transdermal route bypasses initial exposure to the GI tract, transdermal fentanyl has been postulated to produce less constipation than orally administered opioids. However, current data are not convincing, particularly since transdermal opioids are well known to result in significant constipation that requires aggressive laxative therapy, irrespective of whether they produce less constipation than oral agents do.

When initiating any opioid, it is important to prescribe medications to concomitantly maintain regular bowel motility. Treatment of opioid-induced constipation should include an active laxative such as senna, lactulose, or bisacodyl; passive agents such as stool softeners or fiber-based bulking agents may be ineffective because they rely on triggering gastric motility, which in the case of opioids is usually inhibited. Alternatively, use of an adjunctive agent with a side effect profile that includes diarrhea, such as misoprostol, can coexist well with constipating opioids. However, misoprostol should be used with caution in females of childbearing age because it can initiate uterine contractions and miscarriage.

Methylnaltrexone, a quaternary derivative of naltrexone, contains a permanently charged tetravalent nitrogen atom and therefore cannot cross the blood-brain barrier. Methylnaltrexone is an antagonist at the μ receptor. It blocks the peripheral actions of opioids while sparing their central analgesic effects and reverses the slowing of bowel motility that can often occur with opioid-related therapy. Methylnaltrexone was approved by the U.S. Food and Drug Administration (FDA) in 2008 as an indication for opioid-induced constipation. Alvimopan, which was also approved in 2008 by the FDA, functions as a peripherally acting μ-opioid antagonist with limited ability to cross the blood-brain barrier. Alvimopan can treat constipation without affecting analgesia or precipitating withdrawal. The primary indication for this medication is in patients to avoid postoperative ileus following partial large or small bowel resection with the primary anastomosis.

NAUSEA AND EMESIS

Nausea and vomiting are frequently seen in patients who take opioids, but it is usually a transient side effect that often only lasts 2 to 3 days. The underlying mechanism of nausea and vomiting appears to be related to several causative factors. One is activation of receptors in the brainstem site that producesafferent input to the medullary chemoreceptor trigger zone, which is responsible for afferent input to the emetic center of the brain. These areas are dense in neurotransmitter receptors that correspond to the antiemetic agents used clinically. A potential cause of nausea is stimulation of receptors in the vestibular apparatus. Another underappreciated cause of opioid-related nausea is constipation, which will often respond to treatments that increase motility.

In evaluating a patient who reports nausea and vomiting while taking opioids, one should determine important history-related factors involved in the genesis of nausea, such as the time of the last bowel movement, whether it worsens with movement, or whether there is a temporal relationship between opioid ingestion and the onset of nausea. The choice of antiemetic agent depends on the historical aspects surrounding the reported side effect. Patients who experience nausea when they are more ambulatory may be more likely to have vestibule-related nausea. In such cases, drugs such as meclizine, promethazine, or scopolamine may be useful in relieving this type of induced nausea. Droperidol, prochlorperazine, ondansetron, or hydroxyzine may have greater benefit for nausea that is not associated with movement, a type of nausea thought to be related to chemoreceptor trigger zone–associated activation. One should also ensure that reversible metabolic causes, intracranial pathology, or other factors such as medications are not the origin of the nausea or emesis before it is attributed solely to opioids.

Several approaches can be taken when treating opioid-induced nausea and vomiting. An antiemetic may be added, often choosing an agent that offers secondary benefits such as promotility, sedative, antipruritic, anxiolytic, or antipsychotic effects, depending on the needs of the individual patient. Another option to reduce the frequency and severity of side effects is to decrease the opioid dose to the minimum acceptable dose that will still achieve adequate analgesia. Based on the observation that tolerance to opioid-induced nausea accrues rapidly, the dose that had previously been reduced may be titrated upward slowly to increase analgesia without inducing nausea. If the nausea is protracted, one may consider changing to a different opioid. The emetogenic response to opioids is idiosyncratic, and therefore a different opioid may not produce nausea.

PRURITUS

Opioid-induced pruritus occurs more frequently with opioids delivered by the intravenous or neuraxial route than with oral administration. Tolerance to pruritus usually develops fairly quickly, but in rare cases it can be more persistent. The underlying mechanism of pruritus appears to be related to release of histamine, which activates C-fiber itch receptors on C fibers that are distinct from pain-transmitting C fibers. Clinically, pruritus is often limited to the face and perineum but can become generalized and severe. Treatment includes antihistamines, but the therapeutic effect may be related more to sedation than to a direct antihistaminergic effect. In patients receiving intrathecal or intravenous morphine who have significant pruritus that is unresponsive to antihistamines, low dosages of nalbuphine, a μ-receptor antagonist and κ-receptor agonist, may effectively reduce pruritus without reversing the analgesia.

SEDATION

Opioid-naïve patients or those chronically taking opioids who are undergoing dose escalation often experience sedation and drowsiness. Sedation is usually temporary as patients accommodate to the new medication or new dose, and it has been demonstrated that patients maintained on a stable dose of opioids for 7 days rarely have psychomotor impairment. The importance of this fact cannot be overemphasized because patients are increasingly being prescribed opioids for cancer- and non–cancer-related pain. Patients and others may question whether it is safe to
operate a motor vehicle while taking opioids. This is a controversial issue, and strong arguments can be made on both sides. Some physicians may recommend taking no precautions, whereas others may counsel their patients to never drive while taking opioids. Emerging evidence is not completely clear on this issue, but some studies have suggested that patients managed with long-term opioid therapy may be alert enough to drive safely. However, it seems prudent to restrict driving, at least for 1 week or longer at the onset or with dose escalation of an opioid regimen.

Sedation that persists despite an adequate adjustment period to the opioid dose can become as problematic as the pain itself. In such cases, lowering the dose of opioid to the minimal acceptable analgesic level, increasing (widening) the dosing interval, or changing to another opioid that may not be as sedating may be considered. It is important to consider additional causes of sedation such as other medications (e.g., benzodiazepines, antiemetics, tricyclics, muscle relaxants), renal or hepatic dysfunction leading to accumulation, or progression of the patient’s primary disease state itself. If the sedation is thought to be secondary to accumulating levels of the drug or its metabolites, changing to a different agent that is not as dependent on renal clearance or does not have active metabolites, such as fentanyl, may reduce the sedation. In patients with continued unremitting sedation after limiting CNS depressants, attempting opioid dose reduction, and excluding all other underlying causes, psychostimulants may be useful (e.g., amphetamines, modafinil).

RESPIRATORY DEPRESSION

One of the most serious concerns and feared complications of opioid prescribing is respiratory depression. The underlying mechanism of respiratory depression is µ-receptor–induced depression of brainstem centers that subserve respiratory drive. It has long been recognized that depressed respiratory drive may occur more rapidly in patients who have received combined intrathecal-epidural and oral or intravenous opioids. Although there is minimal evidence to support this claim, recognizing that this is a possible risk often supports an acceptable risk management–oriented approach to opioid administration. In addition, combining opioids with other sedating drugs can hasten respiratory depression. This is particularly important in view of the escalating rates of unintended overdose deaths associated with opioids, many involving multiple drugs that include additional respiratory depressants such as benzodiazepines. Clinically, the patient manifests sedation as the first sign of respiratory depression, which can pose a problem in detection during the evening hours when the patient is sleeping. Because respiratory depression can occur after the administration of epidural and intrathecal opioids and is often delayed and does not appear until approximately 12 hours after injection, the signs of sedation may be lost during sleep. Therefore, it is advisable to use alarmed pulse oximetry in patients in whom clinical suspicion is warranted.

Pain is a powerful physiologic stimulant of respiratory drive and opposes the respiratory depressant effects of opioids. In patients in whom pain relief is anticipated from a nonopioid analgesic treatment (e.g., neurolytic procedure, radiation therapy, adjuvant analgesics, surgery), a reduction in opioid dose may be required.

If a patient cannot be aroused and opioid-induced respiratory depression is suspected, the specific opioid receptor antagonist naloxone should be administered. Care must be taken when giving naloxone to patients who have been taking opioids for longer than 1 week or to older adult patients because severe withdrawal symptoms, seizures, and severe pain can be induced. Administration of naloxone has also led to congestive heart failure in susceptible patients. Naloxone is often packaged in an ampule containing 0.4 mg, which can then be diluted in 10 mL of normal saline and administered as 0.5-mL boluses (0.02 mg/0.5 mL) every 2 minutes.

OPIOIDS AND IMMUNOLOGIC EFFECTS

Opioids have been suggested to play a role in the incidence of infection in heroin addicts and act as a contributing factor in the pathogenesis of human immunodeficiency virus. Of note, despite the suggestion that exogenous opioids may cause immunosuppression, endogenous opioids such as endorphins promote immunoactivation. Inhibitory effects on antibody and cellular immune responses, natural killer cell activity, cytokine expression, and phagocytic activity have all been implicated with acute and chronic opioid administration. Furthermore, it has been noted that peripheral immune cells express opioid receptors and this allows intricate communication between cells and cytokines. Opioid-induced alteration of immune function can be categorized into central and peripheral components. It has been postulated that central opioid receptors mediate peripheral immunosuppression via the hypothalamic-pituitary-adrenal axis and autonomic nervous system. Interestingly, severely chronic pain in and of itself has been suggested to be associated with a reduction in immune function.

OPIOIDS AND HORMONAL CHANGES

The oral, intravenous, and intrathecal routes of administration of chronic opioid therapy have been well described to alter hormonal effects in both men and women. Mendelson and colleagues found that in illicit drug users, serum hormones that were altered by opioid administration subsequently returned to normal following suspension of the drug. Hormones disrupted by opioids are not relegated to testosterone (both total and free) but also include estrogen (estradiol), luteinizing hormone, gonadotropin-releasing hormone, dehydroepiandrosterone, adrenocorticotropic, corticotropin-releasing hormone, and cortisol. Opioid-related endocrinology research focuses on androgenic hormones because of the well-described symptomatic side effects. Sexual dysfunction (erectile dysfunction, decreased libido), depression, and fatigue are some of the many side effects that men may experience when prescribed chronic opioid therapy. Many of the aforementioned side effects have been correlated with hypogonadism. Symptoms such as depression and sexual dysfunction are not relegated just to men; women can experience such side effects as well. Women also experience dysmenorrhea and potentially reduced bone mineral density. Testosterone levels likewise appear to be reduced in women and may have some correlation with body mass index.
OPPIOID-INDUCED SLEEP DISTURBANCES
A considerable amount of study on the effects of chronic opioid therapy on sleep is still needed. Despite the paucity of data, some research suggests that opioids increase the number of shifts in sleep/waking states and reduce total sleep time, sleep efficiency, delta sleep, and rapid eye movement (REM) sleep. In various studies it is difficult to separate the effect of opioids on sleep from those of comorbid condition (e.g., cancer, addiction or dependence, postoperative pain). Research suggests that γ-aminobutyric acid (GABAergic) signaling via inhibition of acetylcholine release in the medial pontine reticular formation is the primary focus for disruption of sleep by opioids. Morphine has been demonstrated to reduce REM sleep. The resulting disruption in sleep architecture affects the state of arousal during wakefulness.

OPPIOID TOLERANCE AND PHYSICAL DEPENDENCE
There are substantial differences that distinguish tolerance, dependence, and addiction from each other. Unfortunately, these concepts are frequently misunderstood. In 2001, the American Pain Society, American Academy of Pain Medicine, and American Society of Addiction Medicine approved definitions of addiction, physical dependence, and tolerance in the hope of reducing misguided treatment of patients who require opioids for pain treatment. In a patient who is chronically administered opioids, it should be anticipated that physical dependence and tolerance will develop, but the maladaptive changes in behavior witnessed in patients with addiction (see later discussion) should not necessarily follow.

TOLERANCE
The term opioid tolerance is often used to describe the phenomenon that occurs when a fixed dose of an opioid results in decreasing analgesia, thus requiring higher doses of medication to achieve the same or less effect over time. The mechanisms responsible for this phenomenon are not entirely understood, but the N-methyl-D-aspartate (NMDA) receptor has been demonstrated to be involved. The clinical usefulness of NMDA receptor involvement has yet to be determined fully, but nonhuman studies have continued to promulgate the potential for using NMDA receptor antagonists in conjunction with opioids to attenuate tolerance and physical dependence. A subpopulation of dorsal horn neurons expressing NMDA receptors and treated with high-dose morphine have been shown to have enhanced NMDA receptor–mediated activity. Furthermore, μ-receptor antagonist and NMDA receptor antagonist treatment of this subpopulation has attenuated the increased activity. Another study has demonstrated that in “morphine-tolerant” rats treated with an NMDA receptor antagonist, the morphine-induced tolerance reversed. The relevance of these findings at the bedside have, to date, not been clear.

Human studies on the effect of the NMDA receptor on tolerance have been less promising. There has been great hope that NMDA receptor antagonists such as ketamine or dextromethorphan might potentiate the analgesic effect of opioids, but not much convincing evidence has emerged from replicated trials. In a double-blind controlled clinical trial comparing morphine and a combination of morphine and dextromethorphan, statistical differences in analgesia or dose were not seen between groups. Nonetheless, basic concepts continue to support the understanding that the NMDA receptor is a key component in the development of opioid-induced tolerance. In particular, ketamine continues to be a drug of major interest because of its potential to improve opioid performance through preventing tolerance and enhancing opioid-induced analgesia.

When it is suspected that a patient has become tolerant to one medication, the cause may be opioid tolerance, but it may also relate to increased pain, which requires adjustment in dosing. The need for dose escalation in a patient treated with chronic opioids should always stimulate consideration that the underlying disease may be progressing. When opioid-induced tolerance is present, opioid rotation can be performed. This is based on the clinical observation that patients often have intrindividually analgesic responses to different opioids and that improved analgesia with fewer side effects may occur when a different opioid is used. Although the full mechanism of this phenomenon is not completely understood, it is usually thought to occur because of incomplete tolerance, possibly related to differing μ-opioid and other opioid receptor affinities of one opioid versus another. When opioid rotation is performed in an opioid-tolerant as opposed to an opioid-naïve patient, equal analgesic doses may not be necessary. The patient may respond with analgesia to half the equianalgesic dose, and if not, the dose may be titrated to an adequate analgesic effect that is less than would be expected by calculation of equianalgesic conversion from standard formulas. This is a potentially useful phenomenon whereby the overall opioid requirement of the patient may be reduced, thereby achieving an opioid-sparing effect.

PHYSICAL DEPENDENCE AND WITHDRAWAL
Physical dependence is a physiologic state that occurs when a medication is abruptly stopped and a withdrawal syndrome results. It is not synonymous with addiction. This separation of physical dependence and addiction is supported by evidence of two distinct anatomic areas within the CNS that are involved in physical dependence versus addiction. Noradrenergic neurons within the locus coeruleus are implicated in the maintenance of dependence and development of withdrawal, whereas the ventral tegmental dopaminergic area and orbitofrontal glutamatergic projections to the nucleus accumbens are particularly thought to subserve addiction. It has been shown that drugs of abuse such as heroin, cocaine, nicotine, alcohol, phencyclidine, and cannabis initiate their habit-forming actions by activating a common reward pathway in the brain. There is also evidence for the involvement of noradrenergic neurons in the development of withdrawal. Not only do norepinephrine levels change in the brain following opioid dependence, but the administration of an α2-agonist such as clonidine or a β-antagonist such as propranolol also attenuates many of the symptoms of opioid withdrawal but does not reverse addiction.

The clinical manifestations of opioid withdrawal usually begin with irritability, anxiety, insomnia, diaphoresis, yawning, rhinorrhea, and lacrimation. If it progresses without intervention, a flu-like condition develops, with chills, myalgia, fever,
abdominal cramping, nausea, diarrhea, tachycardia, and other features of a heightened adrenergic state occurring. Though uncomfortable for patients, it is self-limited and lasts approximately 3 to 7 days. Opioid withdrawal may occur in patients who abruptly discontinue opioids or who have relative discontinuation because of taking SAOs after accommodating to the longer plasma half-life of LAOs.32

It is usually possible to taper patients from opioids to prevent withdrawal symptoms. Although faster tapering can be accomplished without the advent of withdrawal symptoms, if time allows, few patients will be symptomatic if the dose is decreased by 10% to 20% every 48 to 72 hours over a prolonged period (usually 2 to 3 weeks, depending on the dose).67 If, however, symptoms of withdrawal develop during discontinuation or taper, clonidine, 0.2 to 0.4 mg/day, may be used to decrease discomfort.68 Clonidine is often maintained for 4 days during taper of an SAO and for 14 days during taper of an LAO. Once opioids have been discontinued, clonidine can be tapered over a period of approximately 1 week.32

### ADDICTION

Opioids are associated with addiction at a rate that is high enough to be a significant concern; however, the exact rate of addiction as a result of therapeutic opioid use is controversial. Opioid addiction is a disorder characterized by opioid use that results in physical, psychological, or social dysfunction (or a combination of these), as well as continued use of the opioid despite the dysfunction. Neurobiologic evidence has suggested that this phenomenon may be subserved by positive reinforcement and sensitization of the dopaminergic system in the brain, which may explain the continued seeking of a substance destructive to the patient’s life.59 Patients who are receiving an inadequate dose of opioid medication may engage in drug-seeking behavior to obtain more pain medication for relief of pain, which can be mistaken for the drug-seeking behavior associated with addiction. Physicians are often challenged to distinguish true addiction from undertreated pain because on the surface, undertreated pain may appear similar to addiction because of features such as drug seeking and self-escalation. However, unlike addiction, with increased doses of opioids, an undertreated patient experiences pain relief and improved function. Whereas undertreated pain should resolve when the patient obtains adequate analgesia, true addictive behavior does not. Addiction exists in direct contradistinction to what is seen in a patient with undertreated pain who goes through dose escalation. With opioid addiction, the aberrant behavior not only continues despite an increase in opioid but is also usually further stimulated and promoted by increased exposure to the addicting drug. It is difficult to make a prospective diagnosis of addiction because there is no single behavior or diagnostic test that can confirm the diagnosis. The Committee on Pain of the American Society of Addiction Medicine has defined addiction in the context of pain treatment with opioids as a persistent pattern of dysfunctional opioid use.70 Patient behavior may be used cumulatively to support the diagnosis of addiction, but absolute conclusions cannot always be made, particularly without longitudinal information over extended periods. Many types of behavior may indicate the possibility of addiction to some degree (Box 36.1).

Nonadherence to opioid therapy may be related to many possibilities, including adverse effects, forgetfulness, incompatibility with lifestyle, and confusion about the drug regimen. It may rarely be related to aberrant behavior such as diversion or drug abuse, and an astute physician will maintain a position of vigilance without feeling compelled to reach immediate conclusions. If a physician chooses to pursue pain treatment with an abusable drug in a patient at risk for addiction, collaboration with an addiction specialist or addiction psychiatrist is advised to ensure that the necessary resources to support an appropriate risk management program are available. Such resources are usually far greater than those available to the average prescriber, and without the necessary resources to ensure safety, prescribing should not begin. As always, high vigilance and tempered judgment are required.

The prevalence of addiction, abuse, or dependence in patients with chronic pain is not known exactly but is

estimated to range from 3% to 19%. Treating chronic pain in a person with a history of addiction is challenging but is not an absolute contraindication. Nonetheless, responsible prescribers of opioids must ensure that the appropriate resources for safe use are in place before initiating treatment. If appropriate risk management is not available, treatment should not be started. Moreover, treatment should not be started unless it can be terminated when necessary.

Although a low percentage of the population with chronic pain appears to have an addiction problem, the remainder of the population has been shown to receive suboptimal analgesia because of prescribers’ fears of patient misuse of the opioid. A growing debate has emerged that focuses on analgesia because of prescribers’ fears of patient misuse of the nonopioid agent. The population has been shown to receive suboptimal pain appears to have an addiction problem, the remainder of the population has been shown to receive suboptimal analgesia because of prescribers’ fears of patient misuse of the opioid.73 A growing debate has emerged that focuses on understanding how opioids should be used in the setting of substantial rates of chronic pain while balancing the imperative for vigilant use of opioids with sufficient risk management for acceptable safety.

**SELECTED OPIOIDS**

Although therapeutic options to provide analgesia continue to emerge, opioids remain the “gold standard” of currently available analgesics. Despite the widespread use of opioids for the treatment of acute and chronic pain, controversy exists over whether opioids should be used for the treatment of chronic nonmalignant pain. There are proponents on each side of the controversy, and part of the fear of prescribing opioids stems from an inaccurate understanding of appropriate outcomes for prescribing opioids and the risk for abuse or side effects. Although opioids can be a useful tool to provide adequate analgesia for patients, fear of the development of addiction, dependence, or untoward side effects often precludes physicians from prescribing opioids.73 If it is decided to initiate opioid therapy in patients with chronic nonmalignant pain, the decision should be based on a well–thought-out rationale for treatment, with clear end points in mind.

SAOs are generally used for acute pain, whereas LAOs are prescribed for patients with chronic pain syndromes. Because SAOs have relatively brief peak serum blood levels of active analgesic metabolites, using them to treat persistent baseline chronic pain will require frequent dosing. This roller coaster effect is thought to promote nonoptimal pain-related behavior, which is why LAOs have been considered more appropriate in such cases. However, science has not clearly demonstrated such an advantage.

SAOs are often combined with other analgesics such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or aspirin, which may offer drug-sparing effects because less medication may be used. Although combination opioids may help reduce potential opioid-related side effects and toxicity, there is a potential for harm to major organs from the nonopioid components (e.g., acetaminophen, NSAIDs, aspirin). When using combination opioids, physicians must be aware of renal and liver function problems, as well as the potential harm that could occur to the GI system. Patients must be educated about the risks of taking other analgesics such as acetaminophen, NSAIDs, and aspirin in conjunction with the combination opioids. Moreover, physicians must also consider that the compounded nonopioid drug is likely to have a ceiling effect beyond which it is no longer efficacious. Because opioids induce tolerance and have no ceiling effect, the pharmacologically appropriate need for increased opioid may inadvertently push the dose of a combination drug to appropriate levels of the opioid component but to toxic levels of the nonopioid agent. Although reviewing all available opioids is beyond the scope of this chapter, we will review the most commonly used opioids for pain management. Minor opioids such as hydrocodone are discussed in Chapter 37.

**CODEINE**

Codeine is an alkaloid found in very low concentrations in opium; it is now derived from morphine. Codeine is frequently administered in combination with acetaminophen, butalbital, and caffeine. It has been shown to be an effective analgesic for chronic nonmalignant pain, but with limitations. It is a weak μ-opioid agonist and has a half-life of 2.5 to 3 hours. The major metabolic pathway leads to glucuronidation of codeine to codeine 6-glucuronide, with a minor metabolic pathway catalyzed by the polymorphically expressed enzyme CYP2D6 through N-demethylation of codeine to norcodeine and O-demethylation of codeine to morphine. Evidence has suggested that the analgesic effects of codeine rely on its conversion to morphine, and patients with genetic variations in the enzymes needed to make this conversion may find codeine to be less effective. The genetic polymorphism of CYP2D6 is responsible for the variable response to the medication. Patients with the genotype CYP2D6 PM (poor metabolizers) do not achieve adequate analgesia with codeine. In addition, certain medications that inhibit CYP2D6, such as quinidine, paroxetine, fluoxetine, and bupropion, can alter the phenotype of normal patients with normal genetics and thus decrease the therapeutic analgesic effect of codeine. Urinary excretry products of codeine include codeine (70%), norcodeine (10%), normorphine (10%), normorphine (4%), and hydrocodone (1%). This may be important to remember when interpreting the urine toxicology screens of patients taking codeine.

**MORPHINE**

Morphine, a hydrophilic phenanthrene derivative, is the prototypical opioid against which all other opioids are compared for equianalgesic potency. Because of its hydrophilic nature, it exhibits delayed transport across the blood-brain barrier, thus delaying its onset of action. Conversely, it has a longer duration of action, 4 to 5 hours, than its plasma half-life of 2 to 3 hours. Metabolism of morphine to its two major metabolites, M6G and M3G, occurs mainly in the liver (see Table 36.1). Although the parent compound produces analgesia and side effects, M6G may also produce some analgesia along with some adverse effects. M6G accounts for 5% to 15% of morphine’s metabolites and is a μ- and δ-agonist, which accounts for its analgesic effects. It has been demonstrated that M6G does not exert antinociceptive effects in knockout mice lacking the μ receptor. M3G, which accounts for 50% of morphine’s metabolites, does not appear to possess opioid agonism but may produce effects that oppose morphine’s analgesic actions, such as allodynia, hyperalgesia, myoclonus, and seizures. Oral administration of morphine has been shown to result...

in higher levels of M3G and M6G than achieved with the intravenous, intramuscular, or rectal routes, which bypass hepatic metabolism.78 Chronic administration of morphine ultimately results in higher circulating levels of M3G and M6G metabolites than the parent compound.79 It has been found that patients receiving chronically high morphine doses metabolize morphine to hydromorphone and test positive for hydromorphone on urine toxicology screens.80 This is of critical importance in patients using morphine for chronic pain who undergo urine drug screening.

Although extrahepatic metabolism of morphine has been shown to occur in gastric and intestinal epithelia, morphine should be used with caution in patients with decreased hepatic function, such as those with cirrhosis.10 In addition, glucuronides have been shown to undergo deconjugation back to the parent compound by colonic flora and to be reabsorbed as morphine.10 Morphine metabolites are excreted by the kidneys, so caution should also be taken when prescribing morphine to patients with renal impairment because accumulation of M6G and M3G can be toxic. Currently available forms of morphine include short- and long-acting preparations. Short-acting agents may be compounded for almost any route of administration, and long-acting preparations generally use specialized sustained-release matrix technology, such as found in MS Contin, Kadian, Oramorph SR, and Avinza.

**OXYCODONE**

Oxycodone is a semisynthetic opioid that is closely related to morphine. It has been available for analgesia since 1917, when it was introduced into clinical practice in Germany.81 It is processed from thebaine, an organic compound found in opium. Like morphine, currently available forms of oxycodone include short- and long-acting preparations. Short-acting oxycodone may be used alone (e.g., Roxicodone) or may be compounded with acetaminophen (e.g., Percocet, Roxicit, Endocet) or aspirin (e.g., Percodan). Long-acting oxycodone preparations are designed for oral administration and involve the use of specialized sustained-release technology (e.g., OxyContin and similar generics).

Oxycodone has high bioavailability, 60%, when compared with morphine, which has a bioavailability of 33%, thus making oxycodone almost twice as potent as morphine.58 Oxycodone is a prodrug that undergoes hepatic metabolism via the CYP2D6 isozyme, whereby it is converted into its active metabolite oxymorphone, a µ-opioid agonist, and its inactive metabolite noroxycodone. Oxymorphone is reportedly often undetectable and is 14 times more potent than the parent compound.

Similar to codeine, there is genetic polymorphism in 10% of the population, which accounts for significant variation in the metabolism of oxycodone. This variation explains why some patients require higher than usual doses of oxycodone to achieve analgesia. Another factor to be considered when prescribing oxycodone is whether other potential competitors of the CYP2D6 isozyme are being prescribed. Such interacting medications include neuroleptics, tricyclic antidepressants, and selective serotonin reuptake inhibitors (SSRIs). Cases of serotonin syndrome have been described in the literature when SSRIs and oxycodone were used concomitantly.81,82

**MEPERIDINE**

The use of meperidine for analgesia has been declining recently because of its potential for neurotoxicity. It is a weaker µ-opioid agonist than morphine with 10% of its potency, more rapid onset, and a shorter duration of action.79 The half-life of meperidine is 3 hours, and it is hepatically demethylated to its neurotoxic metabolite normeperidine, which has a half-life of 12 to 16 hours. Normeperidine has been well documented to cause CNS hyperactivity and seizures.25 Excretion of normeperidine is via the kidneys; therefore, caution should be taken when administering meperidine to patients with renal impairment or those prone to CNS hyperactivity. Initially, the toxic effects may be seen as subtle changes in mood that can progress to naloxone-irreversible tremors, myoclonus, and seizures. Chronic administration of meperidine to patients with normal renal function and administration of meperidine in conjunction with SSRIs, monoamine oxidase inhibitors, tramadol, and methadone can also result in neurotoxic side effects.79

**HYDROMORPHONE**

Hydromorphone has strong affinity for the µ receptor. It is a hydrogenated ketone analogue of morphine and can be formed by N-demethylation of hydrocodeine.53 Hydromorphone is similar to morphine in that it is hydrophilic and has a comparable duration of analgesia, but it differs with respect to side effects and potency. Pruritus, sedation, nausea, and vomiting occur less frequently. Furthermore, hydromorphone is five times more potent than morphine.
when administered orally (see Table 36.2) and seven times more potent when administered parenterally. Though essentially hydrophilic when administered orally, it is 10 times more lipophilic than morphine. This lipophilicity may be an advantage when treating patients who are unable to take oral medications and cannot maintain intravenous access, such as in hospice environments. It can be given subcutaneously at a dose of 10 or 20 mg/mL; this route delivers approximately 80% of the dose absorbed through intravenous delivery. The onset of analgesia occurs in 30 minutes after oral administration and 5 minutes after intravenous administration, with peak analgesic effects occurring within 8 to 20 minutes.

Hydromorphone is metabolized in the liver to H3G and, like its parent compound, is excreted renally. Similar to M3G, H3G lacks analgesic effect but may be an active metabolite that potentiates neurotoxic effects such as allodynia, myoclonus, and seizures. Production of H3G is relatively low, so the risk for neurotoxic side effects is relatively low, except in patients with renal insufficiency, in whom H3G may accumulate.

### FENTANYL

Fentanyl is a highly lipophilic agent with high affinity for the μ-opioid receptor. It is 75 to 125 times more potent than morphine and has a faster onset of action. Because of its higher potency, smaller quantities of the medication can be delivered to the patient relative to other opioids. Even though fentanyl is considered to be a short-acting medication, its lipophilic nature allows long-acting transdermal and very rapid-onset transmucosal administration for the treatment of chronic and acute pain, respectively. Although there are other minor pathways, fentanyl undergoes hepatic biotransformation via CYP3A4 N-dealkylation to norfentanyl. Its half-life and onset of action vary greatly by route of administration. (Transmucosal fentanyl undergoes first-pass metabolism and has an onset of action within 5 to 10 minutes.)

A transdermal fentanyl patch is used by some patients with chronic pain or with pain related to cancer. Transdermal fentanyl has been used for acute postoperative pain but may be associated with hypoventilation. Transdermal patches are typically placed on a hairless part of the body that is flat and free of any defects that could interfere with adherence of the patch. Patients should be advised to avoid submerging the patch in hot water or placing a heating pad over the area because this influences absorption. Patients report local skin erythema or irritation as the most common side effect.

Transdermal fentanyl is an alternative choice for patients who have significant GI issues, such as persistent emesis, chronic nausea, or “short gut” syndrome, or for those believed to be at risk of diverting oral medications. Use of the patch offers the opportunity to have patients return the old patches for inspection at the time of prescription refill. Theoretically, transdermal delivery may induce less constipation than oral opioids because it avoids direct exposure to the GI tract, but this is questionable in light of the common finding of significant constipation in almost all who use transdermal opioids.

Unlike other LAOs, transdermal fentanyl may be challenging to titrate because of variation in individual patient characteristics, such as skin perspiration, skin temperature, fat stores, and muscle bulk. The rate of achieving therapeutic serum levels can be variable (ranging from 1 to 30 hours with a mean of 13 hours). Because of the wide variation in reaching therapeutic levels, a short-acting oral analgesic or intravenous patient-controlled analgesia may be necessary to address breakthrough pain while the transdermal opioid effect is ramping up or to prevent withdrawal symptoms if rotation from another opioid has occurred. Achieving steady-state levels may require up to 6 days, and the amount of SAO needed after a steady state is attained will help determine whether the dose of fentanyl must be increased. If the patch is removed, however, it may take up to 16 hours for serum fentanyl concentrations to drop by 50%.

Oral transmucosal fentanyl has a more rapid onset of analgesia than do other SAOs and offers some special advantages. Because it is transmucosal, it avoids the GI tract and first-pass hepatic metabolism and has a rapid onset of action, within 10 to 15 minutes. One study compared intravenous morphine with transmucosal fentanyl in an acute postoperative setting and demonstrated similar onset of analgesia.

Transmucosal fentanyl can be beneficial for patients with acute breakthrough pain. To date, a major limitation in using this route has been cost.

### METHADONE

Methadone may be an attractive choice for analgesia because of several of its unique properties, but it also has many features distinguishing it from other opioids that have raised its potential for adverse outcomes. Recently, methadone has become the most common opioid found to be related to unintended overdose deaths in the United States. Thus, the need for caution with this drug should be self-evident. On the positive side of the methadone risk-benefit profile, its attributes include no known neurotoxic or active metabolites, high absorption and bioavailability, and multiple receptor activities, including μ- and δ-opioid agonism, NMDA antagonism, and serotonin reuptake blockade. Methadone has been shown to have a bioavailability that is approximately threefold that of morphine.

In patients who require high-dose LAOs, methadone appears to be a theoretical second-line choice despite of the lack of accumulation of neurotoxic metabolites that induce myoclonus, hallucinations, seizures, sedation, and confusion.

States. Thus, the need for caution with this drug should be self-evident. On the positive side of the methadone risk-benefit profile, its attributes include no known neurotoxic or active metabolites, high absorption and bioavailability, and multiple receptor activities, including μ- and δ-opioid agonism, NMDA antagonism, and serotonin reuptake blockade. Methadone has been shown to have a bioavailability that is approximately threefold that of morphine.

In patients who require high-dose LAOs, methadone appears to be a theoretical second-line choice despite of the lack of accumulation of neurotoxic metabolites that induce myoclonus, hallucinations, seizures, sedation, and confusion.
Unfortunately, it is methadone’s unique pharmacokinetics and pharmacodynamics that render its effects somewhat unpredictable.

Methadone is structurally unrelated to other opioid-derived alkaloids. It is a racemic mixture of two enantiomers, the D isomer (S-methadone) and L isomer (R-methadone). R-Methadone accounts for its opioid receptor affinity and thus its opioid effect. Animal studies have demonstrated that methadone has lower affinity than morphine for the μ receptor. This may explain why methadone may have fewer μ-opioid–related side effects than morphine. Methadone, however, has higher affinity for the δ receptor than morphine does.

Methadone has a slow but variable elimination half-life that averages approximately 27 hours, which may be related to its lipohilicity and extensive tissue distribution. The delayed clearance of methadone is the basis for its use in maintenance therapy. Surprisingly, although methadone may be efficacious for purposes of opioid maintenance therapy since it potentially prevents withdrawal symptoms for 24 hours or longer, its analgesic half-life is shorter than 24 hours, usually found to range from 6 to 8 hours. This discrepancy is related to its biphasic elimination. The alpha elimination phase lasts 8 to 12 hours and correlates with the period of analgesia, which lasts approximately 6 to 8 hours. The beta elimination phase ranges from 30 to 60 hours and is responsible for preventing withdrawal symptoms; this property is exploited in maintenance therapy.

Methadone has multiple drug interactions related to inducers or inhibitors of the CYP system, particularly the 2D6 and 3A4 subtypes. Because these interactions are not commonly seen with other opioids, drug interactions with methadone may not be as readily anticipated or detected. In addition to interacting with drugs, 3A4 is an auto-inducible enzyme, which accounts for the fact that methadone can bring about its own metabolism and increase its clearance with prolonged use.

Other issues affecting methadone absorption and accumulation are gastric and urinary pH. Decreased gastric pH, such as in patients taking proton pump inhibitors, results in increased rates of methadone absorption. Renal failure and hemodialysis do not alter the excretion of methadone; however, as urinary pH increases, methadone clearance in urine decreases. Urine pH higher than 6 can reduce methadone clearance from 30% to almost 0% and thereby result in increased circulating levels. Most methadone is eliminated in feces. Another source of methadone’s potential metabolic instability relates to its avid protein binding. Acute changes in protein binding may lead to sudden increases or decreases in circulating methadone levels.

The difference between methadone and other LAOs is that methadone’s duration of effect is intrinsically long acting, whereas most other LAOs are sustained-released forms based on compounding technology. It is beneficial in patients with impaired GI absorption. In addition, methadone is available as a powder, which allows it to be formulated for almost any route of administration. Methadone pills can be broken and cut in half, and it is also available as a liquid elixir (1 or 10 mg/mL). This avoids having to crush pills, which offers a potential advantage in patients with gastrostomy tubes. In addition, because methadone elixir has a low-concentration formulation, careful and precise titration of methadone can be performed to achieve adequate analgesia.

One of the most disturbing aspects of methadone use in the United States has been the reported increase in methadone-related deaths. Although the mechanism for these deaths is not exactly clear, many appear to be related to overdose and drug interactions. In some cases, overdose may be related to misunderstanding the standard conversion rates for methadone from other opioids. Contrary to conventional wisdom, methadone appears to be more potent (milligram for milligram) in patients whose treatment is being switched to methadone from high doses of other opioids. Although standard conversion tables may suggest that the ratio of conversion from morphine to methadone may be from 1:1 to 1:3, these ratios were taken from studies on acute pain or normal controls. Many of these conversion tables were developed more than 20 years ago, far before recent increases in methadone use as a chronic analgesic. In cases in which much higher pre-switch dosages are converted to methadone, the appropriate morphine-to-methadone ratio may range from 1:5 to 1:20 or higher. Obviously, such a counterintuitive dosing phenomenon leads to the potential for overdose.

Another possible source of methadone-related mortality includes torsades de pointes arrhythmias, which have been reported in some patients. Although a prospective study has demonstrated QT prolongation on electrocardiogram in patients taking methadone, it was also concluded that the magnitude of the increase is less than that with other antiarrhythmic drugs and is not higher than the QT widening caused by other drugs such as tricyclic antidepressants.

Use of methadone requires awareness of possible QT prolongation and the possible additive effect that other QT-prolonging agents may have when combined with methadone. Table 36.1 shows the oral bioavailability, half-lives, duration of action, and metabolites of selected opioids. Table 36.2 shows the equianalgesic doses of different opioids.

Methadone must be used with significant knowledge of the special properties that predispose it to substantial risk. Slow dosing titration and careful monitoring are essential to safe use. If this and all other elements of safe prescribing of opioids are not possible, the drug should not be prescribed.

### RATIONAL OPIOID PRESCRIBING

Opioids work for some pain but not all. They may be problematic for many and even life-threatening for some, but knowing who is susceptible is not always clear. Treatment of substantial pain may necessitate the use of opioid-related medications. Opioids are not the first choice, nor should they necessarily be the last choice in the pain management armamentarium. A detailed diagnosis with a thorough history and physical examination and an essential focus on risks and benefits will drive the selection of specified analgesic treatments. Nonopioid treatments will often be the initial choice. The decision to use opioid therapy has undergone intense scrutiny as the public health epidemic of prescrip-
that has been well documented through approximately 15 years of retrospective data. A history of psychiatric comorbidity and a history of substance abuse are known variables suggestive of increased risk for abuse and unintentional overdose death. A full discussion of the safe use of opioids is beyond the scope of this chapter but can be found in other resources, such as the White House Office of the National Drug Control Policy and the National Institute on Drug Abuse (http://www.medscape.org/viewarticle/770687 and http://www.medscape.org/viewarticle/770440 [as of 10/2012]), Boston University (http://www.opioidprescribing.com [as of 10/2012]), the National Institutes of Health (http://www.opioidrisk.com [as of 10/2012]), and the Federation of State Medical Boards (http://www.fsmb.org/cme/ [as of 10/2012]).

Before the initiation of opioid therapy, a detailed evaluation is necessary. This evaluation must include risk stratification, assessment of functional activity, a thorough review of the patient’s medical history with special attention paid to previous experience with opioid analgesics, and a review of other related comorbid factors, including previous substance abuse; mental illness; hepatic, renal, or pulmonary dysfunction; or sleep apnea. Informed consent is a critical element of opioid treatment that requires patient education on the benefits and risks associated with treatment. The expectations and responsibilities on the part of the patient must be clarified early. Monitoring for and management of opioid-induced side effects are imperative. The use of opioid agreements, urine drug screens, and well-defined boundaries of care must be considered in advance of initiating treatment, as well as an exit strategy if treatment fails to be successful for any variety of reasons.

Should the patient be opioid naïve, low-dose SAOs such as propoxyphene, hydrocodone, or oxycodone may be initiated and carefully titrated to establish an opioid requirement. Because of the rapid clearance and brief half-life of SAOs, toxic accumulation of the medications is less likely than with LAOs. The severity and duration of the patient’s pain should help guide whether PRN or fixed dosing is required. In patients with acute pain secondary to an injury or surgery for which rapid healing is expected, PRN dosing is reasonable. However, in patients with the expectation of prolonged recovery or with chronic pain and significant baseline or persistent pain, opioids may be administered in fixed-dosing intervals, as well as in PRN intervals for breakthrough pain. Scheduled dosing decreases clock-watching anxiety and reinforcement of pain behavior. If a patient is able to tolerate an SAO and its side effects, consolidation of the daily opioid requirement into an equianalgesic LAO regimen may be an appropriate step.

Although opioids may be excellent analgesics, they are often used as second-line treatment of chronic pain, mainly because chronic pain may respond to nonopioid treatments that might carry fewer risks. When other pharmacologic, rehabilitative, or interventional procedures are not appropriate or are unsuccessful, chronic opioid therapy should be considered. It is not uncommon to combine opioid treatment with other modalities, including psychological treatment and physical rehabilitation. Simultaneously, interventional pain procedures and adjunctive analgesics may be useful as well.

The effectiveness of opioid therapy for certain types of chronic pain, such as neuropathic pain, remains controversial. Because antidepressants and anticonvulsants have been shown to provide less than 50% pain relief on average, opioids have been used for the treatment of chronic neuropathic pain despite their narrow therapeutic window. When treating neuropathic pain, it has been shown that opioid potency may be relatively lower than that for other conditions. The basis of this seems to be secondary to changes that occur in the endogenous opioid system after nerve injury. It appears that endogenous peptide levels and opioid receptor density decrease in nociceptive pathways. It also appears that GABAergic tone decreases after nerve injury and that the inhibitory effect of morphine on dorsal horn neuron projections after nerve injury is reduced in comparison to its effect on noninjured nerves. Despite these findings, there is evidence in the literature that opioids are efficacious for neuropathic pain; a trial demonstrated that combining gabapentin and morphine for the treatment of neuropathic pain was superior to either alone.

In forms of chronic pain unrelated to nerve injury that have not responded well to other treatments, opioid therapy has been shown to be more effective than placebo or anti-inflammatory medications alone in reducing pain. However, studies have struggled to show substantial improvement in overall functioning with opioid therapy. In a meta-analysis comparing analgesia and function in subjects taking opioids, NSAIDs, or placebo, there was no statistical difference among the groups with regard to improved function. It should be noted, however, that this study did not use adjunctive medications or physical therapy. This emphasizes the point that although opioids may be effective, if used as the sole agent for changing all the primary and secondary effects of chronic pain, they may not be effective enough. The importance of a multidisciplinary approach to the treatment of chronic pain syndromes cannot be overstated.

The use of opioids requires a comprehensive strategy, including consideration of other potentially effective therapies that have less risk. Rational prescribing also requires consideration of all potential risks associated with the treatment and should include a plan to avoid or deal with these risks.

**CONSIDERATIONS FOR OPIOID PRESCRIBERS**

In response to a surging public health crisis regarding the misuse of prescription drugs, the Obama Administration in 2011 developed the Prescription Drug Abuse Prevention Plan through the Office of National Drug Control Policy (ONDCP). The ONDCP plan entails specialized efforts with regard to monitoring, proper medication disposal, enforcement, and education. In fact, education of patients, parents, and youth is a key element of focus for the White House–implemented drug abuse prevention plan. Equally important is education of prescribing physicians and providers of care. In 2012 the Federation of State Medical Boards of the United States revised and expanded the book *Responsible Opioid Prescribing: A Clinician’s Guide*. The revised guide reviews the new data on opioid risk and toxicity, including high rates of unintended overdose deaths, that were not available when the first edition was written in 2006. It offers clinicians strategies to reduce the risk for addiction,
abuse, and diversion of opioids. Moreover, the revised edition includes but is not limited to defined strategies for patient evaluation that includes risk assessment, treatment plans that incorporate functional goals, periodic review and monitoring of patients, documentation, informed consent, and termination strategies for chronic opioid therapy. It also emphasizes the special care that is needed when using methadone and treating children and adolescents, as well as prescriber responsibilities for consumer education on the safe use of opioids. The use of defined risk stratification methods by prescribers of chronic opioid therapy has become paramount. Gourlay and colleagues endorsed taking a universal precautions approach and suggested that addiction can only be elucidated on a behavioral prospective basis.

TREATMENT END POINTS

Because pain is a subjective experience, using “pain relief” as a treatment end point is a subjective and nontestable marker of therapeutic success or failure. One of the most feared consequences of chronic opioid therapy is drug addiction, which as discussed earlier, is compulsive use of an opioid that causes dysfunction and continued use of the opioid despite the dysfunction (i.e., negative impact on or harm to the patient’s life). Because effective analgesia should improve function and because of fear of the side effect of addiction, which hinges on dysfunction, a major focus of chronic opioid therapy should be on functional improvement as an objective end point. It is expected that patients who are treated carefully and judiciously with opioids and achieve analgesia should have functional gains. This is in contradistinction to an addict, who becomes impaired by substance abuse as manifested by dysfunction. The challenge for physicians treating chronic pain with opioids is to devise a system of objective markers that distinguish function from dysfunction and that emphasize a wide spectrum of therapeutic goals.

Several markers of functional improvement can be used in patients treated chronically with opioids. Several standardized functional measurements (e.g., the 36-Item Short-Form Health Survey [SF-36], Oswestry Disability Index [ODI]) can be used to subjectively measure the reduction in pain with supportive and objective evidence of improvement in functional status and effect on quality of life. However, psychological and social factors, as well as the status of coexistent disease, may influence the perception of pain, suffering, and entitlement and can alter the overall assessment. Unfortunately, not all of these parameters will improve concomitantly or proportionately following the initiation of opioid therapy. If factors related to psychological and physical reconditioning have not been addressed, pain perception and reduction of pain after a trial of an opioid may be less than optimal.

Determining effective treatment end points during an opioid trial may require flexibility in considering the many possible variations in efficacy and functional gain. A central question that may be useful at the beginning of an opioid trial is “What do you need to do with this medicine that you cannot do now?” What follows should be the creation of a list of reasonably attainable functional goals that cover multiple domains of the patient’s life. Equally important in documenting this list is the process by which the goals will be attained and how the patient plans to document progress toward each functional goal for the clinician on every subsequent follow-up visit. Each goal is monitored regularly and adjusted on the basis of progress. Expectations may need to be reduced if goals are not being met or may be advanced as the patient improves.

One approach to determining whether a patient is benefiting from opioid therapy is to gather collateral information from others involved in the patient’s care and life. Input from physical and occupational therapists, psychologists, family members, and caregivers may prove invaluable. Evidence of improved function may include gains in employment, increased activities of daily living, and socializing with family and friends. On the contrary, if a patient becomes dysfunctional in employment or in social or private life, concerns about possible medication-related deterioration should be raised, including addiction. However, decreased function is not pathognomonic of addiction. It may be related to other factors beyond a patient’s control, such as sedation, cognitive impairment, or other external causes. If these or other external problems are not the cause of a patient’s deteriorating mental or physical health, it may be helpful to consider seeking additional support in the form of a multidisciplinary program or referral to other specialty providers, such as psychologists, social workers, psychiatrists, or addiction specialists.

It remains controversial whether subjective relief without objective evidence of improved quality of life is sufficient to justify the chronic use of opioids. Pain reduction is a subjective variable. Its use as an assessment tool for therapeutic success represents only a single aspect of adequate chronic opioid therapy. For example, consider a patient with significant disability related to pain that is rated 6 on a pain severity scale of 1 to 10. Although opioid therapy may not be successful in significantly reducing subjective pain scores, this does not signify treatment failure. In fact, despite no reported reduction in pain scores, objective signs of return to work and increased physical activity clearly demonstrate that treatment has improved the patient’s quality of life. Conversely, if an opioid trial is characterized by subjective reports of marked pain relief but there are no observable functional gains and possibly even signs of persistent sedation with decreased physical activity, voluntary unemployment, dysfunctional interpersonal relationships, or diminished physical activity, the physician must consider why the patient would regard this as a positive outcome and attempt to resolve any underlying conditions or misunderstandings.

As noted by the Federation of State Medical Boards, a critical aspect of safe opioid management is documentation of a patient’s care, including current functional status on initial evaluation and throughout follow-up. Documentation not only requires clarity of events but should also offer transparency about the physician’s decision process, particularly in regard to risk-benefit considerations, choices, and plans for risk management. Vigilance for decreased function is important; this may help reveal problems such as addiction, progressive disease, or pain unresponsive to opioids.

Another critical issue to consider before and during the course of treatment is when to discontinue opioid therapy if the treatment is deemed to be ineffective. Many factors must be considered before a treatment is considered to be a
failure, including inadequate dosing, inappropriate dosing schedule, improper drug delivery route, opioid-insensitive pain, side effects limiting dose escalation, and social and psychological issues.

The appropriate duration of effective opioid therapy remains controversial. Currently, there are no clear guidelines and consensus on this issue. The efficacy of treatment related to adverse effects and progression of the underlying disease must be considered fully when formulating decisions regarding the length of treatment, and these factors must be reconsidered on a regular basis. Once opioid therapy has been initiated, it may be difficult to know whether pain would be present without opioid therapy unless the opioids are tapered.

**KEY POINTS**

- Opioid drugs have been used for control of pain for thousands of years.
- Opioids may be reliable and potent analgesics, but they do not work for all pain, for everyone, or for every condition, and they may pose serious risks.
- The evidence for sustained benefits of opioids in relieving chronic pain is weak and inadequate, whereas evidence of risk associated with use of the drugs is significant.
- Modulation of pain perception is controlled by multiple systems, including the endogenous opioid system.
- The most common side effect of opioid administration is constipation, and unfortunately, tolerance to it does not usually develop.
- Opioids are associated with addiction at a rate that is high enough to be a significant concern; however, the exact rate of addiction because of therapeutic opioid use is controversial.
- A growing debate has emerged that focuses on understanding how opioids should be used for chronic pain while balancing the imperative for vigilant use of opioids with sufficient risk management for safety.
- Methadone has many features that distinguish it from other opioids, including heightened risk and significant life-threatening adverse outcomes.
- Methadone has recently been found to be the most common opioid to be related to unintended overdose death in the United States.
- Opioid therapy has undergone intense scrutiny as the public health epidemic of prescription drug abuse has been elevated to a national discussion.
- Focal attention on the risk-benefit ratio for safe use of opioids underscores the serious potential for opioid abuse and overdose death, which has been well documented through approximately 15 years of retrospective data.
- A detailed diagnostic assessment with a thorough history and physical examination, as well as an essential focus on risks and benefits, will drive the selection of specified analgesic treatments.

The use of naturally occurring plant material for the relief of pain dates back to early times. Advances in antipyretic and analgesic medications began in the late 1800s with the development of salicylic acid, antipyrine, phenacetin, and acetaminophen (APAP). These basic medications are still used today to various degrees in both over-the-counter (OTC) and prescription preparations—the minor analgesics salicylic acid and APAP are widely marketed and heavily consumed. Minor analgesics for acute and chronic pain include a number of prescription and OTC agents, which may be used in isolation or as adjuvants in a more comprehensive multimodal pharmacologic approach. Adjuvants refer to agents that enhance the effect of other medications but may not be fully effective when used alone. A population survey has reported that the use of OTC medications, many of which include minor analgesics, account for the most common method of relieving pain (53%). This is closely followed by physical exercise (52%) and prescription medications (35%).

The minor analgesics reviewed in this chapter include oral APAP, opioid combination preparations, tramadol, steroids, and caffeine, as well as topical compounds and delivery systems (Box 37.1). See the chapters in this text that discuss opioids, anticonvulsants, antidepressants, and nonsteroidal anti-inflammatory drugs (NSAIDs) for complete information on these topics (Chapters 36, 38, 39, and 40). Additional combination OTC formulations with minor analgesics include convenience combinations—those that contain aspirin, APAP, or ibuprofen plus other remedies such as nasal decongestants, antihistamines, cough suppressants, or antacids. These medications are useful for treating the sequelae of a primary illness (e.g., cold and flu symptoms, insomnia, cough) and any pain symptoms that may coexist.

Prescribing habits regarding the use of analgesics for the treatment of various musculoskeletal conditions continue to evolve. Caudill-Slosberg and colleagues compared prescribing habits between 1980 and 1981 with those between 1999 and 2000 and demonstrated a significant increase in patients receiving prescriptions for acute and chronic musculoskeletal pain. Increases were seen in the use of NSAIDs and cyclooxygenase-2 (COX-2) agents, as well as more potent opioids, including combination opioid preparations containing APAP and NSAIDs.

Minor analgesics are used widely, with reported prevalence rates of twice-weekly use of approximately 8.7% for prescription drugs and 8.8% for OTC analgesics. Analgesics have been found to be the largest selling group of OTC medications in a number of population studies. Daily use was more common for prescribed analgesics, whereas OTC analgesics were used a few times per week. Among prescription and OTC medications, APAP, ibuprofen, and aspirin were the most commonly used (17% to 23% of the population). Use of analgesics, many of which include minor agents, accounts for a significant amount of health care dollars. In a recent population study, analgesic cost ranked second behind diagnostic imaging in expenditures for the treatment of acute low back pain. Chronic use of prescription and OTC analgesics (i.e., aspirin, non-aspirin-containing NSAIDs, and APAP) may continue for longer than 1 year. In the same survey, approximately 2.3 million adults reported using non-aspirin-containing NSAIDs and 2.6 million used APAP on a frequent basis for longer than 5 years. This widespread use occurs despite general knowledge of the increased risk for gastrointestinal (GI), renal, and cardiac toxicity with short-term and chronic use. Unfortunately, the perception remains that as a class of medications, OTC and prescription NSAIDs are relatively safe. This misbelief leads to frequent inappropriate use and the potential for serious adverse events. The increased availability and marketing of OTC agents has probably contributed to patient misuse, with consumers still being unaware of the potential catastrophic risks associated with their use—60% of people cannot identify the active ingredient in their analgesics, and 40% of Americans believe that OTC drugs are too weak to cause significant harm.

The use of OTC and prescription analgesics is not only confined to the outpatient setting. Significant use of these agents in nursing home facilities was reported in a group of Medicare beneficiaries during 2001. Patients averaged 8.8 unique medications per month, including 2.9 OTC medications. Of these subjects, 70% used nonopioid OTC analgesics and 19.0% used nonopioid prescription analgesics.

### SPECIFIC DRUGS

#### MINOR OPIOIDS

In this chapter, minor opioids are defined as analgesic combination products with codeine, hydrocodone, or oxycodone. These products continue to account for a large percentage of prescriptions written for chronic nonmalignant pain. Combination opioid analgesics—compounds containing APAP or anti-inflammatory medications—make up a significant
CHAPTER 37 — MINOR AND SHORT-ACTING ANALGESICS, INCLUDING OPIOID COMBINATION PRODUCTS

PHARMACOKINETICS AND PHARMACODYNAMICS

An understanding of pharmacokinetics and pharmacodynamics is essential for appropriately prescribing minor opioid analgesics, interpreting related toxicity screens, and appreciating the potential mechanisms for adverse side effects. In general, medications are primarily metabolized by the cytochrome P-450 (CYP) and glucuronidation pathways. Opioid analgesics, like any medication, may be metabolized by the CYP drug-metabolizing enzyme system 2D6. Genetic polymorphism of CYP2D6 may lead to variability in enzyme breakdown and clinical effectiveness of the medication. Deficiency of CYP2D6 may be seen in whites (7%) and those of Asian descent (1%).18 These enzyme systems can be induced (activated) or inhibited by various agents, including drugs, alcohol, and cigarette smoke, as well as by endogenous substances. Inducers are agents that activate the CYP enzyme system and thereby lead to increased metabolism and reduced drug effect. Inhibitors may impair the CYP enzyme system and thus limit metabolism of the drug and increase the effect of the drug. Although pharmacokinetic drug-drug interactions may affect serum levels of a drug, this may be subclinical in most patients, with significant interactions occurring rarely in vivo in only about 10% to 15% of patients.19 Patients’ response to individual opioids may vary markedly. Recent evidence has supported more than one mechanism for µ-opioid analgesic reactions, which may be related to receptor polymorphism.20

Morphine, hydromorphone, and oxymorphone are not metabolized by CYP but are metabolized by uridine diphosphate glucuronosyltransferase (UGT) enzymes. Except for morphine and codeine, UGT enzymes metabolize medications primarily to inactive metabolites. Morphine is converted into large quantities of relatively inactive morphine-3-glucuronide (M3G) and smaller quantities of the active metabolite morphine-6-glucuronide (M6G). M6G is 50 times more potent than morphine. M3G may account for central nervous system (CNS) toxicity, including lowering of seizure thresholds.21 Equianalgesic oral doses of the various minor opioid combination products and morphine are listed in Table 37.3.

CODEINE

Along with morphine and thebaine, codeine (methylmorphine) is a naturally occurring opium alkaloid derivative. A weak analgesic, codeine is similar in structure to morphine but has affinity for the µ-opioid receptor that is 300 times lower. Classically, codeine is thought to be metabolized by O-demethylation to its primary active metabolite morphine by the CYP2D6 enzyme.22 Studies have demonstrated that only a small percentage of the total dose (3%)23 is converted by CYP2D6 to morphine. Approximately 80% is directly glucuronidated by uridine diphosphate glucuronosyltransferase 2B7 (UGT2B7) enzyme to codeine-6-glucuronide (C6G), an additional active metabolite. The remaining inactive metabolites are primarily norcodeine (2%) and normorphine (2.4%).24 Nonfunctional CYP2D6 renders codeine ineffective, perhaps because of genetic mutations or deletions25 or pharmacologic inhibition.26 Effects of codeine not related to the formation of morphine include cognitive impairment,27 sedation, dizziness, euphoria and dysphoria, headache, blurred vision,28 and prolongation of GI transit time.29 The average half-life of codeine is 2.5 hours.

Efficacy

When used alone, codeine is typically prescribed in doses of 30 to 60 mg every 4 to 6 hours, with onset of analgesia taking place in 30 to 60 minutes and the duration of effect lasting 4 to 6 hours.

Table 37.4

| Amount of opioids prescribed by primary care physicians13 and pain specialists. Combination analgesics are advocated in several treatment guidelines, including the three-step analgesic ladder of the World Health Organization (step 2)14,15 (Fig. 37.1). Since the 1990s, the use of minor analgesic combinations containing oxycodone and hydrocodein has continued to increase, whereas the use of those containing codeine has declined. Clinic type (e.g., primary care, spine center, pain center), geographic, and socioeconomic variables may also affect prescribing practices.16

Opioid analgesics as a class can be categorized into three chemical groups: (1) synthetic phenylpiperidines (e.g., meperidine, fentanyl), (2) synthetic pseudopiperidines (e.g., methodone, propoxyphene), and (3) naturally occurring alkaloids derived directly from the poppy seed (e.g., heroin, morphine, codeine) and their semisynthetic derivatives (e.g., hydromorphone, oxycodone, oxymorphone).17

This chapter reviews codeine, oxycodone, hydrocodein, and tramadol, all natural or synthetic opioids used in isolation or combination forms for the treatment of mild to moderate pain (Tables 37.1 and 37.2).

* Doses reflect the opioid component only and are equianalgesic to 30 mg morphine.
† Doses for moderate to severe pain not necessarily equivalent to 30 mg morphine.

Codeine has been shown to be an effective cough suppressant (10 to 120 mg/day) and is present in a number of OTC cold and cough convenience preparations. However, codeine’s potential opioid analgesic effect has long been questioned. Houde’s classic study in the 1960s reported the analgesic effects of codeine (32 mg) to be no more than that of 650 mg of aspirin, although both were more effective than placebo. The number needed to treat (NNT), or the number of patients needed to receive the medication to achieve at least 50% pain relief, with 60 mg codeine has been reported to be 16.7, which has led to its widespread use as a combination analgesic.

Codeine (10 to 60 mg) is more commonly prescribed in combination with APAP (400 to 1000 mg), aspirin, or NSAIDs such as ibuprofen (400 mg). A systematic review of codeine and APAP trials for acute non-cancer-related pain concluded that the benefit over codeine alone is only modest (5%). A systematic review of trials of APAP alone or in combination with codeine noted efficacy in patients prescribed APAP plus 60 mg codeine versus APAP alone. At doses higher than 60 mg, there was diminishing incremental analgesia with increasing dose and a higher incidence of side effects (e.g., constipation, nausea, and sedation). A head-to-head study of codeine (30 mg) plus APAP (300 mg) and hydrocodone (7.5 mg) plus APAP (500 mg) showed significant relief of moderate to severe acute (6 hours) postoperative pain in comparison to placebo, but the analgesia was no greater than that achieved with hydrocodone-APAP.

PROPOXYPHENE (DEXTROPROXYPHENE)

Propoxyphene (dextropropoxyphene) is a mild synthetic opioid originally synthesized in the 1950s and primarily marketed in its hydrochloride form as Darvon (65 mg; maximum, 400 mg/day), as propoxyphene napsylate (Darvocet-N 50, Darvocet-N 100), and in Europe, as co-proxamol (32.5 mg dextropropoxyphene plus 325 mg paracetamol). By the late 1960s, propoxyphene was the most widely prescribed analgesic in the United States. Reports of propoxyphene overdoses led to warnings by the U.S. Food and Drug Administration (FDA) in 1978 and a subsequent reduction in use. Use of propoxyphene continued for a number of years, primarily in older adults, because of its perceived safety profile. However, Smith suggested that its analgesic activity is lower than that of aspirin. Propoxyphene’s major metabolite norpropoxyphene has fewer CNS effects than propoxyphene does but accumulates in cardiac tissue, thereby leading to a local anesthetic effect and prolongation of action potentials, in some cases fatal torsades de pointes. Because of the increasing number of fatal overdoses of co-proxamol and limited evidence supporting its efficacy versus APAP for acute and chronic pain, the British government announced the gradual withdrawal of co-proxamol from British markets in January 2005. As a result of increasing public outcry from patient advocacy groups and recommendations by an FDA advisory board group, propoxyphene was voluntarily removed from the U.S. market in 2011 (Propoxyphene: withdrawal—risk of cardiac toxicity. Available at www.fda.gov/Safety/MedWatch/SafetyInformation/ucm234389.htm. Accessed August 28, 2012). It is interesting to note that at the time of its withdrawal from the market, a survey showed that 68% of pain medicine practitioners saw patients who were prescribed propoxyphene by their primary care physicians.

OXYCODYONE

Oxycodone is a semisynthetic opioid analgesic derived from the opium alkaloid thebaine. Human studies have demonstrated it to have analgesic potency 1.5 times that of morphine after oral administration. A number of active metabolites have been proposed to contribute to the clinical pharmacokinetics of oxycodone. One theory supports 3'-O-demethylation by CYP2D6 to oxymorphone. Oxymorphone is a potent μ-opioid ligand with two to five times higher receptor affinity than morphine has. Though potent, oxymorphone accounts for only 10% of oxycodone metabolites. Oxymorphone has been available for a number of years for parenteral and rectal use and was reformulated and released in an immediate-release (IR) and extended-release (ER) schedule II formulation. In vitro studies have shown that O-demethylation of oxycodone accounts for 13% of its oxidative metabolism. Oxidation of oxycodone primarily occurs via N-demethylation by CYP3A4/5 to noroxycodone, which is the most abundant circulating metabolite in human studies. Unfortunately, noroxycodone has weak affinity for μ-opioid receptors.

In vivo, oxycodone has potent μ-opioid receptor effects, but data suggest that the intrinsic antinociceptive effects may be additionally mediated by κ-opioid receptors. This has led some to consider oxycodone an ideal medication for opioid rotation in patients not responsive to morphine, a classic μ-opioid receptor agonist. Recent studies have proposed...
non-CYP2D6 metabolites (noroxycodone, noroxymorphone, noroxycodols, oxycodeol) as additional substances responsible for its μ-opioid receptor binding and analgesic effects. Animal studies have recently demonstrated conflicting gender-related differences in female versus male rats when examining the antinociceptive effects of oxycodone.

HYDROCODONE

Hydrocodone is similar in structure to codeine but is six to eight times more potent. Hydrocodone is a prodrug and undergoes CYP2D6 metabolism to hydromorphone and CYP3A4 metabolism to noroxycodone. Hydrocodone is less potent than morphine by receptor affinity and demonstrates a relative analgesic potency of 0.59 in comparison to morphine. The discrepancy between hydrocodone’s binding affinity and potency versus that of morphine is possibly the result of active hydrocodone metabolites or the intrinsic efficacy of receptor activation, which is more efficient for hydrocodone than for morphine. Hydrocodone is marketed as a combination product with APAP, ibuprofen, and aspirin.

Efficacy

The hydrocodone-ibuprofen combination product was introduced in the United States in 1997 as a fixed dose of hydrocodone (7.5 mg) and ibuprofen (200 mg) and has demonstrated efficacy for acute postoperative pain. Neither hydrocodone (7.5 mg) nor ibuprofen (200 mg) given alone was superior to placebo, thus supporting the concept of analgesic synergy between the two agents. Similar findings were demonstrated in patients with acute low back pain and postoperative obstetric and gynecologic pain. Hydrocodone-APAP (7.5, 200 mg), one and two tablets, was compared with a fixed-dose combination of codeine (30 mg) and APAP (300 mg). The two-tablet dose of combination hydrocodone-APAP was more effective than the one-tablet dose and one or two tablets of the fixed codeine-APAP combination.

In 2010, more than 139 million prescriptions for hydrocodone combination products (APAP, ibuprofen) were dispensed in the United States (Drug Enforcement Administration. Hydrocodone, June 2011. Available at: www.deadiversion.usdoj.gov/drugs_concern/hydrocodone.pdf. Accessed June 11, 2012). Hydrocodone-APAP combination products are classified as schedule III controlled substances. Pure hydrocodone is schedule II but is not presently commercially available in the United States (Code of Federal Regulations. Title 21: Food and Drugs Part 1308; Schedules of Controlled Substances 1308.13; Schedule III, June 2012). Because of high rates of misuse and abuse of hydrocodone products, the U.S. House of Representatives is considering legislation that would reclassify all products containing hydrocodone from schedule III to schedule II. As a result of increasing reported toxicity of APAP in combination opioid and OTC products, the U.S. FDA has mandated a reduction in APAP in combination opioid products by 2014. Reformulations of these products will include a maximum of 300 mg of APAP (Abbott Laboratories, 2012). Commonly prescribed hydrocodone-APAP combination products presently include 10, 7.5, and 5 mg hydrocodone and 325, 500, 750 mg APAP, with ranges between 5 and 10 mg hydrocodone and 325 and 750 mg APAP (Hydrocodone Bitartrate/Acetaminophen Tablets, package insert, Mallinckrodt, Inc., St. Louis).

Pipeline hydrocodone formulations in development include an ER hydrocodone product (hydrocodone bitartrate ER capsules [Zohydro], Zogenix, Inc., San Diego. Available at www.zpgenix.com/index.php/products/zx002. Accessed June 11, 2012) and a tamper-resistant (Teva Pharmaceuticals) long-acting formulation. A “tamper-deterrent” pure hydrocodone product with approximately 45 mg hydrocodone is also in development (Teva Pharmaceuticals).

ACETAMINOPHEN

APAP (paracetamol) and APAP combination products (i.e., containing opioids) are commonly prescribed as a minor analgesic for acute and chronic pain (see Table 37.2). The American College of Rheumatology and similar European professional colleges have recommended it as first-line pharmacologic therapy for osteoarthritis (OA). Prescription APAP is available as an opioid-containing combination product (e.g., codeine, hydrocodone, oxycodone), whereas OTC preparations may be combined with pseudoephedrine or dextromethorphan as convenience drugs.

MECHANISM OF ACTION AND DESCRIPTION

APAP (paracetamol) is a p-aminophenol analgesic that was introduced in the late 1800s in Germany, a product of the rapidly developing chemical industry. Newly synthesized compounds included synthetic antipyretics and analgesics such as acetophenetidin (phenacetin), antipyrine (phenazona), and acetylsalicylic acid (ASA; aspirin). Paracetamol, the active metabolite of phenacetin, was found to demonstrate less intense GI side effects, which led to its use as an analgesic. Paracetamol was formally introduced in the United States in the 1950s, and though found in the 1960s to have hepatotoxic effects with unintentional misuse and overdose, it became one of the most widely used OTC and combination prescription analgesics worldwide.

Although APAP has been in use since the 1890s, its pharmacologic mechanism of action remains unclear. Generally, it has known analgesic and antipyretic activity with no known peripheral anti-inflammatory or platelet effects. Its antipyretic activity may be secondary to blockade of prostaglandin (PG) production and inhibition of PG endoperoxide H2 synthase and COX centrally. APAP may block COX activity by reducing the active form of COX to an inactive form, but with only limited effects in the GI tract and peripherally at sites of inflammation, thus contributing to a lower GI side effect profile than that of NSAIDs. Also, recent studies have suggested that its central analgesic qualities may be related to decreased activation of a subtype of endogenous opioid peptide, β-endorphin.

APAP is available in oral and rectal formulations and is rapidly absorbed from the GI tract, mainly the small intestine. APAP has a half-life (t½) of between 1.25 and 3 hours and serum therapeutic levels of 10 to 30 µg/mL. Twenty-five percent of the dose undergoes first-pass metabolism in the liver. Up to 90% of APAP is metabolized in the liver via glucuronidation and sulfate conjugation to nontoxic metabolites. The remaining 10% undergoes oxidative metabolism via the CYP system (CYP2E1 and CYP1A2), which is responsible for formation of the potentially hepatotoxic and nephrotoxic metabolite N-acetyl-β-phenzoquinoneimine (NAPQI; Fig. 37.2). This minor pathway becomes more critical when
the enzyme system responsible for sulfonation and glucuronidation becomes saturated with doses higher than 150 mg/kg, thereby increasing the total fraction of NAPQI. Approximately 85% of the dose is excreted in urine within 24 hours of oral dosing. NAPQI is itself detoxified by conjugation with glutathione.\textsuperscript{62} Case reports have suggested that clinical situations characterized by low glutathione levels (e.g., chronic hepatitis C, malnourishment, human immunodeficiency virus infection, cirrhosis) may place these patients at greater risk for adverse events from APAP. However, one study found no significant evidence that these populations are at higher risk for APAP toxicity.\textsuperscript{63} There are few clinically significant pharmacokinetic interactions with therapeutic doses of APAP. Although case reports have attributed an elevated international normalized ratio (INR) to APAP and oral anticoagulant drug interactions,\textsuperscript{64} randomized controlled studies have found no evidence of clinically significant changes in the INR.\textsuperscript{65} Even though studies have demonstrated an association, there is no clear evidence of cause and effect.\textsuperscript{66}

**RISKS AND PRECAUTIONS**

APAP-induced toxicity is often associated with liver and renal dysfunction. APAP hypersensitivity reactions are rare, but severe reactions are possible. In general, chronic administration of APAP may cause depletion of glutathione stores and hence lead to greater production of the hepatotoxic and nephrotoxic metabolite NAPQI. Current recommendations for a maximum daily dosage of APAP are approximately 4 g/day in adults and 75 mg/kg/day in infants and children\textsuperscript{67} (Box 37.2). Unintentional liver injury, such as hepatic necrosis or acute liver failure from self-medication with OTC and prescription APAP products, can develop with dosages exceeding 4 g/day.

The serum alanine transaminase (ALT) level may be elevated with acute use of recommended doses of APAP. Watkins and Seeff\textsuperscript{68} studied healthy adults given 4 g of APAP for 14 days. They found that 31% to 44% of the study subjects, which included patients taking APAP and various opioid-APAP combination products, demonstrated elevations to three times the upper limit of normal (typically considered clinically significant). Opioids were found to have no additional effect on ALT levels. Elevated liver function is not routinely seen with chronic use and is thought to occur because of cellular adaptation.\textsuperscript{68} This APAP tolerance may be characterized by possible downregulation of CYP bioactivation and increases in glutathione production by liver hepatocytes.\textsuperscript{69}

The concomitant use of alcohol and APAP resulting in increased risk, lower threshold for hepatic and renal toxicity, or both remains controversial and has been reported primarily in retrospective reviews and case reports.\textsuperscript{70} Acute and chronic alcohol use contributes to drug-induced hepatotoxicity via induction of CYP2E1 and NAPQI formation.\textsuperscript{71} Enhanced ethanol-related toxicity was demonstrated only in patients at high risk with APAP levels above 300 mg/mL, a level far above the package insert recommendation for no more than three alcoholic beverages daily.\textsuperscript{72} When consumed with APAP, ethanol may block the formation of NAPQI.\textsuperscript{73} Other inducers of hepatic isoenzymes CYP2E1 and CYP1A2 that are commonly used for pain management include carbamazepine, oxcarbazepine, barbiturates, and phenytoin\textsuperscript{74} (Box 37.3). Most importantly, the risk for APAP-induced hepatotoxicity may be increased in patients with alcoholic hepatic disease, viral hepatitis, or alcoholism because of a reduction in glucuronide conjugation and subsequent depletion of glutathione reserves.

Chronic APAP prescribing should be avoided in patients with renal disease, although the exact mechanism of injury is unknown and may be relevant only in patients with preexisting renal compromise or systemic disease.\textsuperscript{75} Patients with a history of salicylate hypersensitivity characterized

---

**Box 37.2 Acetaminophen Dosing Considerations**

**Dosing for Mild Pain**
- 325-1000 mg PO, per rectum, q4-6h
- Maximum dose: 1 g/dose; 4 g/24 hr
- American Liver Foundation: patients should not exceed 3 g/day for any prolonged period\textsuperscript{a}

**Renal Impairment**
- Adjust dose frequency
- Creatinine clearance (CrCl) = 10-50 mL/min, q6h; CrCl < 10 mL/min, q8h

**Hepatic Impairment**
- Use with caution
- Consider decreasing the dose, monitor liver function, avoid chronic use

**Counseling Patients**

Acetaminophen (APAP) in over-the-counter products:
- Regular-strength APAP products commonly contain 325 mg/tablet
- Extra-strength APAP products commonly contain 500 mg/tablet

\textsuperscript{a}Based on a recent study by Watkins and Seeff.\textsuperscript{68}
by drug-induced urticaria have demonstrated 11% cross-reactivity to APAP.

Similar studies in healthy men failed to show an association with use of APAP and hypertension. Analogics, in general, may modestly affect blood pressure via a number of mechanisms, primarily through kidney or systemic COX-2 inhibition of PGs, which leads to an imbalance between the vasodilators PGI2 and PGE 2 and the vasoconstrictors PGF 2α and thromboxane A 2. These effects on PG synthesis are greater with NSAIDs than with APAP.

**CLINICAL USE**

Although a number of guidelines have recommended APAP as a first-line agent, its advantages over NSAIDs in managing OA-related pain remain controversial. A double-blind trial of paracetamol, 4 g/day, for 1 month found it to be as effective as both analgesic and anti-inflammatory doses of ibuprofen in patients with knee OA. More recent studies have demonstrated the efficacy of both a traditional NSAID (diclofenac) and a COX-2 inhibitor (celecoxib) versus APAP in hip and knee OA cohorts. A Cochrane database review of the use of APAP for the chronic pain of OA found the drug to be less effective than NSAIDs in terms of pain reduction scores, although the superiority of NSAIDs over APAP appeared to be more evident in OA patients with more severe pain. Both the NSAID and APAP groups had similar efficacy with regard to functional status. Recent evidence has suggested that APAP may retain anti-inflammatory action comparable to that of NSAIDs in patients with knee OA. Brandt and associates performed a pilot study of 30 subjects in whom OA of the knee was diagnosed and showed that treatment with APAP results in similar significant decreases in mean total knee effusion volume (measured by magnetic resonance imaging) as does treatment with NSAIDs.

**TRAMADOL**

Tramadol, (+)-cis-2-[(dimethylamino)methyl]-1-(3-methoxyphenyl)-cyclohexanol hydrochloride, is a synthetic racemic mixture typically used for its centrally acting analgesic properties. However, clinical and basic science studies have described numerous mechanisms of action at central and peripheral sites. Tramadol is classified as a weak synthetic opioid with mild serotonin and norepinephrine reuptake–inhibiting effects.

**MECHANISM OF ACTION AND DESCRIPTION**

The most well-studied mechanism of action of tramadol is its weak affinity for opioid receptors, the most significant of which involves the µ receptor. However, tramadol-induced analgesia is only partially inhibited by the opiate antagonist naloxone, thus suggesting additional non–opioid-related analgesic mechanisms. Tramadol also displays an inhibitory effect on the central neuronal norepinephrine and serotonin (5-HT) reuptake systems. More recently, noted actions include a local anesthetic effect, anti-inflammatory effects in rat experimental models, and reduction of substance P levels in human synovial fluid. Although α2-agonist activity has also been reported, concentrations in the range of 10 to 100 µmol/L do not bind significantly to α2-adrenergic receptors.

**OPIOID RECEPTORS**

Tramadol’s affinity for the µ receptor appears to be approximately 10 times weaker than that of codeine, 60 times weaker than that of dextropropoxyphene, and 6000 times weaker than that of morphine (Table 37.4). The active O-demethylated metabolite M1 has 300 times higher affinity for the µ receptor than the parent compound and is up to six times more potent in producing analgesia.

**CENTRAL NEURONAL ACTIONS**

Multiple actions affecting the descending inhibitory pain pathways have been reported. The first system involves...
neurons originating in the periaqueductal gray matter in the midbrain that synapse at the nucleus raphe magnus, from which fibers then project to the spinal cord. Inhibition of 5-HT reuptake may contribute to inhibition of pain. Another pathway originates at the locus coeruleus in the pons, with fibers projecting to the spinal cord. The norepinephrine released from this pathway inhibits pain responses at the spinal cord via an α-adrenergic mechanism.

Activation of these descending pain inhibition pathways stimulates interneurons that inhibit the transmission of painful stimuli in the dorsal horn by the action of endogenous opioids. Opioid receptor activity has been proposed to be mediated by the dextrorotatory (+) enantiomer as opposed to the levorotatory (−) enantiomer. The (−) enantiomer is approximately 10 times more potent than its (+) counterpart in the inhibition of norepinephrine uptake, and the (+) enantiomer is approximately 4 times more potent than the (−) enantiomer in the inhibition of 5-HT uptake. M1 retains higher affinity for the µ-opioid receptor (300 to 400 times) and possesses greater analgesic activity than the parent compound does. The M1 (+) enantiomer acts at the µ receptor, whereas the M1 (−) enantiomer mainly inhibits reuptake of norepinephrine, (Table 37.5).

Formulations include IR and sustained-release (SR) oral forms (SR, dosing every 12 hours; ER, dosing every 24 hours); injectable solutions for subcutaneous, intravenous, spinal, or intramuscular administration; and a rectal formulation. SR formulations are available in a number of countries worldwide, but only the ER formulation is currently available in the United States. In addition, an orally disintegrating tablet version of tramadol (Ralivia FlashDose) for the treatment of moderate to moderately severe pain is under development.95 An orally disintegrating tablet (UltraB 泡 FlashDose) for the treatment of moderate to moderately severe pain is under development.95 A wide variety of tramadol formulations are available in a number of countries worldwide, but only the ER formulation is currently available in the United States. In addition, an orally disintegrating tablet version of tramadol (Ralivia FlashDose) for the treatment of moderate to moderately severe pain is under development.95 Tramadol is currently recommended for the treatment of moderate to moderately severe pain in patients unresponsive to previous oral therapies or who have a contraindication to COX-2–selective or COX-2–nonselective NSAIDs.9

HISTORY

Tramadol has been available in Germany since 1977, where it remains one of the most widely prescribed analgesics. Before its U.S. release in 1995, clinical96 and epidemiologic studies97 suggested that tramadol demonstrates low abuse potential, which led the Drug Abuse Advisory Committee to recommend FDA approval of tramadol as a nonscheduled analgesic.98 Current studies continue to support the low abuse potential of tramadol. A postmarketing survey has demonstrated limited evidence of tramadol use–related dependence, withdrawal, and abuse.99 Another study assessing the prevalence of abuse compared tramadol with NSAIDs and hydrocodone-containing analgesics in patients with chronic non–cancer-related pain.100 This study used an abuse index that identified subjects according to the following behavior: (1) increased doses without physician approval, (2) used for purposes other than intended, (3) demonstrated an inability to stop use, and (4) experienced withdrawal. The percentage of subjects who scored positive (at least one of the four types of behavior) during a 12-month period was 2.5% for NSAIDs, 2.7% for tramadol, and 4.9% for hydrocodone.

FORMULATIONS

Currently available oral formulations of tramadol include 50-mg scored IR tablets, SR tablets and capsules (every-12-hour dosing available worldwide but not in the United States), two ER once-daily tablets (Ultram ER and Ryzolt [Purdue Pharma]), and combination tablets consisting of tramadol, 37.5 mg, plus APAP, 325 mg.101 The SR preparations are available in strengths of 50, 100, 150, and 200 mg taken on a twice-daily schedule. ER tramadol hydrochloride tablets (Ultram ER) are available in 100-, 200-, and 300-mg strengths taken on a once-daily basis. The bioavailability of Ultram ER, 200 mg, relative to tramadol, 50-mg ER formulation every 6 hours, is approximately 85% to 90%. Steady-state plasma concentrations of tramadol and M1 are achieved within 4 days of once-daily dosing. Important pharmacokinetic parameters of the 200-mg ER formulation include a time of maximum concentration (T max) of 12 and 15 hours for tramadol and the M1 metabolite, respectively, as compared with a T max of 1.5 and 1.9 hours for tramadol and the M1 metabolite, respectively, with the 50-mg IR formulation (Table 37.6).

Once-daily ER Ultram was formulated to counter the need for doses of IR tramadol hydrochloride (Ultram) every 6 hours, improve compliance, and decrease sleep interruptions because of more stable serum concentrations. The bioavailability of ER tramadol is comparable to that of IR tramadol and demonstrates steady-state bioequivalence.

(area under the plasma drug concentration–vs.-time curve and maximum concentration [C\text{max}] values) when compared with IR tramadol administered four times daily.\textsuperscript{101} ER tramadol (200 mg) has a longer T\text{max} (tramadol, 12 hours; M1 metabolite, 15 hours) than IR tramadol does (tramadol, 1.5 hours; M1 metabolite, 1.9 hours) but reaches steady-state plasma concentrations (tramadol and M1) within 4 days with once-daily dosing.

ER tramadol (100, 200, 300 mg) was found to be superior to placebo in average change from baseline pain from 1 through 12 weeks in a randomized trial of OA of the knee. The average ER tramadol dose was 276 mg/day.\textsuperscript{102}

Tramadol hydrochloride ER tablets (Ryzolt, Purdue Pharma L.P., Stamford, Conn, 2009) contain both IR and ER characteristics (100, 200, and 300 mg). Ryzolt is indicated for the management of moderate to moderately severe chronic pain in adults who require around-the-clock treatment of their pain for an extended period. The median time to peak pain in adults who require around-the-clock treatment of moderate to moderately severe chronic pain is 4 days with once-daily dosing.

Steady state is achieved after 2 days with a relative bioavailability of approximately 95% with 200 mg of Ryzolt versus IR tramadol, 50 mg every 6 hours (Ryzolt Package Insert, Purdue Pharma L.P., 2009).

**PHARMACOKINETICS**

The maximum serum concentration of oral tramadol is reached in approximately 2 hours.\textsuperscript{103} Its mean bioavailability after a single dose is 68%,\textsuperscript{104} and this increases to 90% to 100% after multiple doses. Mean bioavailability after intramuscular administration is 100% and after rectal administration is 78%. Tramadol is 20% bound to plasma proteins and crosses the placenta.\textsuperscript{105} Metabolism is primarily hepatic via the CYP enzyme system. Tramadol is excreted by the kidneys (90%) and in feces (10%). Biotransformation in the liver creates 23 metabolites; the primary metabolite is \(\text{O-desmethyltramadol (M1)}.\textsuperscript{106} Polymorphism of the CYP2D6 isoenzyme in the liver (present in approximately 7% to 10% of whites) may cause attenuation of analgesia in poor metabolizers. Such patients may require higher loading doses and more rescue analgesia.\textsuperscript{107} The elimination t\text{\beta} of tramadol is 5 to 6 hours and that of M1 is approximately 8 hours. Adjustments in dosage are required for patients with hepatic and renal failure and for geriatric patients (Table 37.7).\textsuperscript{108} Bioequivalence has been demonstrated between IR and SR-ER formulations\textsuperscript{91} (see Table 37.6).

### MANAGEMENT CONSIDERATIONS

For improved tolerability of tramadol, various titration regimens have been proposed (Table 37.8). An alternative example of a titration schedule for the IR 50-mg tablets in patients with moderate to moderately severe chronic pain is as follows:

1. Start at 25 mg/day and titrate in 25-mg increments as separate doses every 3 days to reach 100 mg/day (25 mg four times daily).
2. Increase the total daily dose by 50 mg as tolerated every 3 days to reach 200 mg/day (50 mg four times daily).
3. After titration, tramadol, 50 to 100 mg, can be administered as needed for pain relief every 4 to 6 hours, not to exceed 400 mg/day.

Patients with moderately severe pain who need more immediate pain control may benefit from a more aggressive dosing schedule. In this case, the increased risk for adverse events associated with higher initial doses must be clearly discussed and acceptable. In this subset of patients, tramadol, 50 to 100 mg, may be administered as needed every 4 to 6 hours, not to exceed 400 mg total per 24-hour period.

The initial recommended dose of tramadol SR formulations is 50 to 100 mg twice daily. Titrations to doses of 150 to 200 mg twice daily pending side effect tolerability and

efficacy of pain relief as needed may be carried out. Tramadol ER dosage recommendations include an initial dose of 100 mg daily, with upward titration by 100 mg every 5 days to a maximum daily dosage of 300 mg.

RISKS AND PRECAUTIONS

When compared with traditional opioid analgesics, tramadol retains a more favorable side effect profile and may be associated with a lower risk for addiction with chronic use.109

Common Side Effects

The most commonly reported side effects include nausea, vomiting, dizziness, fatigue, sweating, dry mouth, drowsiness, sedation, and orthostatic hypotension. The incidence of side effects has been reported to be as high as 16.8% in patients with chronic pain complaints. Controlled-release formulations may produce a lower incidence of side effects (6.5%).110

Despite its improved side effect profile and early consideration as an alternative to pure µ-opioid receptor agonist medications, reports of overdose and fatality have led to a change in the package insert information that includes a contraindication in patients with a past or present history of addiction or dependence on opioids.97 Other more severe side effects include angioedema,111 bleeding complications because of the increased effect of oral anticoagulants,112 and serotonin toxicity.113-115

Tramadol and Serotonin Toxicity (Serotonin Syndrome)

Concomitant use of tramadol with other serotonergic medications (e.g., selective serotonin reuptake inhibitors [SSRIs], monoamine oxidase inhibitors [MAOIs], and serotonin-norepinephrine reuptake inhibitors [SNRIs]; Box 37.4) has been associated with case reports of serotonin toxicity.116,117 Given the fact that a number of medication classes commonly used for management of pain may predispose patients to mild to severe symptoms of serotonin toxicity, a review to gain a more clear understanding of serotonin toxicity and serotonin syndrome is in order.

Definition

Serotonin toxicity is an iatrogenic drug-induced toxidrome, a group of signs and symptoms occurring together with a particular type of chemical poisoning. Life-threatening serotonin toxicity, though rare, is usually precipitated by ingestion of MAOIs and SSRIs and leads, in some cases, to hyperpyrexia and death.118 The pathophysiology remains unclear but may involve overstimulation of 5-HT1A and 5-HT2 receptors in the brain. Serotonin toxicity has been described by Gillman and Whyte as a triad involving neuromuscular hyperactivity, autonomic hyperactivity, and altered mental status (Table 37.9).115

Sternbach proposed criteria for serotonin syndrome in one of the earlier published comprehensive reviews of serotonin syndrome.113 In 2000, Radomski and associates114 published an updated review of the subject with revised diagnostic criteria (Table 37.10).

Mechanisms of Serotonin Toxicity. Serotonin toxicity may be related to the mechanisms and potency of drugs. Tricyclic antidepressants (TCAs) exhibit a 100-fold variability in affinity for the serotonin transporter in humans. Overdose of amitriptyline alone does not precipitate serotonin toxicity.119 More potent TCAs, such as clomipramine, may actually have more potent serotonergic effects clinically and in overdose. In overdoses of SSRIs or SNRIs such as with venlafaxine alone, 15% of individuals exhibit moderate serotonin toxicity without life-threatening symptoms or pyrexia.120 Although venlafaxine has less potency than amitriptyline at the receptor level, it precipitates serotonin toxicity more frequently than SSRIs do (30% vs. 15%). This may be related to mechanisms other than inhibition of serotonin reuptake.121 Trazodone and nefazodone differ from TCAs and SSRIs in that they are primarily 5-HT2A antagonists. Neither exhibit serotonergic side effects, nor do they induce signs of serotonin toxicity in overdose.118

A number of other pharmacologic agents, including illicit substances, enhance 5-HT activity and must be considered in

the workup for possible serotonin toxicity (e.g., buspirone, ergot alkaloids, amphetamine, cocaine, TCAs, MAOIs\textsuperscript{122}; see Box 37.3).

**CLINICAL USE OF TRAMADOL FORMULATIONS**

Earlier reports evaluating the effectiveness of tramadol for varied painful conditions yielded conflicting results. In comparative studies of acute pain, oral tramadol was found to have efficacy similar to that of propoxyphene in a postoperative pain study and comparable efficacy as codeine for pain related to dental surgery.\textsuperscript{125} However, tramadol hydrochloride, 50 and 100 mg, was found to have efficacy similar to that of placebo for pain after total hip arthroplasty\textsuperscript{124} but provided analgesia inferior to that of hydrocodone-APAP in an emergency room acute musculoskeletal pain cohort consisting of fracture, sprain-strain, and contusion.\textsuperscript{125}

More recent clinical and evidence-based practice has recommended tramadol for patients who fail to achieve analgesia with APAP, COX-2 inhibitors, or NSAIDs.\textsuperscript{56,130} Guidelines for the pharmacologic management of OA have demonstrated efficacy for acute and chronic pain conditions.\textsuperscript{137} A 2004 Cochrane collaboration review of tramadol for neuropathic pain identified a number of eligible trials, including two comparing tramadol with placebo,\textsuperscript{131,132} one comparing tramadol with clomipramine,\textsuperscript{133} and one comparing tramadol with morphine for cancer pain.\textsuperscript{134} Tramadol was found to be effective for the treatment of neuropathic pain based on this limited number of short-term studies (4 to 6 weeks). The NNT for tramadol in relieving neuropathic pain states (3.5) was similar to that for other commonly used medications—2.4 for TCAs, 2.5 for carbamazepine, and 3.7 for gabapentin.

**Spectrum of Serotonin Syndrome**

Coincident with the addition of or an increase in a known serotonergic agent. Clinical features were not an integral part of the underlying psychiatric disorder before commencing the serotonergic agent. Other causes (e.g., infectious, metabolic or endocrine, substance abuse or withdrawal) have been ruled out. A neuroleptic drug has not been started or increased in dosage before onset of the signs and symptoms listed. From Gnanadesigan N, Espinoza RT, Smith R, et al. Interaction of serotonergic antidepressants and opioid analgesics: is serotonin syndrome going undetected? J Am Med Dir Assoc. 2005;6:265-269.
a meta-analysis evaluating the efficacy of a tramadol-APAP combination for moderate to severe postoperative pain.140

**ORAL STEROIDS**

The first glucocorticoid was isolated in 1935. This naturally occurring corticosteroid, cortisone, was later synthesized in the laboratory in 1944. Four years later, Hench and colleagues at the Mayo Clinic were able to obtain a portion of the total 9 g of synthetic cortisone available from Merck for clinical trial use. They injected this “compound E” (cortisone) into patients with rheumatoid arthritis. Accounts describe the treatment of multiple patients with 100-mg injections, with astonishing results—patients experienced dramatic pain reduction and remarkable improvement in their functional mobility. Reports noted that one of their formerly totally bedridden patients was able to get out of bed and tried to dance. However, when the supplies ran out just 1 week later, all the treated patients went into remission.141 This report led not only to the widespread use of cortisone for the treatment of rheumatologic conditions but also earned Hench a joint award (along with Kendall and Reichstein) of the Nobel Prize in Medicine and Physiology in 1950. As oral steroid preparations evolved, their use increased in addition to injection therapy as a method of producing systemic levels for chronic treatment regimens. Pulsed dosing schedules are now routinely used for disease management and episodic flares of a wide range of conditions, including rheumatic, pulmonary, dermatologic, neurologic, ophthalmologic, hematologic, and endocrine disorders. Exogenous glucocorticoid administration has been shown to have a suppressive effect on the hypothalamic-pituitary-adrenal (HPA) axis. Some believe that this can occur in as few as 5 days when using high supraphysiologic doses, whereas at physiologic doses this may not occur for 3 to 4 weeks. Thus, a tapered dosing schedule is typically recommended when treatment exceeds 2 to 3 weeks.142 The use of steroids for the treatment of painful conditions is largely based on the premise that there is an inflammatory role in the mediation of pain.143 Chronic oral steroid therapy is used for the treatment of rheumatologic inflammatory conditions (e.g., rheumatoid arthritis, polyarthritis rheumatica, Crohn’s disease), as well as cancer pain. In addition, oral steroids are commonly used in short-term or pulsed dosing schedules for conditions such as complex regional pain syndrome (CRPS), rheumatoid arthritis flares, gouty or OA flares, painful radiculopathy, bursitis, carpal tunnel syndrome, and other acute or chronic musculoskeletal conditions.144-146

**MECHANISM OF ACTION AND DESCRIPTION**

Adrenocortical steroids such as prednisone, methylprednisolone, and dexamethasone act by inhibiting multiple cellular mechanisms, including accumulation of inflammatory cells at sites of inflammation, macrophage phagocytosis, lysosomal enzyme release and synthesis, and release of mediators of inflammation. In regard to their ability to attenuate pain responses, this action is probably related to their strong anti-inflammatory action. Steroids suppress or prevent cell-mediated immune responses and decrease or prevent tissue response to the inflammatory process. The mechanisms for reduction of cancer pain are thought to be secondary to inhibition of PG synthesis and reduction in peritumoral and perineural edema by decreasing capillary permeability.143 Oral prednisone is readily absorbed in the GI tract. It is highly protein bound (up to 70% to 90%) and is distributed widely in a variety of tissues. The plasma t½ of prednisone is 3.4 to 4 hours, with a biologic t½ of 18 to 36 hours. It is metabolized in the liver to its active metabolite prednisolone, which is further metabolized to inactive compounds. The active metabolite and inactive compounds are excreted in urine, and the drug is not removed by hemodialysis.147 The pharmacodynamics of commonly used glucocorticoids is presented in Table 37.11.

Prednisone tablets are available in multiple dosage forms ranging from 2.5- to 50-mg tablets. Other glucocorticoids commonly prescribed for painful conditions include methylprednisolone (Medrol Dosepak) and dexamethasone (Table 37.12). The Medrol Dosepak consists of 21 4-mg tablets in a tapering fashion from 6 tablets on day 1 to 1 tablet on day 6. See Box 37.5 for common glucocorticoid dosing schedules.

**RISKS AND PRECAUTIONS**

In general, long-term administration at physiologic replacement doses does not lead to adverse effects. Similarly, short-term dosing at supraphysiologic levels typically does not cause adverse effects. Many have recommended a tapering dose schedule to avoid glucocorticoid withdrawal, which can occur in as few as 5 days at high supraphysiologic doses or in 3 to 4 weeks at physiologic doses.142 Suppression of the HPA...
axis can persist for up to 12 months after cessation of prolonged corticosteroid therapy, and supplementation may be required during periods of physiologic stress such as surgery, acute blood loss, or infection. Because of the depression and prevention of cell-mediated immune responses, oral corticosteroids are not well tolerated by patients with immunocompromised states, whether acute or chronic. However, they do play an adjuvant role in the management of cancer pain. In such cases, new pain complaints in cancer patients or palliative care patients must be monitored vigilantly because in the presence of opioid analgesics and corticosteroid therapy, symptoms may be less severe and related to a new diagnosis, such as appendicitis.

A population-based study examining more than 2400 patients maintained on long-term oral glucocorticoid therapy found that side effects are associated with cumulative and average doses in a dose-dependent fashion. The study allowed the use of varied glucocorticoid preparations and converted them into a prednisone-equivalent dose. The most common side effects, with approximate prevalence, included weight gain (70%), skin bruising (53%), sleep disturbance (45%), mood symptoms (42%), cataracts (15%), acne (15%), and fractures (12%). An increasing daily dosage was more significantly associated with fractures and sleep disturbance than was an increased duration of use.

Use of prednisone during pregnancy is schedule D during the first trimester and schedule C in the second and third trimesters. A population-based study examining more than 2400 patients maintained on long-term oral glucocorticoid therapy found that side effects are associated with cumulative and average doses in a dose-dependent fashion. The study allowed the use of varied glucocorticoid preparations and converted them into a prednisone-equivalent dose. The most common side effects, with approximate prevalence, included weight gain (70%), skin bruising (53%), sleep disturbance (45%), mood symptoms (42%), cataracts (15%), acne (15%), and fractures (12%). An increasing daily dosage was more significantly associated with fractures and sleep disturbance than was an increased duration of use.

Use of prednisone during pregnancy is schedule D during the first trimester and schedule C in the second and third trimesters. First-trimester exposure to systemic corticosteroids (category C) has been associated with intrauterine growth retardation and an increased incidence of cleft lip, with or without cleft palate. If necessary, the maternal benefits of short courses of oral corticosteroids may outweigh the fetal risks when given beyond the first trimester.

**CLINICAL USE**

Oral corticosteroids have a limited role in the treatment of painful conditions. They may be useful in the treatment of acute painful inflammatory conditions, including CRPS, carpal tunnel syndrome, rotator cuff arthropathy–adhesive capsulitis, and painful cervical or lumbar radiculopathy.

**Box 37.5 Common Glucocorticoid Dosing Schedules**

- Prednisone taper—prednisone, 10-mg tablets: 3 tablets PO bid x 4 days, 2 tablets PO bid x 3 days, 1 tablet PO bid x 3 days
- Medrol Dosepak—methylprednisolone, 4-mg tablets: Day 1: 2 tablets before breakfast, 1 tablet after lunch and dinner, and 2 tablets at bedtime (total = 6 tablets). If given later in the day, may take all 6 tablets at once or in divided doses.Day 2: 1 tablet before breakfast, 1 tablet after lunch and dinner, and 2 tablets at bedtime.Day 3: Same as day 2, except 1 tablet at bedtime.Day 4: 1 tablet before breakfast, after lunch, and at bedtime.Day 5: 1 tablet after breakfast and at bedtime.Day 6: 1 tablet after breakfast.Day 7: 1 tablet before breakfast, 1 tablet after breakfast, and 1 tablet after lunch and dinner.Dexamethasone taper—dexamethasone, 8-mg tablets: Tapering schedule over 7 days: 64, 32, 24, 16, 8, 8, 8 mg.
Steroids have been and continue to be administered by multiple routes for the treatment of CRPS. After early reports of success with systemic steroids,152 Christensen and coworkers146 studied 23 patients and reported that 30 mg/day of oral prednisone is significantly better than placebo based on their stated clinical outcome measures. Braus and colleagues153 studied the effects of methylprednisolone, 32 mg/day for 2 weeks, followed by a taper over 2 weeks, for the treatment of CRPS in post-stroke patients. This randomized study showed a significant clinical improvement in the steroid-treated patients at 4 weeks. A recent investigation of the effects of chronic methylprednisolone treatment on the rat CRPS type 1 model (tibia fracture) has revealed that glucocorticoids reverse hindpaw edema and warmth after fracture, with persistent effects occurring after discontinuation of treatment. However, glucocorticoid treatment has no effect on the allodynia, hindpaw unweighting, or periarticular bone loss observed after tibia fracture.154

The use of minor analgesics in the cancer pain population is common. The most commonly used opioid co-analgesics are NSAIDs and APAP, but up to 39% of cancer patients take various types of corticosteroids, with dexamethasone being the most common formulation. These patients have a wide range of conditions, with breast, lung, and colorectal cancer topping the list. This cross-sectional study did not specifically determine whether each adjuvant medication was given specifically for control of pain as opposed to other diseases, but other studies have documented the usefulness of corticosteroids for the rational polypharmacy of cancer pain management.148,155,156 Efficacy has been demonstrated for neuropathic pain caused by tumor compression (malignant compression of the spinal cord or brachial or lumbar spinal plexus), tumor-induced bone pain, and hepatic capsule distention secondary to liver metastases.143,157 In addition to NSAIDs and disease-modifying antirheumatic drugs, low-dose oral corticosteroids may also be helpful in managing joint symptoms caused by chemotherapy-induced arthropathy.158

Despite the lack of many directed controlled clinical trials, corticosteroids are frequently prescribed in an adjunctive role for palliation and control of the side effects of chemotherapy; therefore, these agents may play a dual role in selected patients. Many believe that corticosteroids may help in preventing chemotherapy-induced nausea and emesis and hypersensitivity reactions. In addition, they may also help ameliorate asthenic symptoms and fatigue, as well as stimulate appetite.145,159

The use of oral glucocorticoids in the form of methylprednisolone or prednisone burst or taper is common practice in the acute treatment of disk herniation with radicular pain complaints. Despite a significant increase in studies evaluating the efficacy of fluoroscopically guided epidural steroid injections,160 there is a paucity of reports on the usefulness of oral or systemic corticosteroids in this pain population. In the only prospective, double-blind, randomized controlled trial evaluating the use of oral corticosteroids for the treatment of radicular pain, a tapering dose of dexamethasone over a 7-day period was not superior to placebo for early or long-term relief of lumbosacral radicular pain. Dexamethasone, however, was superior to placebo in reducing stretch-invoked pain during the straight-leg raise test. This study did allow the concurrent use of meperidine, oxycodone, and APAP for analgesia.161 Systemic dexamethasone taper via the intramuscular route has been studied to a limited degree, with conflicting results.162,163 The rationale for the use of oral corticosteroids is based on the observance that proinflammatory mediators and neurosensitizing chemicals are released from the damaged intervertebral disk.164,165 One study suggested that epidurally administered glucocorticoids do not appear to have a negative effect on spontaneous resorption of disk herniations.166

With most musculoskeletal injuries there is a close relationship between injury and pain. Therefore, individual treatments in a comprehensive management program may serve dual purposes—reducing inflammation to control local damage and concurrently reducing pain. Although few trials have evaluated the efficacy of oral corticosteroids for musculoskeletal injuries, clinical practice reveals that their use is widespread. A questionnaire-based study involving 99 physicians at a national sports medicine conference found that 59% of the physicians prescribe oral corticosteroids for musculoskeletal injuries, with prednisone being the most commonly used.167 The study did not differentiate whether the medication was being prescribed specifically for pain or for its anti-inflammatory properties, but prescriptions were written for acute and chronic conditions equally.

Although the mainstays of treatment of carpal tunnel syndrome include neutral wrist splints, ergonomic evaluation and modification of biomechanics, oral NSAIDs, steroid injections, and surgical release of the transverse carpal ligament, there is evidence to suggest that oral corticosteroids may play a role in the short-term management of patients with mild to moderate symptoms and in those not interested in or awaiting surgical release of the transverse carpal ligament. Studies have examined varied dosing and duration-of-treatment regimens with prednisolone (10 days to 3 weeks, doses of up to 25 mg daily); the results suggest that regardless of dosing, the global symptom score is improved in patients treated with oral corticosteroid versus placebo.144

Short-term dosing of oral prednisolone at variable doses has been studied for adhesive capsulitis. Binder and associates168 used 10 mg daily for 4 weeks, followed by 5 mg daily for 2 weeks. Night pain was significantly lower in the treatment group at 8 weeks. However, by 5 months this difference had resolved. Over the total 8-month period, no difference was found in pain at rest or with movement, range of motion, or the cumulative recovery curve between the oral steroid group and the control group, which received no specific therapy. Other studies have evaluated a 3-week
course of 30 mg prednisolone daily and reported a significant reduction in pain and disability, improved active range of motion, and better participant-rated improvement at 3 weeks. By 6 weeks, the improvements were still evident, but none of the values were statistically significant; at 12 weeks, the placebo group was favored.145

The use of oral corticosteroids for the treatment of rheumatoid arthritis has been studied since 1949, when Hench and coworkers169 showed efficacy of the treatment in an uncontrolled trial. Although oral corticosteroids may show beneficial effects with respect to radiologic progress of the disease,170 they are more commonly used during episodes of symptomatic flares to control pain or as bridge therapy with slower-acting agents.171,172 A meta-analysis evaluating the effectiveness of low-dose prednisolone versus placebo and NSAIDs found that low-dose prednisolone (<15 mg daily) has greater effect than placebo and NSAIDs on joint tenderness and pain.172

CAFFEINE
Caffeine is an important adjuvant compound used in combination with OTC and prescription analgesics. Caffeine exhibits antinociceptive effects and analgesic properties when used in combination with opioid analgesics.173 Caffeine combination products have been studied for a number of pain conditions, including headache,174 oral surgery,175 low back pain,176 and postpartum-related pain.177 Caffeine (65 to 130 mg) was shown to increase the potency of other analgesics by 40%.178 OTC headache medications typically include 65 or 32.5 mg caffeine combined with APAP, 250 to 500 mg, and/or ASA, 250 to 520 mg (Table 37.14).

MECHANISM OF ACTION AND DESCRIPTION
Caffeine, a methylxanthine, is a nonselective adenosine receptor antagonist that blocks multiple adenosine receptors (A1, A2A, A2B, and A3) in peripheral tissues and the CNS.179,180 Centrally, caffeine may increase dopamine and norepinephrine, as well as act as a vasoconstrictor of vessels, thereby contributing to its analgesic effect in certain headache conditions.181 A recent animal study using a fixed dose of aspirin, APAP (paracetamol), and caffeine demonstrated increased secretion of norepinephrine and a reduction in dopamine in rat striatal tissue.182

CLINICAL USE
Studies examining the relationship between dietary caffeine intake and chronic low back pain have yielded conflicting results.183,184 One review that included more than 10,000 patients in 30 trials found that caffeine is successful as an adjuvant for analgesia. Without the combination of caffeine, 40% higher doses of aspirin, APAP, or salicylamide would have been required to achieve equivalent analgesia. When used for the treatment of nonmigrainous headache, 65 mg of caffeine was found to be as effective as 648 mg of APAP.

TOPICAL MEDICATIONS
Prescription and OTC topical medications for pain, including topical analgesics, counterirritants, heat and cold preparations, and patches, constitute a growing area of development in pain management. In the previous decade alone, topical analgesics accounted for approximately 6% of the growing U.S. analgesic market.185 In addition, a smaller evolving niche market of compounding pharmacies—those that provide the unique service of customized compounding of various creams and gels for topical use—has broadened the use of topical medications for analgesia. Commonly used medications include ketamine, lidocaine, gabapentin, cyclobenzaprine, and various NSAIDs.186

The use of topical analgesics may be a viable option for patients because of safety concerns of NSAIDs in the popular media and scientific literature.187 The FDA's black box warnings of prescription and OTC NSAIDs, including COX-2 inhibitors,188 may have led to renewed interest in safer pharmacologic alternatives to oral medications. In general, topical preparations have considerably less potential for systemic adverse effects and organ toxicity. Interestingly, a recent meta-analysis of randomized placebo-controlled trials for OA found topical NSAIDs to be more effective than oral nonselective NSAIDs and COX-2 inhibitors and second to intra-articular steroid injections, as measured by patient-perceived improvement during the first 2 to 3 weeks following treatment.189 Commonly prescribed topical medications include the following: lidocaine 5% patches, indicated for post-herpetic neuralgia (PHN)190, topical TCAs, including doxepin and amitriptyline, for neuropathic pain states191,192; topical NSAIDs, including diclofenac; and counterirritants and vanilloid receptor agonists, such as capsaicin, for neuropathic pain.193 This section reviews various prescription-strength and OTC topical medication classes, including analgesics, anesthetics, counterirritants, and hot or cold products used commonly for the treatment of acute and chronic pain conditions (Table 37.15).

METHODS OF DELIVERY
Topical agents may potentially achieve a similar level of efficacy as oral formulations without the associated systemic side effects. Some evidence has shown that topically delivered agents can accumulate to therapeutic concentrations within

ASA, acetylsalicylic acid; N/A, not applicable; NSAID, nonsteroidal anti-inflammatory drug.
the local tissues to which they have been applied while maintaining low serum levels and subsequently resulting in less organ toxicity. **Box 37.6** lists the benefits and limitations of dermal and transdermal delivery systems. 194-215

Topical agents can be delivered by passive and active methods. Passive methods involve application of drugs to the skin (e.g., ointments, creams, gels, patches) and may include modified systems that enhance the driving force of the agent through the skin. These systems include thermodynamic and permeability enhancers, such as penetration enhancers, prodrugs, and liposomes. Passive methods currently on the market are usually well tolerated but are limited by skin irritation, poor adhesion, and limitation in size because of practical cosmetic issues. 194 Active methods use modalities to facilitate the distribution of medication.

**“Topical” versus “Transdermal”**

“Topical” and “transdermal” are distinct modes of delivery of medication to the skin. Both delivery methods must traverse the stratum corneum, the major barrier to delivering treatment. Transdermal methods deliver medication through percutaneous absorption, with the goal of achieving similar therapeutic systemic levels as active oral preparations do. Transdermal pharmacotherapies can be administered distal to the site of injury (e.g., SR nicotine and clonidine patches, long-acting fentanyl delivery systems). In contrast, topical agents use cutaneous delivery to target the site of application specifically. The sites of action of topical agents are the soft tissues and peripheral nerves underlying the site of application. 216 Serum levels generally remain relatively low with topical agents, and systemic side effects or drug-drug interactions are consequently more unlikely. 216

The vehicle in which the active ingredient or ingredients are delivered can affect the skin penetration depth and absorption rate into the epidermis. 216 Primarily, penetration of topical modalities is limited by the relatively dense stratum corneum, a layer of flattened dead cells or keratinocytes covering the live epidermis. 217,218 Once past this relatively impermeable barrier, analgesics may access cutaneous nociceptors, including unmyelinated C fibers of the epidermal layer. Below the epidermis, the dermal layer also contains nociceptive fibers, along with fibroblasts, connective tissue, blood vessels, hair follicles, and glands. 218

Animal models have suggested that the variability in transcutaneous absorption rates between topical agents is probably derived from their ability to negotiate the superficial layer of skin. 219 Ideally, the most effective topical agent will have a low molecular weight (less than 500 Da) 217 and both hydrophobic features to transverse the stratum corneum and hydrophilic components to penetrate the predominantly aqueous epidermis. 219,220 Occlusive dressings and specialized delivery agents may also help improve penetration. 220 Lecithin organogels are biocompatible jelly-like phases composed primarily of hydrated phospholipids and organic liquid. 221 Poloxamer-lecithin organogel (PLO) is a commonly used vehicle that includes a viscosity-enhancing agent that facilitates oil-in-water preparations and is used by a number of compounding pharmacies. 222 PLO also includes lecithin and propylene glycol, which help disperse the drug more uniformly. Additionally, polyethylene glycol and limonene 223 have been used as topical penetration enhancers to increase the absorption rate of NSAIDs by up to 75-fold. 220

**Modalities**

Active delivery of medication may be enhanced by the use of physical modalities, including iontophoresis and phonophoresis. 224 Iontophoresis is the migration of charged particles across biologic membranes under an electric field, usually applied transcutaneously. 225 This method, generally under the direction of a physical therapist or other health care professional, uses low-level current to enhance the permeability of the topically applied agent (e.g., corticosteroid, [Table 37.15](#)

**Box 37.6 Benefits and Limitations of Analgesia by Cutaneous Delivery**

**Benefits**

- First-pass metabolism, other variables associated with the gastrointestinal tract (e.g., pH, gastric emptying time) avoided 195-197
- Reduced side effects, minimization of drug concentration peaks and troughs in blood 197,198
- Ease of dose termination in case of untoward side effects
- Delivery can be sustained and controlled over a prolonged period 199,200
- Direct access to the target site 201
- Convenient, painless administration 195,196
- Improved patient acceptance, adherence to therapy 202-204
- Ease of use—may reduce overall health treatment cost 205,206
- Provides a viable solution for treatment when oral dosing not feasible (e.g., in unconscious or nauseated patients) 197

**Limitations**

- Diffusion across the stratum corneum occurs only with molecules smaller than 500 Da 207
- Topical agents must have both aqueous and lipid solubility 208
- Both intraindividual and interindividual variability in skin permeability, as well as between healthy and diseased skin, causes variable efficacy 209,210
- Skin enzymes can cause metabolism before cutaneous absorption, thereby reducing drug potency 211
- Localized skin irritation (e.g., erythema, edema) can be common Da, dalton.

NSAID). Phonophoresis involves migration of drug through the skin via an ultrasound transducer. Phonophoresis is commonly used in the treatment of musculoskeletal conditions to enhance the delivery of topical NSAIDs to inflamed tissues.226

TOPICAL TREATMENT: CLINICAL TRIAL EVIDENCE

Nonsteroidal Anti-inflammatory Drugs

Topical NSAIDs are more widely used and studied in Europe than in the United States. Several proposed peripheral mechanisms of their analgesic activity include inhibition of PGE synthesis, the lipoxygenase pathway, and excitatory amino acids, as well as modulation of G protein–mediated signal transduction.216 A large variety of topical NSAID formulations are available commercially (Table 37.16).

Pharmacokinetic data suggest that topically applied NSAIDs can result in enhanced local concentrations without significant toxic systemic levels. Heyneman and colleagues220 reviewed single- and multiple-dose NSAID absorption studies. Collectively, these studies indicated that following topical administration of NSAIDs, peak plasma levels are less than 10% of the concentrations obtained from oral dosing (range, 0.2% to 8.0%), with total systemic absorption from topical application being only 3% to 5% of the oral route. The time to achieve $C_{max}$ following topical application ranged from 2.2 to 23 hours, approximately 10 times longer than the time required for the equivalent oral dose. Topical NSAIDs generally achieve steady-state concentrations within 2 to 5 days of repeated application.220

Furthermore, penetration studies have indicated that topically applied NSAIDs reach therapeutic concentrations below the site of application.220 A two-way crossover design assessed the levels of subcutaneous and muscle absorption of 800 mg of oral ibuprofen versus 16 g of 5% ibuprofen gel applied to the thigh.227 Microdialysis probes inserted 25 to 30 mm into the muscle found average values of 63.5 ± 90.3 and 213.4 ± 117 ng/hr/mL of ibuprofen for the oral and topical routes, respectively. Ibuprofen concentrations in the dermis were 22.5-fold greater when delivered topically; mean values of ibuprofen in subcutaneous tissue were 731.2 ± 605.0 and 176.6 ± 122.9 ng/hr/mL for the topical and oral routes, respectively.227 Another study of 100 patients who underwent knee arthroscopy evaluated ketoprofen concentrations in intra-articular tissue following a single application of a 30-mg plaster, multiple applications of plaster over a 5-day period, or a 50-mg oral dose.228 The median $C_{max}$ levels in the cartilage with topical and oral administration were 568.9 and 85.7 ng/g, respectively (a 6.8-fold difference). In contrast, plasma values were 18.7 ng/mL for topically administered ketoprofen and 2595.3 ng/mL for the oral route. Overall, when administered by a topical route, ketoprofen levels were 30-fold greater in cartilage than in plasma.228

Relative to all other topically administered drugs, NSAIDs have accumulated the largest amount of clinical evidence for their use.216 A meta-analysis by Moore and associates229 considered 86 randomized controlled trials of NSAIDs for the treatment of pain conditions. This review included a total of 10,160 patients. Following 1 to 2 weeks of topical application, placebo-controlled trials demonstrated the benefit of NSAIDs for the treatment of acute pain conditions, such as soft tissue trauma, sprains, and strains, as well as for chronic pain conditions, such as OA and tendinitis.

Overall, the NNT was 3.9 for acute pain conditions—more specifically, 2.6 for ketoprofen, 3.5 for ibuprofen, and 4.2 for piroxicam. For chronic pain conditions, the NNT was 3.1 (range, 2.7 to 3.8). Side effects encountered for all the pain conditions studied were minimal; topical NSAIDs rarely induced local skin reactions (3.6%) or adverse systemic effects (<0.5%). Similarly, a smaller meta-analysis of 26 double-blind, placebo-controlled trials by Mason and coworkers found that topical NSAID treatment is safe and effective for acute pain after 1 week of application.

**Osteoarthritis and Topical Nonsteroidal Anti-inflammatory Drugs**

A meta-analysis of randomized controlled trials assessed the efficacy of topical NSAIDs relative to placebo or oral formulations for the treatment of OA. When compared with placebo, a positive treatment effect was observed for topical NSAIDs only during weeks 1 and 2 of treatment, with effect sizes of 0.41 (95% confidence interval [CI], 0.16 to 0.66) and 0.40 (95% CI, 0.15 to 0.65), respectively. In contrast, even during the first week, topical NSAIDs were found to provide analgesia inferior to that of oral versions, and topical agents induced more local side effects. The authors concluded that no trial evidence has supported the benefit of NSAIDs over placebo in treating OA after 2 weeks of application and even suggested that current practice guidelines on OA that advocate the use of topical NSAIDs be revised. However, two recent randomized, controlled trials of topical diclofenac solution for the treatment of pain secondary to knee OA reported benefit at 4 and 12 weeks of application. As measured by Western Ontario and McMaster Universities (WOMAC) OA index scores, relative to baseline the study group had a 42.9% decrease in pain at 4 weeks and a 45.7% decrease after 12 weeks as opposed to 26.9% and 33.3% decreases in pain for the vehicle control groups, respectively. Measurements of physical function, stiffness, and pain on walking indicated similar benefit of topical diclofenac over placebo in both studies. Probably because of the skin penetration enhancer dimethyl sulfoxide (DMSO), 30 of 84 patients in the 4-week study group and 68 of 164 patients in the 12-week study group reported skin irritation (typically dryness), which led to discontinuation by 5 patients in each of the treatment groups.

**Diclofenac**

Various novel NSAID patches and plasters have been developed that confer more constant, continuous delivery of a standardized dose of analgesic, although individual skin variability affects the actual amount absorbed. Galer and colleagues conducted a multicenter, randomized, parallel-design trial to assess the efficacy of a topical diclofenac patch for the treatment of pain from sports-related soft tissue injuries such as sprains, strains, and contusions. A 1.3% diclofenac epolamine or placebo patch was applied twice daily onto 222 patients for 2 weeks. The study group achieved statistically significant differences in pain intensity from placebo on clinic visits at day 5 ($P = 0.036$) and day 14 ($P = 0.044$) following initiation of treatment, but not on day 7. Forty percent of participants given placebo reported adverse events, whereas 34% of the study group patients reported side effects. A similar study comparing a diclofenac patch (140 mg diclofenac sodium) and placebo applied within 3 hours of blunt, soft tissue trauma-type injury found a statistically significant analgesic effect over placebo ($P < 0.0001$) as measured by tenderness produced by pressure and the time required to for the pain to resolve at the site of injury ($P < 0.0001$). Adverse events, most commonly local cutaneous reactions, were experienced at a similar frequency by both groups.

Topical 1.5% diclofenac solution (Pennsaid) is presently approved in Canada and Europe for the treatment of OA. Topical 1.5% diclofenac in a carrier containing DMSO solution applied three times daily demonstrated efficacy when compared with vehicle-controlled solution and placebo in patients with OA of the knee. Adverse effects included skin irritation (36%), most commonly skin dryness, which led to discontinuation in only 6% of cases. A similar study of knee OA found that a 1.5% diclofenac solution (40 drops, four times daily) resulted in improvements in pain, physical function, patient global assessment, stiffness, and pain on walking.

**Ketoprofen**

Topical ketoprofen has been suggested to demonstrate more favorable physicochemical properties than other available NSAIDs, including greater lipophilicity and more rapid absorption. Some studies have demonstrated plasma ketoprofen levels to correlate with measures of efficacy in a postoperative orthopedic cohort for up to 12 hours of oral dosing. Another study found variability in serum levels of topical ketoprofen (20%) in a PLO-based formulation after a single application, with a low rate and extent of systemic absorption (approximately 0.5%). A placebo-controlled study of patients with pain from an ankle sprain assessed the analgesia achieved over a 2-week period by the application of a 100- ng topical ketoprofen patch. Significantly less spontaneous pain was observed in the study group than in the control group during all visits (days 3 to 4, 7 ± 1 and 14 ± 2). Most notably, there was a 49.9- ± 20.2-mm (73%) decrease in pain from baseline at day 7 ± 1 for patients given the ketoprofen patch as compared with a 37.6- ± 24.3-mm (57%) decrease in patients given a placebo patch. The intergroup difference in pain relief was significant ($P = 0.0007$), but the difference in adverse events was not. Thirty-one percent of the study group and 24% of the control group experienced adverse events. A similar study with a topical ketoprofen patch, 100 mg, demonstrated efficacy for symptomatic tendinitis, with a reduction in pain occurring after 1 week in the treatment group (−38.4 ± 25.6 mm) versus placebo (−25.8 ± 24.5 mm).

Ketoprofen, an arylpropionic acid derivative, has been associated with an increasing number of case reports describing contact allergic and photosensitization skin reactions in Europe and Asia. The unique photoallergy may be related to the benzophenone structure of ketoprofen. Caution or avoidance of use may be necessary during periods of significant skin exposure to sun.

**NEUROPATHIC PAIN AND TOPICAL ANALGESICS**

Mechanisms of action for neuropathic pain include spontaneous discharges of peripheral or central neurons, spontaneous ectopic electrical activity mediated by abnormal expression and upregulation of Na+ channels or peripheral sensitization via Na+ channel phosphorylation in injured...
peripheral nerves, demyelination, or discharges in cell bodies in the dorsal root ganglion. This all results in longer depolarizations in specific Na⁺ channels and increases in the release of neurotransmitters. Sodium channel blockers bind rapidly to open channels and limit their accessibility, thereby ultimately reducing neurotransmitter release.

Commonly used topical agents for neuropathic pain are amitriptyline, ketamine, lidocaine, and capsaicin (described later). As mentioned previously, along with commercially available products are pharmacy-compounded preparations, which unlike the former, lack the support of controlled trials and are potentially variable in preparation without established safety. Compounded preparations include gabapentin, ketamine, nifedipine, and TCAs. Commercially available and studied products include capsaicin cream, 5% lidocaine patch, lidocaine/prilocaine topical cream, and doxepin. In a double-blind, randomized, placebo-controlled 3-week study, topical 2% amitriptyline, topical 1% ketamine, and a combination of the two achieved a reduction in pain scores (in patients with CRPS type 2, painful diabetic neuropathy, or PHN) by 1 to 1.5 units. In addition, blood concentrations revealed no significant systemic absorption.

Lidocaine patches work by binding to and blocking sodium channels, which theoretically reduces the pain signal. In a randomized, double-blind vehicle-controlled, 3-week efficacy study with use of the neuropathic pain scale, 5% lidocaine patch, lidocaine/prilocaine topical cream, and doxepin. In a double-blind, randomized, placebo-controlled 3-week study, topical 2% amitriptyline, topical 1% ketamine, and a combination of the two achieved a reduction in pain scores (in patients with CRPS type 2, painful diabetic neuropathy, or PHN) by 1 to 1.5 units. In addition, blood concentrations revealed no significant systemic absorption.

In addition, blood concentrations revealed no significant systemic absorption.

TOPICAL COUNTERIRRITANTS AND HOT OR COLD PREPARATIONS

An increased understanding of nociceptor physiology, including a greater understanding of thermosensation, has been spurred by the identification of proteins called vanilloid receptors, detectors of noxious heat, and the subsequent identification of a new family of thermosensation receptors, the transient receptor protein (TRP) channel family. The vanilloid receptor (TRPV1) is a nonselective cation receptor activated by capsaicin, the pungent agent found in chili peppers. TRPV1 is also activated by heat (>43° C) and decreased pH and enhanced by bradykinin and nerve growth factor. The TRPV2 receptor, which is 50% identical to TRPV1, may mediate high-threshold noxious heat (>52° C). TRPV3 is activated by increased temperature (>31° C) and is expressed in the skin, tongue, and nervous system, where it may act as a “warm sensitive neuron.” Another TRPV receptor, the cold- and menthol-sensitive receptor (CMR1), has been identified and may help us better understand cold thermosensation and the development of targeted cold-producing analgesics. Pharmacologic studies of menthol have suggested possible κ-opioid receptor effects, thereby contributing additional analgesic properties to the substance.

Review and Physiology

Counterirritants such as capsaicin, camphor, menthol, and garlic represent a category of analgesics that excite and subsequently desensitize nociceptive sensory neurons (Table 37.17). Although many of the group’s members have had a long history of common medical use, it was not until recently that their molecular mechanisms of action were elucidated. All these pungent plant derivatives act on the TRP superfamily, a group of structurally similar, thermosensitive ion channels. As noted earlier, members include TRPV1 (also called vanilloid receptor subtype 1 [VR1]), TRPV3, TRPM8, and TRPA1, which are activated by capsaicin, camphor, menthol, and garlic, respectively (Fig. 37.4). These thermosensitive receptors detect a wide range of temperatures, from noxious heat to extreme cold, as well as other stimuli, including heat, protons, lipids, changes in extracellular osmolarity or pressure (or both), and depletion of intracellular Ca²⁺ stores. These proteins are expressed in primary sensory neurons, as well as in other tissues. On activation of TRP receptors, release of calcitonin gene–related peptide,
substance P, and other inflammatory neurotransmitters is induced, and local irritation and inflammation ensue.\(^{255}\) This can lead to two types of desensitization: acute or “pharmacologic” desensitization, characterized by a diminished response during constant agonist application, and a longer period of tachyphylaxis, or “functional” desensitization, characterized by desensitization to other stimuli such as chemicals, pressure, or temperature.\(^{252}\)

**Capsaicin**

As early as the 19th century the selective effects of capsaicin on sensory nerve fibers were recognized.\(^{218}\) The spicy ingredient in chili peppers has been used to relieve neuropathic pain, uremic pruritus, and bladder overactivity, as well as to provide efficacy.\(^{218,256}\) The combination of topical capsaicin (0.025%) application reduce patient adherence and may adversely limit treatment of musculoskeletal and neuropathic pain.\(^{257}\) The mechanism of action of capsaicin is characterized by a paradoxical biphasic pharmacologic action on sensory neurons. An initial excitatory phase (pain and inflammation), mediated by activation of the TRPV1 receptor, is followed by a secondary analgesic phase that has been attributed to long-term desensitization of nociceptors and depletion of substance P.\(^{258}\) A systematic review of topical capsaicin for the relief of musculoskeletal pain pooled the results of three double-blind, placebo-controlled trials with a total of 368 patients.\(^{259}\) After 4 weeks of treatment with 0.025% capsaicin or plaster, the mean response rate (percentage of patients with at least 50% pain relief) was 38% (range, 34% to 42%), and the placebo response rate was 25% (range, 17% to 37%). The NNT was 8.1, and approximately a third of patients experienced local, treatment-related adverse events.\(^{259}\) An older meta-analysis reported that capsaicin cream provides better pain relief of OA pain than placebo does (odds ratio, 4.36; 95% CI, 2.77 to 6.88).\(^{260}\) However, products with low concentrations of capsaicin require multiple applications to provoke desensitization of nerves,\(^{256}\) which may be problematic for daily use because of potential adverse application effects such as burning or irritation of the eyes or other mucous membranes if not adequately removed from the hands after application.\(^{218}\) Additionally, burning and pain on application reduce patient adherence and may adversely limit efficacy.\(^{218,256}\) The combination of topical capsaicin (0.025%) with 3.3% doxepin provided more rapid analgesia than did treatment with either of these two agents independently.\(^{261}\) For neuropathic pain, topical capsaicin was compared with oral amitriptyline and found to be similar in analgesia and improvements in daily activities, with lower side effects noted in the capsaicin group.\(^{262}\) Most recently, Qutenza, a high-concentration capsaicin (8%) patch, has been approved for use in patients with PHN. Its mechanism of action is thought to be due to a reduction in TRPV1 expression and a decrease in the density of epidermal nerve fibers in the application area.\(^{263}\) When compared with a control 0.04% capsaicin patch, Qutenza was shown to achieve higher reductions in pain levels for 12 weeks (32% vs. 24% reduction).

**Camphor**

Camphor is derived from the wood of the camphor laurel tree (Cinnamomum camphora). Historically, the sweet-smelling compound has had many medicinal applications, including use as a decongestant, cough suppressant, and antipruritic agent.\(^{252}\) OTC camphor-containing balms have also been used to provide analgesia. Recent studies have implicated three receptors in camphor’s mechanism of action: TRPV3, the capsaicin receptor TRPV1, and the garlic receptor TRPA1.\(^{252}\)

**Menthol**

In contrast, menthol—the component that confers the mint smell and flavor to the *Mentha* species—is often included in eutectic formulations of local anesthetic agents.\(^{251}\) Anecdotally, menthol induces tingling and cooling sensations when applied topically. Menthol confers analgesia through its Ca\(^{2+}\) channel-blocking actions. In addition to binding TRPM8,\(^{253,257}\) menthol binds \(\kappa\)-opioid receptors and thus may confer an additional opioid analgesic effect.\(^{251}\) Furthermore, similar to other terpenes, menthol is an effective topical permeation enhancer for water-soluble drugs, such as the TCA imipramine.\(^{264}\)

**Salicylates**

Topical rubefacients containing salicylates, another type of counterirritant, have an unidentified mechanism of action.\(^{262}\) It is thought that analgesia is conferred by a mode different from that of NSAIDs, yet salicylates are often found in many topical preparations. Further randomized, clinical trial evidence for salicylates has been systematically reviewed by Mason and coworkers.\(^{265}\) Three double-blind, placebo-controlled trials examined topical salicylates for the treatment of acute musculoskeletal pain. The study groups exhibited significantly better reductions in pain than did the placebo group (relative benefit, 3.6; 95% CI, 2.4 to 5.6; NNT, 2.1; range, 1.7 to 2.8). The long-term efficacy data and adverse events reported were poor for chronic musculoskeletal pain, but information from six double-blind, placebo-controlled trials indicated a relative benefit versus control of 1.5 (range, 1.3 to 1.9; NNT, 5.3; range, 3.6 to 10.2).

**CONCLUSION**

Analgesics play an important role in the treatment of many acute and chronic pain conditions. They represent the first line of agents in the World Health Organization’s analgesic ladder and range from OTC convenience medications to adjuvants for the treatment of musculoskeletal, arthritis, spine-related, and cancer pain conditions. Though considered relatively safe in comparison to many other prescription-strength medications, minor analgesics must be used with caution. Side effects and adverse events related to common use and misuse of these medications include liver toxicity (APAP); GI, renal, and cardiac toxicity (NSAIDs and COX-2 inhibitors); and physiologic dependence, tolerance, and addiction (combination opioid analgesics and tramadol products).

Topical analgesics (e.g., patches, creams, solutions) represent a growing area of development in pain management because of their relative ease of application, potential for reduced systemic side effects, and lowered risk for end-organ damage. Advancements in pharmaceutical delivery systems may also aid in the development and more widespread use of various OTC and prescription-strength topical compounds. The pain clinician should be cognizant of the vast array of ingredients found in various OTC topical analgesics and counterirritants, including capsaicin, menthol, camphor, and methylsalicylates.
Regular use of over-the-counter analgesic medications is a common method used by patients to relieve various pain-related conditions.

Minor opioid analgesics include propoxyphene, hydrocodone, oxycodone, and tramadol, individually and in combination products.

Patients’ responses to individual opioids and opioid combination products may vary significantly. This is probably explained by opioid receptor polymorphisms, differences in pharmacokinetics, and genetic variation related to enzymatic breakdown by hepatic metabolic systems.

True serotonin toxicity and serotonin syndrome are rare, but potentially deadly conditions seen in the field of pain management. They are characterized clinically by changes in mental status and autonomic and neuromuscular hyperactivity.

The use of over-the-counter and prescription-strength topical preparations represents a growing area of development in pain medicine, with significantly less potential for systemic adverse effects and organ toxicity than noted with oral formulations.

When compared with other topically administered medications, topical nonsteroidal anti-inflammatory drugs have accumulated the largest amount of clinical evidence for their use in relieving acute versus chronic musculoskeletal conditions.

Antidepressants as Analgesics

Howard S. Smith | Charles E. Argoff | Gary McClean

The second half of the 20th century saw the introduction of a range of therapeutic agents that were shown to have an antidepressant effect. Among these agents were those with a tricyclic chemical structure, which led to their classification as tricyclic antidepressants (TCAs). Even before their introduction into clinical practice, the concept of a link between depression and pain was obvious, and the possibility that this link was causal encouraged the use of antidepressants for patients who exhibited features of both pain and depression.

In 1962, Kuipers reported a case series in which the TCA imipramine was used in patients with “nonarticular rheumatism” and in whom 60% to 70% experienced pain relief. Similarly, Scott reported a double-blind trial in patients with rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis in whom imipramine provided significantly more pain relief than placebo did. In both these reports it was postulated that the pain relief produced is secondary to mood elevation rather than an intrinsic analgesic effect of the antidepressant.

It is now recognized that the pain relief apparent with the use of antidepressants can be independent of any alteration in mood caused by the drug, although it has been noted with, for example, doxepin treatment that a reduction in pain is intimately associated with a reduction in depression.

Therefore, the focus of this chapter is on the potential pain-reducing capability of drugs otherwise associated with the treatment of depression. However, pain rarely exists in isolation, and any muscle relaxation, mood enhancement, or improvement in the quality and duration of sleep, all of which are potential effects of antidepressant use, is often a welcome accompaniment of any pain relief that is produced.

The noradrenergic effects of TCAs are thought to be the primary mechanism of action of this drug class, but other indirect actions may also be important. When clomipramine occurs more rapidly (a week or less after initiating TCA therapy), at lower serum blood levels, and at lower doses than those used for antidepressive effects. It is now clear that the TCAs have a number of diverse effects that contribute to their analgesic effect (Table 38.1). The extent to which each individual TCA exerts these effects differs, which may account for differences in the effectiveness and propensity to cause side effects when members of this class of drugs are used. As noted later in this chapter, not all the proposed modes of action of TCAs are the result of central effects, with a number of possible peripheral actions now becoming apparent.

**Serotonergic Effect**

The presence of a descending bulbospinal inhibitory influence on spinal neural activity has been well defined in animal models of antinociception. When 5-hydroxytryptamine (5-HT) antagonists are administered, the antinociceptive effect of TCAs is inhibited. Similarly, when central 5-HT systems are depleted with the use of p-chlorophenylalanine, the antinociceptive effects of TCAs are again reduced. Some tricyclics interfere with serotonin reuptake into nerve terminals. In addition, some TCAs alter binding of serotonin to receptors on neural tissue. Although this evidence exists in the animal literature, the contribution of 5-HT to the antinociceptive effects of TCAs and its role in the anti-hyperalgesic or anti-allodynic properties of TCAs in humans have not been established.

**Noradrenergic Effect**

In a similar fashion to the serotonergic effect of TCAs, the descending bulbospinal noradrenergic inhibitory influence is thought to be important in their analgesic effect. Depletion of central norepinephrine systems with α-methyl p-tyrosine inhibits the antinociceptive actions of TCAs, and α-adrenoreceptor antagonists also have the same effect. Specifically, when phentolamine, a nonspecific α1- and α2-adrenoreceptor antagonist, is administered with a TCA, antinociception is inhibited. However, when the α1-adrenoreceptor antagonist prazosin is coadministered with the TCA amitriptyline in mice, antinociception is observed. Conversely, when amitriptyline is coadministered with the α2-adrenoreceptor antagonist RX821002, antinociception is observed, thus suggesting that TCAs derive at least part of their antinociceptive effect by interacting with α2 adrenoreceptors rather than α1 receptors.

**Opioidergic Effect**

The noradrenergic effects of TCAs are thought to be the primary mechanism of action of this drug class, but other indirect actions may also be important. When clomipramine

---

**CLASSIFICATION OF ANTIDEPRESSANTS**

Antidepressants are currently classified partly on the basis of their chemical structure and partly according to their primary in vivo effects (Box 38.1).

**TRICYCLIC ANTIDEPRESSANTS**

The structures of some TCAs are shown in Figure 38.1.

**ANALGESIC MECHANISM OF ACTION**

In 1987, Max and colleagues demonstrated that TCAs possess analgesic effects independent of their effects on moods. Later, it was found that the analgesic effects of TCAs tend to occur more rapidly (a week or less after initiating TCA therapy), at lower serum blood levels, and at lower doses than those used for antidepressive effects. It is now clear that the TCAs have a number of diverse effects that contribute to their analgesic effect (Table 38.1). The extent to which each individual TCA exerts these effects differs, which may account for differences in the effectiveness and propensity to cause side effects when members of this class of drugs are used. As noted later in this chapter, not all the proposed modes of action of TCAs are the result of central effects, with a number of possible peripheral actions now becoming apparent.

**Serotonergic Effect**

The presence of a descending bulbospinal inhibitory influence on spinal neural activity has been well defined in animal models of antinociception. When 5-hydroxytryptamine (5-HT) antagonists are administered, the antinociceptive effect of TCAs is inhibited. Similarly, when central 5-HT systems are depleted with the use of p-chlorophenylalanine, the antinociceptive effects of TCAs are again reduced. Some tricyclics interfere with serotonin reuptake into nerve terminals. In addition, some TCAs alter binding of serotonin to receptors on neural tissue. Although this evidence exists in the animal literature, the contribution of 5-HT to the antinociceptive effects of TCAs and its role in the anti-hyperalgesic or anti-allodynic properties of TCAs in humans have not been established.

**Noradrenergic Effect**

In a similar fashion to the serotonergic effect of TCAs, the descending bulbospinal noradrenergic inhibitory influence is thought to be important in their analgesic effect. Depletion of central norepinephrine systems with α-methyl p-tyrosine inhibits the antinociceptive actions of TCAs, and α-adrenoreceptor antagonists also have the same effect. Specifically, when phentolamine, a nonspecific α1- and α2-adrenoreceptor antagonist, is administered with a TCA, antinociception is inhibited. However, when the α1-adrenoreceptor antagonist prazosin is coadministered with the TCA amitriptyline in mice, antinociception is observed. Conversely, when amitriptyline is coadministered with the α2-adrenoreceptor antagonist RX821002, antinociception is observed, thus suggesting that TCAs derive at least part of their antinociceptive effect by interacting with α2 adrenoreceptors rather than α1 receptors.

**Opioidergic Effect**

The noradrenergic effects of TCAs are thought to be the primary mechanism of action of this drug class, but other indirect actions may also be important. When clomipramine
is administered to rats in the formalin test, the opioid antagonist naloxone can completely antagonize the antinociceptive effect of that TCA.\(^20\) Similarly, administration of the delta (\(\delta\))-opioid antagonist naltrindole with antidepressants shifts the antinociceptive dose-response curves to the right, thus suggesting inhibition of the antinociceptive effects of TCAs, whereas administration of the enkephalin catabolism inhibitor acetorphan with the antidepressants dothiepin, amitriptyline, or sibutramine enhances their antinociceptive effects.\(^21\) Chronic antidepressant administration can modify opioid receptor densities\(^22\) and increase opioid levels in certain brain regions.\(^23,24\) The alterations seen with opioid receptor antagonists may represent a direct action of TCAs on opioid receptors; however, this is unlikely given the lack of TCA affinity in opioid receptor binding assays.

### N-Methyl-d-Aspartate Receptor Effect

Reynolds and Miller observed that desmethylimipramine and imipramine both prevent the Ca\(^{2+}\) influx into cultured cortical neurons of the rat produced by N-methyl-d-aspartate (NMDA). They also noted that other TCAs had a similar but less intense effect.\(^25\) Others have observed that antidepressants bind to the NMDA receptor complex,\(^25,26\) and that chronic administration of antidepressants alters NMDA binding characteristics.\(^27\) There is considerable debate on the importance of an NMDA effect in regard to the analgesic effect of antidepressants.\(^28\)

### Adenosine Receptor Effect

Adenosine is known to produce analgesia,\(^29\) and antidepressants inhibit the uptake of adenosine in neuronal preparations.\(^30\) The antinociceptive effect of antidepressants is inhibited by adenosine receptor antagonists.\(^31\)-\(^33\) Adenosine receptors have both peripheral and central representation (see later discussion).

### Sodium Channel Effect

Sodium channel blockade may contribute to the analgesic efficacy of antidepressants.\(^34\) Amitriptyline appears to be the most potent TCA in its ability to block sodium channels, with doxepin and imipramine following (all were superior to bupivacaine) and then desipramine (less effective than bupivacaine), and nortriptyline was one of the least effective TCAs in blocking sodium channels.\(^35\) Sudoh and associates concluded that N-methyl doxepin is a potent Na\(^+\) channel blocker and a long-acting local anesthetic for rat sciatic nerve blockade.\(^36\)

Although amitriptyline is more potent than bupivacaine in a subcutaneous infiltration model\(^37\) and in an intrathecal administration model in rats and sheep,\(^38,39\) when amitriptyline was evaluated for ulnar nerve blockade in healthy human volunteers, it was found to be less effective than bupivacaine, contrary to the results of a large number of animal studies.\(^39\) This may be due to the thicker nerve sheaths present in humans than in rats, which presents more of a barrier for amitriptyline to penetrate into the nerve.\(^39,40\) Local anesthetics and TCAs both bind more tightly to the inactivated state of the sodium channel.\(^41\)

Thus, neural blockade with amitriptyline (like local anesthetics) is use dependent.\(^42\)

Potency is extremely difficult to assess because of differences in agents, different routes of administration, different...
environments, different species, different sodium channels, and different measurements.

Rats differ from sheep and humans, topical administration differs from intrathecal and perineural application, and motor function differs from proprioception and nociception. However, in an effort to present a very rough idea of local anesthetic potency, N-phenylethyl amitriptyline is about 50 times as potent as lidocaine, amitriptyline is about 8 times as potent as lidocaine, and bupivacaine is about 4 times as potent as lidocaine. However, N-phenylethyl amitriptyline appears to have a narrow therapeutic index. 43 N-Methyl amitriptyline is similar to amitriptyline but has a much longer duration of action. 38 Furthermore, N-methyl amitriptyline appears to exhibit significant differential blockade (i.e., selective block of a specific [pain-transmitting] nerve fiber group), greater than that achieved with amitriptyline, bupivacaine, and lidocaine in sheep. 38

Figure 38.1 Tricyclic antidepressants.
Since amitriptyline blocks persistently open sodium channels at low plasma concentrations, because of its significantly longer half-life, it may have utility in the perioperative period. Lidocaine has been demonstrated to be effective for chronic neuropathic pain states and has also been shown to diminish acute postoperative pain, as well as facilitate return of normal bowel function; preclinical evidence also seems to support this notion. Amitriptyline demonstrates antinociceptive effects in experimental mouse models of pain states. Additionally, amitriptyline in combination with morphine had better analgesic effects than did morphine alone.

**Calcium Channel Effect**
Although acute treatment with an antidepressant has no observable effect on calcium channels, chronic treatment with citalopram and chlorprothixene (but not imipramine) increases the density of L-type calcium channels. It also has an antinociceptive effect, with this effect being nullified by administration of nifedipine.

**Other Effects**
Antidepressants also interact with histaminergic, cholinergic muscarinic, and cholinergic nicotinic receptors in an inhibitory manner. However, individual antidepressant agents may differ markedly in their potency at different receptors. These interactions may contribute to the side effects of the antidepressants (e.g., dry mouth, sedation, urinary retention). These important side effects are discussed in the following sections.

**ANIMAL STUDIES OF ANTINOCICEPTIVE EFFECTS**
Because of the many proposed pharmacologic effects of TCAs, one would expect them to have an antinociceptive effect. A number of studies have confirmed that this class of antidepressants does have this property. For example, Abdel-Salam and colleagues have shown that antidepressants, including those in the TCA class, display antinociceptive properties in a rat tail electrical stimulation assay, and others have shown that chronic administration decreases self-mutilation in the rat autotomy test produces an antinociceptive effect in the formalin test, and has similar action in a hot plate test.

Ardid and Guilbaud confirmed that both acute and chronic administration of TCAs (e.g., clomipramine, amitriptyline, desipramine) has an antinociceptive effect in a rat mononeuropathy model. This effect on neuropathic pain has been substantiated in other studies.

Some of the TCAs also seem to possess anti-inflammatory effects. For example, when imipramine is administered on a chronic basis to rats that are then exposed to carrageenan, which induces intense inflammation, the local inflammatory response normally observed is significantly reduced. Similarly, clomipramine reduces carrageenan-induced skin inflammation in a dose-dependent fashion, as well as decreases the prostaglandin E2-like biologic and immunologic activity and substance P concentration in the inflammatory exudate. When both amitriptyline and imipramine are administered on a chronic basis to rats with adjuvant-induced arthritis, behavioral tests suggest that they both induce antinociception.

**HUMAN EXPERIMENTAL PAIN**
Even with a single 100-mg dose of imipramine, verbal pain ratings and the amplitude of somatosensory evoked cerebral potentials in response to suprathreshold intradermal electrical stimuli are reduced significantly, more than in subjects taking placebo. Similarly, a single oral dose of desipramine has been shown to increase subjective pain thresholds and the nociceptive withdrawal reflex threshold in response to percutaneous electrical stimulation of the sural nerve. Poulsen and associates examined the effect of a single oral dose of 100 mg of imipramine on pain detection and tolerance thresholds to heat and pressure, thresholds of the quadriceps femoris muscle withdrawal reflex to single and repeated electrical stimulation of the sural nerve, and continuous pain ratings during the cold pressor test in 12 healthy volunteers. They found that imipramine significantly increases pain thresholds to heat and pressure, as well as the pain tolerance threshold and reflex threshold to single electrical stimulation. Pain ratings during the cold pressor test and pain detection thresholds in response to heat and pressure were unaltered. These studies have suggested that TCAs can have a differential hypoalgesic effect in different human experimental pain tests.

**TRICYCLIC ANTIDEPRESSANTS IN CLINICAL PAIN MANAGEMENT**
Historically, TCAs were used for human pain management before their modes of action as analgesics were elucidated. The fact that they can reduce pain and independently elevate mood, as well as normalize sleep patterns and cause muscle relaxation, is an additional potential benefit of their use. In no human field of use is the evidence for an analgesic effect of TCAs greater than in neuropathic pain conditions. A significant body of evidence underpins the use of TCAs for a number of specific neuropathic pain conditions, and because the features of neuropathic pain are not dependent on the causal disease or neural irritation, it is widely accepted that the evidence for analgesia in specific conditions is strong enough to allow uniform use for any condition manifesting the symptoms of neuropathic pain.

**Post-herpetic Neuralgia**
A prototypical neuropathic pain condition involving neural irritation and destruction makes post-herpetic neuralgia (PHN) a particularly difficult condition to treat. With established PHN, palliation rather than cure is the only prospect. Perhaps in no other condition have TCAs made such an impact. Evidence has suggested that amitriptyline, nortriptyline, and desipramine are among the TCAs that can usefully alleviate the suffering associated with PHN. As an example of potential efficacy, Watson and coworkers reported “good to excellent” pain relief in 16 of 24 patients studied. Watson and Max and coauthors reported that 47% of 58 patients studied in their randomized controlled trial obtained “moderate or greater” pain relief with amitriptyline. Interestingly, in a study comparing amitriptyline with the tetracyclic antidepressant maprotiline (which has a predominantly noradrenergic effect), Watson and associates noted that “amitriptyline relieves some patients with postherpetic neuralgia. Many patients suffer side effects and better therapies are necessary.” Incidentally, the pain relief produced by amitriptyline was greater than that apparent after maprotiline.
Watson and coworkers\textsuperscript{67} compared the effect of nortriptyline and amitriptyline and found both to have an analgesic effect but that nortriptyline was associated with fewer side effects. Kishore-Kumar and colleagues\textsuperscript{68} examined the effect of desipramine on PHN and confirmed an analgesic effect. They stated that “other antidepressants—notably amitriptyline—are known to ameliorate postherpetic neuralgia, but these agents are often toxic.” Almost 2 decades after this study, amitriptyline is still considered a frontline agent and arguably the preferential first therapeutic agent for the treatment of PHN.

**Painful Diabetic Neuropathy**

Again, strong evidence exists for pain relief with TCAs in patients with painful diabetic neuropathy (PDN). Amitriptyline,\textsuperscript{3,69} desipramine,\textsuperscript{69-71} clomipramine,\textsuperscript{71} imipramine,\textsuperscript{72-74} and nortriptyline\textsuperscript{75} have all been shown to have an analgesic effect in patients with PDN.

In terms of comparative efficacy, Max and associates\textsuperscript{69} found that desipramine and amitriptyline are equally efficacious, whereas Sindrup and coworkers\textsuperscript{71} found that clomipramine tends to produce better pain relief than desipramine does. When the dose-response relationship is considered, Sindrup and colleagues\textsuperscript{74} found that imipramine is associated with such a relationship. Although a dose-response relationship is also noted when clomipramine is used, this does not seem to be the case with desipramine.\textsuperscript{71}

**Painful Mononeuropathy and Polyneuropathy**

Some evidence exists for an analgesic effect of clomipramine in the treatment of painful mononeuropathy and polyneuropathy pain. Langohr and associates\textsuperscript{76} compared treatment with clomipramine and acetylsalicylic acid in a blinded crossover study and were able to show a greater analgesic effect during the clomipramine treatment phase.

**Pain Associated with Spinal Cord Injury**

Not all studies examining the effect of TCAs on neuropathic pain have produced a positive result. Cardenas and coworkers\textsuperscript{77} studied 84 patients with pain from a spinal cord injury (SCI) who were randomized to receive amitriptyline or an active placebo, benztrapine mesylate. No significant differences in measured pain parameters were found between the treatment groups or when comparing pretreatment and treatment periods. This evidence is in contrast to that presented by others who have suggested a beneficial effect of TCAs on SCI pain, although their evidence is based on case reports rather than blinded, placebo-controlled trials.\textsuperscript{78,79} In contrast to the negative response in studies of SCI pain, Leijn and Boivie\textsuperscript{80} reported a useful analgesic effect when amitriptyline is used in patients with central post-stroke pain.

**Fibromyalgia**

Although the use of TCAs in patients with FM is widespread, consideration of the evidence supporting their use is difficult, largely because FM is a complex disorder with a spectrum of symptoms and signs. From a broad perspective, there can be little doubt that antidepressants do improve the symptoms of FM in some patients.\textsuperscript{81} O’Malley and colleagues\textsuperscript{82} undertook a meta-analysis of studies that examined the effect of antidepressants in patients with FM. They calculated that the odds ratio for improvement with antidepressant therapy was 4.2 (95% confidence interval, 2.6 to 6.8). They concluded that antidepressant therapy has a positive effect on sleep, fatigue, pain, and well-being, but not on trigger points. They also found that in only one of the five studies that measured depression scores was there a correlation between improvement in symptoms and depression scores.\textsuperscript{81} When TCAs are specifically considered, Arnold and associates\textsuperscript{83} concluded from their meta-analysis that TCAs produce the largest improvement in sleep quality, with modest improvement found in measures of stiffness and tenderness.

In terms of the number of patients who can improve with antidepressant treatment, Carette and coworkers\textsuperscript{84} found that after 1 month of treatment of FM, 21% were improved (as opposed to 0% with placebo) and that after 6 months of treatment, the proportion had increased to 36% and 19%, respectively.

**Osteoarthritis**

Historically, an analgesic effect of TCAs was first noted in patients with joint pain.\textsuperscript{1} Limited evidence has suggested that TCAs can reduce joint pain caused by osteoarthritis.\textsuperscript{59}

**Low Back Pain**

Although a diagnosis of low back pain is extremely wide and nonspecific and encompasses a wide range of different problems, it does represent a significant clinical problem for many practitioners. A single report of a randomized, controlled trial involving the use of doxepin in patients with low back pain suggested that it can reduce pain and decrease indices of depression.\textsuperscript{85}

**Cancer-Related Neuropathic Pain**

TCAs seem to exert an analgesic effect on a range of painful conditions, but Mercadante and colleagues\textsuperscript{86} reported that amitriptyline failed to produce any pain relief in 16 patients with advanced cancer who had features of neuropathic pain. However, their study numbers were small, the neuropathic pain may not have been present in isolation given the diagnosis of cancer, and any neuropathic pain arising in association with cancer could have been emanating from a diverse number of neural structures irritated by tumor deposits.

**Human Immunodeficiency Virus-Related Sensory Neuropathy**

TCAs do not seem to be effective in relieving this condition.\textsuperscript{87}

**COMPARATIVE STUDIES**

Morello and associates\textsuperscript{88} studied 28 patients with PDN in a crossover study comparing the effect of amitriptyline and gabapentin. They found that the pain relief produced by the TCA is of similar magnitude and quality to that obtained with gabapentin.

**OVERALL EFFECTIVENESS**

One way of displaying the potential efficacy of any agent is to consider the number needed to treat (NNT; Table 38.2). In terms of analgesic medication, this represents the number of patients who need to take the treatment to obtain a 50% or greater reduction in their pain.
CHAPTER 38 — ANTIDEPRESSANTS AS ANALGESICS

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

TCAs have analgesic potential for various pain conditions and a diverse range of pharmacologic actions, but these actions can also increase their propensity to cause side effects. It was hoped that with the advent of antidepressants with more specific modes of action, analgesia would still be associated with their use and the potential to produce side effects would be reduced.

When the antinociceptive effect of selective serotonin reuptake inhibitors (SSRIs; Fig. 38.2) were examined in a mouse hot plate pain test, fluvoxamine induced a dose-dependent antinociceptive effect, whereas fluoxetine and citalopram induced only a weak antinociceptive effect.89 Escitalopram failed to elicit any antinociceptive effect. The antinociceptive effect of these three SSRIs was not blocked by the opioid antagonist naloxone. In contrast, again using a mouse hot plate test, paroxetine produced an antinociceptive effect that was inhibited by naloxone, thus suggesting that this SSRI may act not only via its serotonergic effect but also via an interaction with the opioidergic system.90 In the same study, paroxetine-induced antinociception was inhibited by the 5-HT3 antagonist ondansetron, but not by the 5-HT2 receptor antagonist ketanserin.

Figure 38.2 Selective serotonin reuptake inhibitors.
When considering the overall results from studies, it has been calculated that the NNT for one patient to obtain a 50% reduction in pain is 5 for paroxetine and 15.3 for fluoxetine. This leads to the conclusion that evidence for a 50% reduction in pain is 5 for paroxetine and 15.3 for fluoxetine.91 This makes intuitive sense since at higher doses most SSRI agents will inhibit the reuptake of norepinephrine and serotonin somewhat. Nakajima and coworkers presented data suggesting that an increase in norepinephrine in the spinal cord plays an important role in the anti-hyperalgesic effects of not only norepinephrine reuptake inhibitors but also SSRIs.99

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND HUMAN PAIN

Painful Diabetic Neuropathy
A number of studies have examined the effect of SSRIs on PDN. Sindrup and colleagues compared the effects of paroxetine and imipramine. Paroxetine did produce pain relief, but less than that obtained with imipramine. On the other hand, use of paroxetine was associated with fewer side effects than occur with imipramine. Max and associates compared the effect of amitriptyline, desipramine, fluoxetine, and placebo in patients with PDN. When subjects were considered in terms of the percentage of those who derived moderate or greater pain relief, the results were 74% in those receiving amitriptyline and 61%, 48%, and 41%, respectively, in those receiving desipramine, fluoxetine, and placebo. Citalopram has also been studied and found to be relatively effective with few side effects.95

Fibromyalgia
A number of studies have suggested that SSRIs have little effect on FM pain. In one, Norregaard and associates studied 22 patients with FM and compared the effect of citalopram with that of placebo. After 8 weeks of treatment (4 weeks taking placebo, 4 weeks taking citalopram), no changes were observed in any pain parameter measured, nor in depression scores. Similarly, Anderberg and coworkers95 found no difference with citalopram treatment when the results were analyzed on an intent-to-treat basis, but there were reductions in pain and well-being scores in those completing the study.

Although in general the analgesic effects of SSRI are limited and inconsistent, when higher doses are used, the analgesic effects may be somewhat better. Arnold and colleagues showed that patients with FM who received fluoxetine at doses of 45 mg/day or higher had a significant improvement in the Fibromyalgia Impact Questionnaire (FIQ) total score, as well as in FIQ pain, fatigue, and depression scores.98 This makes intuitive sense since at higher doses most SSRI agents will inhibit the reuptake of norepinephrine somewhat. Nakajima and coworkers presented data suggesting that an increase in norepinephrine in the spinal cord plays an important role in the anti-hyperalgesic effects of not only norepinephrine reuptake inhibitors but also SSRIs.99

SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS

Serotonin-norepinephrine reuptake inhibitors (SNRIs; Fig. 38.3) selectively block the reuptake of norepinephrine and serotonin (5-HT). Milnacipran blocks 5-HT and norepinephrine reuptake with equal affinity, whereas duloxetine has a 10-fold selectivity for 5-HT and venlafaxine a 30-fold selectivity for 5-HT.100

ANIMAL PAIN STUDIES

The probable effects of drugs in humans can often be predicted by testing them on specific animal pain models. However, there may be species differences in response; in human clinical practice, mixed pain states are common, whereas animal models are based on specific pain types.

When formalin is applied to animal paws, a two-stage response is observed that can be measured electrophysiologically or by behavioral observation. Both duloxetine (an SNRI) and citalopram (an SSRI) attenuate the second phase of the formalin response.101 When compared with venlafaxine and milnacipran, duloxetine attenuates the second phase of this test more significantly.102

In the tail flick test (a test of acute nociception), duloxetine has minimal effect, whereas in the hot plate test, some antinociceptive response with duloxetine is observed.101,103 In the chronic nerve constriction injury model of neuropathic pain, venlafaxine and duloxetine have both a significant antinociceptive effect.

CLINICAL PAIN MANAGEMENT

Duloxetine is the first antidepressant to have a specific pain indication in the United States—treatment of PDN.105 SNRIs may also be useful for other conditions.

Duloxetine and venlafaxine are antidepressants with both serotonergic and noradrenergic reuptake–inhibiting properties (SNRIs). In the treatment of PDN, duloxetine has been demonstrated to be more efficacious than placebo at doses of 60 and 120 mg/day, although the higher dose appears to be associated with similar efficacy but greater side effects. The side effect profile of duloxetine seems to be more favorable than that of TCAs, especially with respect to anticholinergic and cardiac side effects. Nausea is one of the more common side effects but can be reduced by lowering the dose. In many patients, nausea is self-limited and resolves within the first several weeks of use. Duloxetine has been extensively studied in patients with PDN, FM, musculoskeletal back pain, and osteoarthritis and has been approved by the Food and Drug Administration (FDA) for all four indications. Venlafaxine has been effective in the treatment of PDN and other polyneuropathies except for PHN. A small subset of patients demonstrated abnormalities in cardiac conduction; thus, precautions should be taken in patients with a history of cardiac disease. Venlafaxine should be tapered rather than abruptly discontinued because of the potential for a withdrawal syndrome. At doses lower than 150 mg/day, venlafaxine behaves more like an SSRI; at doses above 150 mg, it behaves more like an SNRI agent. Therefore, pain relief is more likely to occur with doses of 150 mg/day or greater. This point should be taken into consideration when prescribing this medication for analgesic purposes. Venlafaxine is not currently approved by the FDA for any pain indication.

Milnacipran is the SNRI (also referred to as an NSRI) with the most balanced activity on inhibition of norepinephrine and 5-HT reuptake. Milnacipran and its metabolites are eliminated primarily by renal excretion, with approximately 55% of milnacipran excreted unchanged in urine, 19% as a carbamoyl-O-glucuronide conjugate, 8% as N-desethyl milnacipran, and the remainder of the administered dose as other minor metabolites, all of which are inactive.106
Desvenlafaxine, or O-desmethylvenlafaxine, is the major active metabolite of the SNRI venlafaxine.\textsuperscript{107,108} Like venlafaxine, desvenlafaxine selectively inhibits neuronal uptake of serotonin and norepinephrine and has little affinity for muscarinic, cholinergic, histaminergic H\textsubscript{1}, and \(\alpha\textsubscript{1}\)-adrenergic receptors.\textsuperscript{109} Desvenlafaxine has been shown to be active in preclinical in vitro and in vivo models used to predict antidepressant efficacy\textsuperscript{110}; however, there are no robust trials of desvenlafaxine for pain relief. Desvenlafaxine succinate is well absorbed following oral administration, with a mean terminal-phase elimination half-life of approximately 9 to 11 hours.\textsuperscript{111}

Few published data are available regarding milnacipran, which has been approved by the FDA in the United States only for FM. In a small randomized study, patients treated with milnacipran were shown to have a greater reduction in pain than were placebo-treated patients with FM.\textsuperscript{112,113} In a published case report, milnacipran was reported to successfully manage trigeminal neuralgia in a 64-year-old patient.\textsuperscript{114} The SNRIs have differing activity in both the serotonergic and noradrenergic systems.\textsuperscript{115,116} Table 38.3 compares effects on the serotonergic system relative to the noradrenergic system for multiple SNRIs.

### Painful Diabetic Neuropathy

It is well established that duloxetine reduces the pain associated with diabetic neuropathy.\textsuperscript{117-119} Bearing in mind the

5-HT, serotonin; NE, norepinephrine.
relatively high risk for side effects when TCAs are used for the treatment of PDN, dropout rates from studies are as low as 12% with the use of duloxetine, and long-term studies examining the use of this drug for up to 52 weeks have shown that it has a favorable safety profile when taken over this prolonged period. Duloxetine treatment has been associated with modest adverse changes in glycemia in patients with diabetic peripheral neuropathic pain, but this does not have an effect on the significant improvement in pain observed with duloxetine treatment.

Fibromyalgia

Traditionally, TCAs have been used for the treatment of FM. However, their side effect profiles often reduce compliance. Conversely, the SSRIs have a more acceptable side effect profile but are relatively ineffective. The SNRIs, however, combine a relatively low risk for side effects with a relatively high chance of alleviating symptoms.

In a number of large studies, duloxetine has been found to be efficacious, not only in terms of pain reduction but also for many of the other problematic complaints associated with this condition. For example, in a study of 207 subjects, Arnold and colleagues found that duloxetine significantly reduces pain, number of tender points, and stiffness scores while significantly increasing the tender point pain threshold when compared with placebo. Furthermore, measures of quality of life were improved by active treatment. In an even larger study of 354 patients with FM, Arnold and associates confirmed their previous findings and also showed that the beneficial effects of duloxetine therapy are independent of its effect on mood.

These positive effects with duloxetine therapy seem to be reproduced by other SNRIs, with milnacipran and venlafaxine also having been shown to have a positive effect. In Vitton and coworkers' study of the use of milnacipran in subjects with FM, of the 125 enrolled in the study, 37% reported at least a 50% reduction in pain intensity (as opposed to 14% in the placebo group).

NOREPINEPHRINE REUPTAKE INHIBITORS

Reboxetine is a selective norepinephrine reuptake inhibitor (NRI; also known as NARI). Reboxetine has little or no affinity for serotonin and dopamine uptake sites or for muscarinic and histaminergic receptors and is no less effective for depression than the TCAs and SSRIs. Limited clinical data point to reboxetine being a poorly effective stand-alone analgesic.

TETRACYCLIC ANTIDEPRESSANTS

Limited evidence for an analgesic effect of tetracyclic antidepressants (Fig. 38.4) exists. When amitriptyline is compared with the tetracyclic antidepressant maprotiline in patients with PHN, even though maprotiline displays analgesic properties, those of amitriptyline are more pronounced. In animal nociceptive models, mirtazapine exhibits antinociceptive properties with evidence of an antinociceptive effect in the hot plate chronic nerve constriction model of neuropathic pain and in the second phase of the formalin response.

MONOAMINE OXIDASE INHIBITORS

Renowned for their multiple side effects, drug interactions, and necessity for a tyramine-free diet when used, monoamine oxidase inhibitors (Fig. 38.5) have no place in pain management. Little evidence exists for any analgesic effect.
DOPAMINE REUPTAKE INHIBITORS

Though classified as a dopamine reuptake inhibitor (Fig. 38.6), bupropion also has noradrenergic activity. Evidence of an analgesic effect is limited, although Semenchuk and colleagues\textsuperscript{130} found that 73\% of subjects with neuropathic pain studied in their placebo-controlled trial obtained pain relief with bupropion treatment.

ANTIDEPRESSANTS: SAFETY AND SIDE EFFECTS

The safety of antidepressants can be considered both from the perspective of normal use and in overdose. Buckley and McManus\textsuperscript{151} provided an interesting insight into the potential dangers of antidepressants when taken in overdose.
They calculated the number of deaths per million prescriptions (Table 38.4).

The implications for use of these drugs are obvious. Careful consideration needs to be given to the use of desipramine if there is any danger that the drug may be taken in overdose. The data in the study cited\textsuperscript{131} are from the United Kingdom, but a similar picture is likely elsewhere. In one study in Virginia, TCAs were found to be the most common antidepressants used in suicide attempts.\textsuperscript{132}

In terms of overall comparative tolerability, one would expect that the newer antidepressants would be tolerated better than the TCAs. In a meta-analysis reviewing the tolerability of TCAs and SSRIs (when used for the treatment of depression), Arroll and coworkers\textsuperscript{133} found that the number needed to harm—in this case the number of subjects receiving the treatment—for one subject to need to drop out because of side effects was calculated to be 5 to 11 for TCAs and 21 to 94 for SSRIs. In sharp contrast, Wilson and Mottram\textsuperscript{134} studied the use of antidepressants in older depressed patients and concluded that “…TCA-related drugs are comparable to SSRIs in terms of tolerability,” but they did note that the use of TCAs is associated with an increased risk for dry mouth, drowsiness, dizziness, and lethargy when compared with SSRIs.

Among the SSRIs, it seems that fluoxetine has a greater chance of causing adverse gastrointestinal effects than do other SSRIs.\textsuperscript{135}

**EFFECT OF ANTIDEPRESSANTS ON WEIGHT**

Weight gain is common with antidepressants. When they are used for the treatment of depression, mood alteration may have an effect on appetite and well-being. TCAs are more likely than SSRIs to cause weight gain (which may interfere with compliance).\textsuperscript{136}

**CHOLINERGIC-TYPE SIDE EFFECTS**

Cholinergic-type side effects, including dry mouth, sedation, and urinary retention, may also complicate TCA use.

**RISK FOR FALLS**

In a study of U.S. veterans, French and colleagues\textsuperscript{137} showed that of 2212 patients with hip fractures, 70% had taken medication before the fracture, which may have contributed to their fall. Patients were twice as likely to have taken a TCA or SSRI as a matched control.

**USE OF ANTIDEPRESSANTS IN PREGNANCY**

Concern always exists when medication is taken during pregnancy. It seems that neither TCA nor SSRI use during pregnancy is associated with an increased risk for major fetal malformation, but poor neonatal adaptation has been reported.\textsuperscript{138}

**AUTOMOBILE DRIVING**

Use of any potentially sedative medication leads to concern about its use while driving. Ramaekers\textsuperscript{139} concluded that after acute dosing of sedating antidepressants (e.g., amitriptyline, imipramine, doxepin, mianserin), a measure of driving ability gave results comparable to those of individuals whose blood alcohol concentration was 0.8 mg/mL. When treatment was continued for 1 week, driving performance returned to that of the placebo group, except for those taking mianserin, in whom the driving impairment continued. It was also noted that concomitant use of a benzodiazepine with an antidepressant makes driving impairment significant. When SSRIs are considered, no impairment in driving ability has been noted.\textsuperscript{140} Consequently, when a TCA is given, the patient should be warned to avoid driving until stabilization with a fixed dose of the TCA has occurred. Also, the patient should be warned of the potential for driving ability to be influenced over the longer term when the TCA is taken with other sedative medication.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

De Jong and colleagues\textsuperscript{141} studied 15,445 new users of antidepressants with or without use of nonsteroidal anti-inflammatory drugs (NSAIDs). They counted the number of first prescriptions of peptic ulcer drugs, with or without an NSAID, from day 2 after starting until 10 days after commencement of an antidepressant. In the 691 individuals given TCAs who were not taking NSAIDs, the incidence of...
peptic ulcer drug request was 0.051. In the SSRI-only group (1181 subjects), the incidence was 1.2. When an SSRI was taken with an NSAID (86 subjects), the incidence of peptic ulcer drug request was 12.4% as opposed to 2.5% in the TCA-NSAID cohort. This would suggest that some caution needs to be taken when SSRIs are given to patients taking NSAIDs.

PARADOXICAL PAIN

We have seen that strong evidence exists for a useful analgesic effect of TCAs. However, two studies have provided interesting and thought-provoking insight into the possibility that perhaps TCAs can produce pain symptoms as well as relieve them. In the first study, Esser and Sawynok55 studied rats with a chronic constriction injury involving the lumbar nerve roots that produced features of neuropathic pain. When amitriptyline was administered systemically, thermal hyperalgesia was completely reversed in the injured paw. It also produced an anti-hyperalgesic effect on that side but had no effect on mechanical allodynia. However and of more importance, systemic administration of amitriptyline produced hyperesthesia on the contralateral (uninjured) side. In the second study, Esser and coworkers56 again looked at a rat neuropathic pain model and found that amitriptyline reduced thermal hyperalgesia on the injured side but had no effect on allodynia. They again noted contralateral hyperesthesia with the use of amitriptyline. The significance of these results for human use of TCAs is not known but warrants investigation.

POSSIBLE ANALGESIC EFFECT WHEN APPLIED TOPICALLY

PERIPHERAL MODE OF ACTION

Thus far discussion has revolved around the use of antidepressants by the oral route of administration. Unfortunately, such systemic use also produces systemic side effects, which particularly with the TCAs, may reduce patient compliance.

Earlier we reviewed the potential modes of action of TCAs when given as oral analgesics, including effects on the serotonergic and noradrenergic pathways, on sodium and potassium channels, and on adenosine, NMDA, and opioid receptors. Not all these potential pharmacologic targets, however, have exclusively central representation.

ADENOSINE RECEPTORS

At peripheral nerve terminals in rodents, adenosine \( \alpha_1 \) receptor activation produces antinociception by decreasing cyclic adenosine monophosphate (cAMP) levels, whereas adenosine \( \alpha_2 \) receptor activation produces pronociception by increasing cAMP levels in the sensory nerve terminals. Adenosine \( \alpha_2 \) receptor activation produces pain behavior as a result of the release of histamine and 5-HT from mast cells and subsequent actions on the sensory nerve terminal.142 Caffeine acts as a nonspecific adenosine receptor antagonist. When caffeine and amitriptyline are administered systemically, the normal effect on thermal hyperalgesia is blocked. When amitriptyline is administered into a neuropathic pain site, an anti-hyperalgesic effect is recorded, but not when it is administered into the contralateral paw. This anti-hyperalgesic effect is blocked by caffeine,143 thus suggesting that at least part of the effect of peripherally applied amitriptyline is mediated through peripheral adenosine receptors.

SODIUM CHANNELS

Sudoh and colleagues144 administered various TCAs by a single injection into rat sciatic notches. They measured the duration of complete sciatic nerve blockade and compared it with the duration provided by bupivacaine. They found that amitriptyline, doxepin, and imipramine produce a longer complete sciatic nerve block than bupivacaine does whereas trimipramine and desipramine produce a shorter block. Nortriptyline and maprotiline failed to produce any block. When the effect of topical application of amitriptyline was compared with that of lidocaine, amitriptyline was found to produce longer cutaneous analgesia than lidocaine did.144 These studies therefore suggest that from a mode-of-action perspective, TCAs could well have an analgesic effect when applied peripherally.

ANIMAL EVIDENCE OF ANTINOCEPTIVE EFFECTS

Neuropathic Pain

When amitriptyline is applied to rodent paws made neuropathic by a chronic nerve constriction injury, an antinociceptive effect is observed. When amitriptyline is applied to the contralateral paw, no antinociceptive effect is observed in the paw on the injured side.55,56,143 When desipramine and the SSRI fluoxetine are considered, desipramine has a similar antinociceptive effect when applied topically, whereas fluoxetine does not.145

Formalin Test

It seems that when amitriptyline146,147 and desipramine145 are coadministered peripherally with formalin, both the first- and second-phase responses are reduced. When amitriptyline is administered peripherally along with formalin, Fos immunoreactivity in the dorsal region of the spinal cord is significantly lower than in animals in which formalin is administered alone.148

Visceral Pain

Using a noxious colorectal distention model in the rat, Su and Gebhart149 have shown that the antidepressants imipramine, desipramine, and clomipramine reduce the response to noxious colorectal distention by 20%, 22%, and 46%, respectively, when compared with control-treated animals.

Thermal Injury

Thermal hyperalgesia is produced by exposing a rodent hindpaw to 52° C for 45 seconds. Locally applied amitriptyline at the time of thermal injury produces anti-hyperalgesic and analgesic effects, depending on the concentration used. When amitriptyline is applied after the injury, the analgesic but not the anti-hyperalgesic effect is retained.150

HUMAN PAIN

Human evidence of an analgesic effect with the topical application of TCAs is limited. A small randomized, placebo-controlled trial (RCT) of 40 subjects with neuropathic pain of mixed cause showed a reduction of 1.18 on a 0 to 10 linear visual analog scale (LVAS) score relative to placebo use with the application of 5% doxepin cream. Minor side effects were seen in only three subjects.151 A larger RCT involving 200 subjects, again with neuropathic pain of mixed cause, suggested that 5% doxepin cream reduces LVAS scores by approximately one relative to placebo and that time until effect is about
2 weeks. Again, side effects were minor and infrequent.\textsuperscript{152} A pilot study examining the effect of topical amitriptyline application failed to produce any pain relief, but the maximum duration of therapy was 7 days,\textsuperscript{153} and therefore the study may have been terminated before the time to maximal effect had been reached. Case studies of a useful reduction in pain may have been terminated before the time to maximal effect duration of therapy was 7 days,\textsuperscript{153} and therefore the study failed to produce any pain relief, but the maximum pilot study examining the effect of topical amitriptyline application is needed to verify this and other effects of TCAs when administered by this method. The evidence would suggest that topically applied doxepin has a local effect and that the consequences of systemic administration and systemic side effects can be substantially reduced.

**CONCLUSION**

There is compelling evidence of an antinociceptive effect when TCAs are used in animal pain models. This is substantiated by the recognition that TCAs have a number of effects that could account for their antinociceptive properties, including serotonergic and noradrenergic effects; actions on opioid, NMDA, and adenosine receptors; and actions on sodium and potassium channels. The results of animal studies, a large number of human clinical studies, and extensive and long-term use of TCAs in clinical practice suggest that these agents have a pain-reducing potential for various pain conditions, including neuropathic pain and pain associated with FM.

The analgesic effect seen when TCAs are used is present only to a slight degree with SSRIs, although their side effect potential is substantially less. The more recently introduced SNRIs appear to have a more favorable side effect profile than the TCAs do, along with many of their analgesic effects. It could be argued, therefore, that SNRIs should be the first choice when an antidepressant is chosen to treat pain and that TCAs should be reserved for use when there is therapeutic failure with an SNRI.

The potential for a peripheral mode of action of TCAs may allow them to be used as topical analgesics, with the reassurance that at least some of their effects are local. Thus, it is possible that systemic side effects can be avoided.

**KEY POINTS—cont’d**

- Antidepressants interact with histaminergic, cholinergic muscarinic, and cholinergic nicotinic receptors in an inhibitory manner. These interactions contribute to the side effects of the antidepressants.
- TCAs are effective in patients with post-herpetic neuralgia and painful diabetic neuropathy; nortriptyline and amitriptyline are equally effective, with nortriptyline having fewer side effects.
- Evidence supporting the use of TCAs for fibromyalgia is difficult because the disease is a complex disorder with a spectrum of symptoms and signs. However, antidepressants seem to improve the symptoms of fibromyalgia in some patients.
- The side effect profiles of TCAs often reduce compliance, whereas the selective serotonin reuptake inhibitors (SSRIs) have a more acceptable side effect profile but are relatively ineffective. The serotonin-norepinephrine reuptake inhibitors (SNRIs) combine a relatively low risk for side effects with a relatively high chance of alleviating symptoms.
- At doses of less than 150 mg/day, venlafaxine behaves more like an SSRI; at doses above 150 mg, it behaves more like an SNRI. It should gradually be discontinued because of the potential for a withdrawal syndrome.
- Neither TCA nor SSRI use during pregnancy is associated with an increased risk for major fetal malformation, but poor neonatal adaptation has been reported.
- No impairment in driving ability has been noted with SSRIs. For TCAs, the patient should be warned to avoid driving until stabilization with a fixed dose of the TCA has occurred. They should also be warned when the TCA is taken with other sedative medications.

Membrane Stabilizers for the Treatment of Pain

Robert W. Hurley | Brian E. McGeeney | Charles E. Argoff

Multimodal medical management of cancer- and non–cancer-related pain can involve the use of nonopioid medications, as well as opioid medications. Nonopioid medications, often referred to as adjuvant medications, can take the form of amine reuptake inhibitors, such as the tricyclic antidepressants (TCAs); neuronal membrane stabilizers, such as the sodium and calcium channel–blocking anticonvulsants; nonsteroidal anti-inflammatory drugs (NSAIDs); topical analgesics; and muscle relaxants. The neuronal membrane stabilizers and data associated with their use for primarily neuropathic pain (NP) are discussed in this chapter.

Based on extensive studies, NP appears to result from a cascade of multiple mechanisms following tissue injury. In broad terms, neural plasticity following nerve injury may result in peripheral nerve fibers communicating abnormal input to the central nervous system (CNS), which in turn may remodel CNS signaling. NP has a heterogeneous origin and may involve both the central and peripheral neural pathways following injury. Although neuroplasticity may help facilitate recovery, unfortunately, this is not always the case, and in fact, the downstream impact of the neuromodulatory changes associated with neuroplasticity, including abnormal stimulation or decreased inhibitory activity, may result in enhanced pain processing. Chronic pain develops when this neural stimulation continues beyond the range of expected healing and the triggering stimulus is no longer present. Moreover, ion channel functioning is affected as well by changes in signaling. Sodium and calcium channels play a fundamental role in the propagation of hyperexcitability in central and peripheral neurons. Accumulation of excessive or misplaced ion channels can lead to ectopic, spontaneous firing of sensory nerves and dorsal root ganglion cell bodies and result in hyperexcitability of the primary afferents and pain.

Research into the physiologic source and pharmacologic management of NP led to a focus on sodium and calcium channel blockade. Clinically available agents that act on these ion channels include the membrane-stabilizing agents typically used for the treatment of epilepsy. Many of these agents have been tried with varying success in patients with pain. Multiple classes of medications that fall under the membrane stabilizer classification are beneficial in the treatment of pain (Table 39.1). These agents include the antiepileptic/anticonvulsants, local anesthetics, TCAs, and antiarrhythmic medications. As a group, they inhibit the development and propagation of ectopic discharges. The primary agents used for NP include antiepileptic/anticonvulsants, local anesthetics, and the TCAs, which are discussed in a separate chapter. Gabapentin and pregabalin, also anticonvulsants, are discussed separately under calcium channel modulators because their mechanism of action differs from that of the other agents typically used for epilepsy.

The effectiveness of medications for pain relief is often determined by using one of several standard outcome measures, each of which assesses the change in average daily pain intensity score on a 10-cm (100-mm) visual analog scale (VAS) or a 11-point Likert (0, no pain; 10, worst possible pain) numeric rating scale (NRS). Patients who report pain relief of 30% or greater (moderate benefit) are considered to have experienced a clinically meaningful result; patients who report pain relief of 50% or greater are considered to have experienced substantial benefit. An often-used tool to allow comparison between different drugs and diseases and more precisely judge the efficacy of an agent is the number needed to treat (NNT). The NNT is the number of patients needed to be treated with a particular drug to obtain one patient with a defined degree of relief. Usually, the parameter “NNT for greater than 50% pain relief” is used because it is easily understood and seems to be related to relevant clinical effect. The number needed to harm (NNH) is the number needed to treat with a certain drug before a patient experiences a significant side effect. The NNH of several drugs used for pain management is not yet known. Drugs with a low NNT/NNH ratio are superior to the drugs with a high NNT/NNH ratio.

**CALCIFIED CHANNEL MODULATORS**

The first-line treatment agents recommended for NP include the calcium channel modulators. The intracellular free calcium ion concentration is only 1 in 10,000 that of the extracellular environment, and influx of calcium through calcium channels has important depolarizing effects on neurons. Voltage-gated calcium channels can be divided into high-voltage–activated (HVA) and low-voltage–activated (LVA) channels. Electrophysiologic characteristics allow division into HVA and LVA channels, depending on the threshold of activation. The HVA group is further divided into types L, P/Q, N, and R. These groups require large membrane depolarization and are mainly responsible for entry of calcium and release of neurotransmitter from presynaptic nerve terminals. Low-voltage channels, such as the T type, regulate firing by participating in bursting and intrinsic oscillations. The spike and wave discharges from the thalamus with absence seizures are dependent on T-type calcium channels; these discharges are inhibited by valproic acid or ethosuximide. The N-type HVA calcium channels are thought to be largely responsible for release of neurotransmitter at synaptic vesicles and can be blocked by dihydropyridines such as nitrendipine and felodipine.
PART 5 — PHARMACOLOGIC, PSYCHOLOGICAL, AND PHYSICAL MEDICINE TREATMENTS

synaptic junctions and become inactivated rather quickly. The P/Q-type calcium channel is so named because it was first described in the Purkinje cells of the cerebellum. The T-type channel, named after the transient currents elicited, starts to open with weak depolarization, near resting potential. L-type channels are found in high concentration in skeletal muscle and in many other tissues, such as neuronal and smooth muscle, where it has been most studied. The voltage-gated calcium channel is composed of five polypeptide subunits and is the target of many drugs. Calcium channels consist of an α-protein, along with several auxiliary subunits; the α-protein forms the channel pore.

**GABAPENTIN (NEURONTIN, GRALISE, HORIZANT)**

The calcium channel modulators that are used for the treatment of NP, such as gabapentin and pregabalin, bind to the α2δ subunit of L-type voltage-gated Ca channel and such binding results in decreased release of glutamate, norepinephrine, and substance P.9,10 Though structurally derived from the inhibitory neurotransmitter γ-aminobutyric acid (GABA), neither gabapentin nor pregabalin bind to or have activity at the GABA receptor. They also have no effect on the uptake or metabolism of GABA.

The standard initial dose of gabapentin is dependent on the particular gabapentin formulation used. For the first available preparation of gabapentin (Neurontin), it is 100 to 300 mg daily. Although the U.S. Food and Drug Administration (FDA)-approved dose of this preparation for the treatment of post-herpetic neuralgia (PHN) (the only painful condition for which this preparation is indicated) is 1800 mg, many clinicians will proceed with a gradual increase to a maximum of 3600 mg/day administered in three divided doses (Table 39.2). To minimize the consequence of certain adverse effects such as sedation and dizziness, the initial dose is often given at bedtime. After 2 to 5 days, the dose is increased to 300 mg twice daily and, after another 2 to 5 days, to 300 mg three times daily thereafter. Subsequently, the dose can be increased by 300 to 600 mg every other week as tolerated until an effective dosage is obtained or the maximum daily dose is reached. The main dose-limiting side effects are fatigue, somnolence, and dizziness, which are often attenuated by gradual dose titration. Although gabapentin has few drug interactions, a reduced dosage is

| **Table 39.1 Membrane Stabilizers for Pain** |
| **Membrane Stabilizer** | **Mechanism** | **Side Effects** |
| Carbamazepine | Na channel blockade | Sedation, dizziness, gait abnormalities, hematologic changes |
| Oxcarbazepine | Na channel blockade | Hyponatremia, somnolence, dizziness |
| Lamotrigine | Stabilizes slow Na channel; suppress release of glutamate from presynaptic neurons | Rash, dizziness, somnolence |
| Gabapentin/pregabalin | Binds to α2δ subunit of voltage-gated Ca channel | Dizziness, sedation |
| Valproic acid | Na channel blockade; increases GABA | Somnolence, dizziness, gastrointestinal upset |
| Topiramate | Na channel blockade; potentiates GABA inhibition | Sedation, kidney stones, glaucoma |
| Mexiletine | Na channel blockade | Nausea, blurred vision |
| Lacosamide | Na channel blockade | Dizziness, nausea, double vision, headache |

GABA, γ-aminobutyric acid.

| **Table 39.2 Dosing Recommendations for Neuropathic Pain** |
| **Membrane Stabilizer** | **Initial Dosage** | **Titration** | **Max Therapeutic Dosage** |
| Carbamazepine | 100-200 mg BID | Increase by 200-mg increments gradually | 1200 mg QD |
| Oxcarbazepine | 600 mg daily BID | Increase by 300 mg | 1200-1800 mg TID |
| Lamotrigine* | 25-50 mg QHS | Increase by 50 mg every 1-2 wk | 300-500 mg QD |
| Gabapentin | 100-300 mg QHS | Increase by 100-300 mg or 100-300 mg TID every 1-7 days as tolerated | 3600 mg (1200 TID) |
| Gabapentin GR | 300 mg QHS | Day 1, 300 mg; day 2, 600; days 3-6, 900; days 7-10, 1200; days 11-14, 1500, then 1800 | 1800 mg QHS |
| Pregabalin* | 50 mg TID or 75 mg BID | Increase to 300 mg daily after 3-7 days, then by 150 mg/day every 3-7 days as tolerated | 600 mg QD (200 mg TID or 300 mg BID) |
| Valproic acid | 250 mg BID | Increase by 250 mg weekly | 500 mg BID |
| Topiramate | 50 mg QHS | Start at 50 mg BID after 1 wk, then increase 100 mg BID after 7 days | 100 mg BID |
| Mexiletine | 150 mg QD | Increase to 300 mg in 3 days and then 600 mg | Maximum: 10 mg/kg daily |

*Reduce if impaired renal function.
BID, twice daily; QHS, at bedtime; QD, daily; TID, three times daily.
necessary in patients with renal insufficiency. However, starting dosages of gabapentin often do not provide immediate pain relief, and the slow titration requirements may result in inadequate pain relief taking up to 2 months to achieve when given as immediate-release gabapentin, although when given as the extended-release formulation, therapeutic doses can be reached in approximately 2 weeks.

Gabapentin has many uses in patients with multiple pain conditions. Studies have been performed on patients being treated for PHN, complex regional pain syndrome (CRPS), painful diabetic neuropathy (PDN), and other forms of NP, as well as for pain of controversial etiology, including opioid-induced hyperalgesia. In one study, patients with PHN being treated with opioids, TCAs, or both were identified and divided into two groups: 113 receiving gabapentin and 116 receiving placebo, in addition to their current baseline pain treatment regimen. For a period of 8 weeks patients were maintained on their respective therapies, with a 4-week titration of gabapentin to a maximum dose of 3600 mg/day. The results indicated that the patients who received gabapentin had a decrease of nearly 2 points in theirVAS score for pain, as opposed to a decrease of just 0.5 in the placebo-treated patients (P < 0.001). Along with a decrease in pain, patients also reported improvement in their SF-36 quality-of-life scores and noted improved functionality and feeling better with more restful sleep at night.

The analgesic effect of gabapentin in patients with PDN has also been evaluated. A randomized, double-blind, placebo-controlled (RCT) multicenter trial demonstrated a decrease of 2.5 in the VAS score in patients receiving gabapentin, up to 3600 mg/day, versus a decrease of 1.4 in patients in the control group (P < 0.001). As with the PHN study, patients also had a favorable change in their SF-36 scores, with more restful sleep at night and overall improvement in functioning.

Gabapentin has also been studied in patients with lumbar spinal stenosis. In a pilot study, both patient groups received “standard care,” including physical therapy, lumbosacral bracing, and NSAIDs. The treatment group also received gabapentin, 900 to 2400 mg, administered in three divided doses. After 4 months, patients who received gabapentin reported improvement in pain scores, increased walking distance, and decreased sensory and motor deficits. These results suggest that in the appropriate setting, gabapentin may provide symptomatic benefit for certain patients with lumbar spinal stenosis. In a double-blind, randomized, placebo-controlled 8-week trial, patients enrolled included those with CRPS, PHN, radiculopathy, post-laminectomy syndrome, post-stroke syndrome, phantom limb pain, and other NP syndromes. Gabapentin was initially started at 900 mg/day for 3 days and then increased to a maximum of 2400 mg/day at the end of week 5. The conclusion of the study showed that gabapentin reduced pain and improved certain quality-of-life measures in these patients. Gabapentin has also been found to be effective in reducing the pain associated with multiple sclerosis, specifically, the paroxysmal pain with a throbbing, pricking, and cramming quality rather than the dull, aching pain experienced by patients with multiple sclerosis. Of interest is that gabapentin appears to improve the analgesic efficacy of opioids in patients with NP.

In studies of gabapentin for postamputation pain and phantom limb pain, it was found to be less effective than for other NP states. Nikolajsen and colleagues administered gabapentin to patients following limb amputation and found no effect on postamputation or phantom limb pain. In a small cohort-control study, gabapentin was found to be effective for the treatment of chemotherapy-induced, painful peripheral neuropathy. However, an earlier, larger RCT found no benefit with gabapentin therapy for the same condition.

Combination therapies for NP have also proved successful. In a crossover RCT, patients received daily active placebo, sustained-release morphine, gabapentin, or a combination of gabapentin and morphine for 5 weeks. Fifty-seven patients underwent randomization (35 with PDN and 22 with PHN) and 41 completed the trial. Mean daily pain at the maximally tolerated dose of the study drug was reduced from 5.72 at baseline to 4.49 with placebo, 4.15 with gabapentin, 3.70 with morphine, and 3.06 with the gabapentin-morphine combination (P < 0.05 for the combination vs. placebo, gabapentin, and morphine). In an extremely important and well-performed trial, combination therapy with gabapentin and the TCA nortriptyline was found to be highly effective in the treatment of NP resulting from diabetes and varicella zoster. Although this study was not designed to examine the manner of interaction (e.g., drug-drug synergism vs. simple additivity), the results are highly suggestive of a synergistic analgesic effect. Patients achieved greater pain relief with a combination of low dosages of gabapentin (600 mg orally three times daily) and nortriptyline (50 mg orally at bedtime) than with either medication given alone at high doses. Importantly, patients receiving combination therapy had good analgesia without the significant side effects experienced by those treated with monotherapy. This trial, supported by the Canadian Institutes of Health, is a rare study in that the investigators had no influence from pharmaceutical companies and two inexpensive generic medications were studied.

A new gastric-retentive formulation of gabapentin (Gralise) has recently been approved by the FDA for PHN. It is intended to provide a simpler dosing paradigm than needed with the traditional generic gabapentin through the use of a polymer-based technology that allows gastric retention of the pill for extended delivery of the active medication. In a blinded RCT examining the analgesic benefit of single-day versus twice-a-day dosing in patients with PHN, the gastric-retentive formulation, when given twice per day, was more effective than placebo with an NNT of 5.9. The single-day dosing was not significantly different from placebo and had an NNT of 7.3, although a more recent multicountry RCT showed a significant improvement in pain after a single dose of 1800 mg given in the evening. Another formulation of gabapentin, gabapentin enacarbil (Horizant), has been developed and was initially approved for the treatment of restless legs syndrome. It is an actively transported prodrug form of gabapentin that allows twice-a-day dosing because of increased stability in bioavailability in comparison to the standard formulation of gabapentin. In a recent RCT, this prodrug formulation was found to be effective in the treatment of PHN when given twice per day. This drug is now approved by the FDA for the treatment of PHN as well as restless leg syndrome.
PREGABALIN (LYRICA)

Pregabalin, like gabapentin, is used for the treatment of NP and acts by binding to the α3δ subunit of L-type voltage-gated calcium channels, which results in decreased neuronal excitation. With respect to NP, pregabalin is approved by the FDA for the treatment of PHN, PDN, and spinal cord injury–associated pain. Initial pregabalin dosing is 150 mg/day given in two or three divided doses or 25-50 mg given at bedtime in elderly patients. Upward dose titration can be completed after 3 to 7 days to 300 mg/day and subsequently increased to a maximum dose of 600 mg/day within 2 weeks of initiation. Similar to gabapentin, dosing of pregabalin must be decreased in patients with reduced kidney function. Advantages of pregabalin over gabapentin include a more rapid onset of pain relief; linear pharmacokinetics with low intersubject variability; fewer dose-related side effects, thereby allowing faster upward dosage titrations; and twice-daily versus three times a day dosing. Additionally, maximum benefit often occurs after 2 weeks of treatment at target doses of 300 to 600 mg/day versus up to 2 months in gabapentin-treated patients.

In patients with PHN, a trial that included 370 patients was conducted to evaluate doses of 150, 300, or 600 mg/day versus placebo. The RCT demonstrated reduced mean pain scores and improvement in sleep interference. Patients responded at all dosages, with the greatest response noted with 600 mg/day. Patients responded as early as the first week, and beneficial effects were sustained throughout the 13-week study duration. Adverse effects were generally mild to moderate, and 13% of patients withdrew from the study, most commonly because of dizziness or somnolence.

In a randomized, double-blind study, the effects of pregabalin on PDN were evaluated. A total of 395 patients were randomized to receive 150, 300, or 600 mg/day. In patients who received 600 mg/day, 46% reported greater than 50% improvement in pain scores from baseline, and the NNT to achieve this response was 6.3. Pregabalin also improved pain-related sleep interference and was well tolerated overall, with an NNH of 10.3 in patients treated with 600 mg/day.

Pregabalin was evaluated in a 12-week multicenter study in patients with central NP secondary to spinal cord injury. A total of 137 patients were randomized either to a flexible-dose regimen of 150 to 600 mg/day or to placebo and were allowed to continue an existing stable pain regimen. Pregabalin was found to be significantly more effective in relieving central NP than placebo was.

Pregabalin has been studied for use in patients with “refractory” NP of various origins. A 15-month open-label study was conducted in 81 patients with PHN and PDN refractory to treatment, including gabapentin, a TCA, and a third medication (e.g., other anticonvulsant, opioid, specific serotonin reuptake inhibitor, tramadol). Patients took 150 to 600 mg/day for 3-month intervals and then had a 3- to 28-day “drug holiday.” As evaluated by VAS scores, patients had a clinically meaningful and sustained reduction in pain intensity during the treatment cycle, with return of pain during “drug holidays.” In patients with an unsatisfactory response to other medications, pregabalin may be considered as an adjunctive therapy.

The advantage of pregabalin is its early response and favorable side effect profile. The most common adverse effects include somnolence and dizziness, and they occur more frequently with higher doses. When discontinuing pregabalin, it should be tapered down gradually over at least a 1-week period to minimize symptoms, including insomnia, nausea, headache, and diarrhea.

ZONISAMIDE (ZONEGRAN)

Zonisamide is indicated as adjunctive therapy for partial seizures in adults and became available in the United States in 2000. It acts by blocking T-type calcium channels and sodium channels; its action also increases release of GABA. The initial dose is 100 mg/day for 2 weeks with increases of 200 mg/wk to a target of 600 mg/day. There have been case reports on its usefulness for post-stroke pain and headache. A randomized, double-blind, placebo-controlled pilot study of the efficacy of zonisamide for the treatment of PDN revealed that pain scores on the VAS and Likert (psychometric response) scales decreased more in the zonisamide group than in the placebo group, but these differences did not reach statistical significance. Side effects included ataxia, decreased appetite, rash, and renal calculi (as a result of the carbonic anhydrase inhibitor effect). Zonisamide is contraindicated in those with sulfonamide allergy because it is a sulfonamide derivative, and the drug is approximately 40% bound to plasma proteins. Children have an increased risk for oligohidrosis and susceptibility to hyperthermia. The exact role of zonisamide in the management of patients with NP is yet to be elucidated, and further research is needed.

ZICONOTIDE (PRIALT)

Ziconotide is a ω-conopeptide (previously known as SNX-111) that is administered intrathecally because of its peptide structure. It is derived from the venom of a marine snail (genus Conus). Ziconotide blocks calcium influx into N-type calcium channels in the dorsal horn laminae of the spinal cord, thus preventing afferent conduction of nerve signals. Administration is via an intrathecal infusion pump, and dosing should be started low, at a recommended dose of 2.4 µg/day (0.1 µg/hr). Because of a lag time, it should be titrated up slowly at intervals of no more than two to three times per week to a recommended maximum of 19.2 µg/day. Ziconotide does not cause tolerance, dependence, or respiratory depression, and adverse effects primarily involve the CNS and include dizziness, ataxia, confusion, and headache. Ziconotide has been evaluated in randomized, double-blind, placebo-controlled trials for severe, chronic, treatment-refractory pain in patients with or without cancer. Patients experienced a significant improvement in mean pain scores and global pain relief. The response rate was higher in patients receiving a maximum of 21.8 µg/day; however, pain relief was accompanied by a high incidence of adverse effects that resulted in frequent interruptions of the trial. A slow titration schedule with a lower maximum infusion rate was associated with significantly lower dropout rates but also resulted in a more modest treatment effect. At the conclusion of one trial, nearly 90% of patients elected to continue receiving ziconotide. Rare, but serious adverse effects include hallucinations; thus, ziconotide is not recommended for use in patients with a history of psychosis. Elevations in creatine kinase (CK) were noted in some studies to be related
to ziconotide. The etiology remains unclear, and CK levels should be monitored periodically.

The role of ziconotide in the management of chronic pain has yet to be fully elucidated. Currently, ziconotide is approved for the management of severe chronic pain in patients in whom intrathecal therapy is warranted and who are intolerant of or refractory to other treatments, including intrathecal opiates; however, this medication should be used cautiously because of its poor side effect profile.

**NIMODIPINE (NIMOTOP)**

Nimodipine has been shown to decrease the dose of morphine needed for relief of cancer pain in 9 of 14 patients. In a colorectal surgery population, concomitant calcium channel blocker therapy did not decrease opioid requirements. Nimodipine taken concurrently with antiretroviral medications demonstrated a trend toward improvement or stabilization of human immunodeficiency virus (HIV)-associated neuropathy when compared with placebo.

**SODIUM CHANNEL BLOCKERS**

Sodium channel blockers are used as primary therapy or adjunctive treatment of processes such as trigeminal neuralgia (TN), CRPS, PDN, radicular extremity pain, chemotherapy-induced peripheral neuropathy, and PHN. When using these agents, as with all membrane stabilizers, it is crucial to be knowledgeable of the proper dosages, toxicities, and their effects when coadministered with other drugs. As a general rule, the dose should be titrated to patient comfort within safety standards.

When neurons are depolarized and approaching an action potential, the voltage-gated sodium channels quickly change conformation in response and permit the flow of sodium ions. Activation of sodium channels (and other voltage-gated ion channels) derives from the outward movement of charged residues because of an altered electrical field across the membrane. Sodium channels play an essential role in the action potentials of neurons and other electrically excitable cells. The flow of sodium ions is terminated by inactivation of the channel in a few milliseconds (fast inactivation). Sodium channels can cycle open and close rapidly, which may result in seizures, NP, or paresthesias. The structure of the channel is essentially a rectangular tube, with its four walls formed from four subunits, the four domains of a single polypeptide. A region near the N-terminus protrudes into the cytosol and forms an inactivating particle. It has been demonstrated that a short loop of amino acid residues, acting as a flap or hinge, blocks the inner mouth of the sodium channel and results in fast inactivation. The highly conserved intracellular loop is the inactivating gate that binds to the intracellular pore and inactivates it within milliseconds. Site-directed antibody studies against this intracellular loop have prevented this fast inactivation.

The voltage-gated sodium channel can be divided into an $\alpha$ subunit and one or more auxiliary $\beta$ subunits. At least nine $\alpha$ subunits have been functionally characterized—Na$_{1.1}$ through Na$_{1.9}$. The sodium channels 1.2, 1.8, and 1.9 are preferentially expressed on peripheral sensory neurons, where they are important in nociception and may be a future target for channel-specific analgesics. Seven of the nine sodium channel subtypes have been identified in sensory ganglia, such as the dorsal root ganglia and trigeminal ganglia. Na$_{1.7}$ is also present in large amounts in the peripheral nervous system. Na$_{1.2}$ is expressed in unmyelinated neurons and Na$_{1.4}$ and Na$_{1.5}$ are muscle sodium channels. Sodium channel mutations that cause well-recognized syndromes have been described. A mutation in Na$_{1.4}$ is responsible for hyperkalemic periodic paralysis, and an inherited long QT syndrome can be caused by a mutation in Na$_{1.5}$.

Increased expression of sodium channels has been demonstrated in peripheral and central sensory neurons in patients with NP; it is one mechanism for the observed hyperexcitability of pain pathways. Anticonvulsants that modulate the gating of sodium channels are phenytoin, lamotrigine, carbamazepine, oxcarbazepine, and zonisamide, with some evidence for topiramate and valproic acid. It is important to note that at clinical concentrations, the sodium channel is only weakly blocked when hyperpolarized. When the neuronal membrane is depolarized, there is a much greater inhibition of the channel. Binding of the channel by anticonvulsants is slow in comparison to local anesthetics. The slow binding of anticonvulsants ensures that the kinetic properties of normal action potentials are not altered. Generally, anticonvulsants have no role in the treatment of acute pain, although they have demonstrated efficacy in chronic pain conditions. Interestingly, local application of phenytoin and carbamazepine has an antinociceptive effect that is more potent than that of lidocaine. It has been demonstrated that phenytoin, carbamazepine, and lamotrigine bind to a common recognition site on sodium channels, and it is probably the result of their two phenol groups, which act as binding elements. At normal resting potentials, these medications have little effect on action potentials. In addition to the fast current of the open channel, there is also a persistent sodium current. This current, carried by persistent openings, is a small fraction of the fast current but may have an important role in regulating excitability. There is evidence that a number of anticonvulsants, such as phenytoin, valproate, and topiramate, also act by blocking the persistent sodium current, which is separate from the fast sodium current.

**SODIUM CHANNEL-MODULATING ANTICONVULSANTS**

**PHENYTOIN (DILANTIN)**

In addition to the widespread use of phenytoin for seizures, it was the first anticonvulsant to be used for NP, with a 1940s report on its use for TN. Phenytoin is known for its nonlinear metabolism, which is manifested as marked increases in plasma level with small increases in dose after saturation of metabolism. Around 95% of a phenytoin dose is excreted as metabolites from the cytochrome P-450 system. The initial dosage of phenytoin is 100 mg two to three times daily. It has been the first anticonvulsant to be used for NP, with a 1940s report on its use for TN. Phenytoin is known for its nonlinear metabolism, which is manifested as marked increases in plasma level with small increases in dose after saturation of metabolism. Around 95% of a phenytoin dose is excreted as metabolites from the cytochrome P-450 system. The initial dosage of phenytoin is 100 mg two to three times daily.
sodium channels, thereby preventing the release of excitatory glutamate and inhibiting ectopic discharges.

Trials have been performed to investigate the efficacy of phenytoin for diabetic neuropathy, with conflicting results. Intravenous phenytoin has been studied in the pain management setting. Doses of 15 mg/kg have provided relief of acute pain when administered over a 2-hour period. Side effects of phenytoin include slowing of mentation and somnolence, with nystagmus and ataxia occurring in some patients. Among the epileptic drugs, phenytoin is unique in the development of facial alterations, including gum hyperplasia and coarsening of facial features. Fosphenytoin, an intravenously administered prodrug that converts to phenytoin, is used by some to avoid long dosing intervals or initial burning at the injection site.

Phenytoin activates the cytochrome P-450 enzyme system in the liver, and hence careful assessment of co-therapy is warranted. For example, phenytoin decreases the efficacy of methadone, fentanyl, tramadol, mexiteline, lamotrigine, and carbamazepine. As a result, dosages of these medications should be adjusted accordingly. Coadministration with antidepressants and valproic acid could lead to an increased blood concentration of phenytoin, thereby lowering the subsequent doses required for effect in patients. Currently, most would not use phenytoin for the treatment of NP except perhaps in refractory situations.

CARBAMAZEPINE (TEGRETOL)

Carbamazepine has been used in the United States since the 1980s to treat partial and generalized tonic-clonic seizures. Carbamazepine was first approved by the FDA for the treatment of TN, not for epilepsy. In addition to its anticonvulsant and TN indications, it is used frequently for bipolar disorder. It was one of the first anticonvulsants studied for the relief of NP. The analgesic properties of carbamazepine were first reported in 1962. It is chemically related to the TCAs; reports have included studies of its use for PHN, PDN, post-stroke pain, and pain in Guillain-Barré syndrome. The initial dosage of carbamazepine is 100 to 200 mg twice daily, titrated to effect, with typical dose ranges of 300 to 1200 mg/day administered in two divided doses. Common maintenance doses are 600 to 800 mg.

Common side effects include drowsiness, dizziness, and nausea and vomiting, which can often be limited by slow titration. Carbamazepine is associated with very deleterious side effects, including pancytopenia (necessitating a complete blood count and monitoring while being treated with this therapy), Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Carbamazepine is considered to be the pharmacologic treatment of choice for TN, a sharp severe facial pain in one or more of the distributions supplied by the trigeminal nerve. Although the pathology of this process has not been fully determined, the majority of cases are thought to be caused by compression of the trigeminal nerve at the pontine origin of the nerve by an aberrant loop of an artery or vein.

With an NNT of lower than 2, carbamazepine is the most studied treatment of TN, and many studies have highlighted its usefulness. One study noted the effect of carbamazepine in 70 patients with TN and reported a 68% decrease in pain episodes and a 58% decrease in the severity of pain. Research from other studies has noted a verbal response of “excellent” or “good” by patients on initiation of therapy for 2 weeks. Additionally, the positive effect of carbamazepine on TN has been tested by crossover, placebo, and controlled double-blinded studies; yet even with these positive results, TN is a disease process that in many patients is difficult to treat completely, with multiple agents often being required.

Carbamazepine has also been investigated for use in pain states caused by diabetes mellitus. Its application in animals resulted in a decrease in hyperalgesia in response to various stimuli. This agent has been shown to be more beneficial than placebo in the human diabetic patient population. Carbamazepine therapy, when compared with a combination of nortriptyline and fluphenazine in patients with PDN, was found to be equally effective with fewer side effects.

Patients maintained on carbamazepine therapy should have blood tests done every 2 to 4 months because of increased risk for the development of agranulocytosis and aplastic anemia with this agent. Studies have noted that the NNH for severe adverse effects was 24 and for minor adverse effects, such as sedation, was 3.

OXCARBAZEPINE (TRILEPTAL)

Oxcarbazepine, the keto-analogue of carbamazepine, was developed to preserve the membrane-stabilizing effects of carbamazepine while minimizing minor adverse effects such as sedation and serious, life-threatening reactions. A major advantage of oxcarbazepine is that monitoring of plasma drug levels and hematologic profiles is not generally necessary. Similar to carbamazepine, oxcarbazepine blocks sodium channels; it does not affect GABA receptors. Significant hyponatremia (sodium <125 mmol/L) may develop during treatment with oxcarbazepine. This typically occurs during the first 3 months, with sodium levels normalizing within a few days of discontinuing the drug. Monitoring of sodium levels should be performed when instituting oxcarbazepine therapy. Frequently reported adverse effects of oxcarbazepine include dizziness, somnolence, and nausea and vomiting, which are generally well tolerated.

In a randomized, placebo-controlled trial lasting 16 weeks, oxcarbazepine was evaluated in patients with PDN. Patients were treated with 300 mg and titrated to a maximum dose of 1800 mg/day. Oxcarbazepine-treated patients reported less pain on the VAS, global improvement, and less sleep disturbances because of pain.

The superior side effect profile of oxcarbazepine over carbamazepine has led to its increased use. In several countries, oxcarbazepine is now the drug of choice for TN. Oxcarbazepine was also found to be effective in treating TN in patients who had no positive response to carbamazepine.

LAMOTRIGINE (LAMICTAL)

Lamotrigine received FDA approval in 1994; it is used as an adjunctive agent for partial seizures and as monotherapy for partial and generalized seizures. Like other agents discussed in this section, lamotrigine is an agent that blocks sodium channels in actively firing nerves. It has no effect on sensation in the native, normally functioning nervous system.
Unique to lamotrigine is the fact that in addition to acting as a sodium channel blocker, the drug prevents release of glutamate, an excitatory transmitter involved in pain propagation. Adverse events such as dizziness, somnolence, and cognitive impairment occur with lamotrigine. There is little dose-dependent toxicity, so monitoring of laboratory values is not necessary. The most concerning side effect is rash, which is known to occur more often with rapid titration; it can be manifested as Stevens-Johnson syndrome. The risk for rash is similar to that with phenytoin or carbamazepine, 5% to 10%. Enzyme-inducing drugs reduce the serum level of lamotrigine. Lamotrigine has no effect on liver enzymes, is metabolized via glucuronidation, and is 55% protein bound with a half-life of 30 hours. It needs slow titration, at least 4 to 6 weeks.

A major use for lamotrigine is in patients with TN. Although carbamazepine has been advocated as the first-line therapy for TN, it is not always effective in these patients. Lamotrigine has been investigated in this patient model for use as a coadministered drug and as a substitute for carbamazepine. Twenty-one patients with TN who received no benefit from carbamazepine therapy were treated with lamotrigine. In a population of 7 men and 14 women, 14 of the patients noted significant to complete relief of their symptoms after the institution of lamotrigine therapy, and the remaining 7 patients had no benefit. Recently, lamotrigine was compared directly with carbamazepine for the treatment of TN and found to be effective in fewer patients than carbamazepine was (70% vs. 90%); however, those who did have benefit with lamotrigine received greater pain relief and suffered fewer adverse effects (especially hematologic, renal, and liver) than those who had benefit in relieving pain with carbamazepine. The use of lamotrigine may therefore be indicated for carbamazepine-resistant TN, or it could be trial-tested before carbamazepine. Lamotrigine may also play a role in the prevention of TN symptoms. This positive result has been seen in follow-up in a group of 15 patients with TN being treated with lamotrigine. In this review, 73% of patients were free of their painful symptoms at the conclusion of the study. Subsequent interval follow-up revealed a continued positive result, with no change in pain scores reported by patients. As a result of these studies, lamotrigine may have a role in the prevention of TN in susceptible patients.

Lamotrigine has also been evaluated for lumbar radicular pain resulting from intervertebral disk herniation. In a 4-week open-label trial it was found to provide pain relief and increased range of motion, but only at high doses (400 mg/day). It has also been evaluated in the PDN population. Lamotrigine for diabetic neuropathy was investigated in two randomized, double-blind, placebo-controlled trials with a total of 360 patients. In patients receiving 400 mg, a reduction in pain intensity score versus placebo was observed in one of the two studies. Doses of 200 and 300 mg did not demonstrate any benefit. A group of 15 patients with diabetes (types 1 and 2 combined in the study) induced peripheral neuropathy were treated in an open study. They were tested with brush and cold stimuli for allodynia and pinprick for hyperalgesia. On completion of the study, patients were tested and reported improvement of pain in all settings, and their relief persisted as noted during the subsequent 6-month interval follow-up.

In one RCT, lamotrigine (300 mg/day) was found to significantly reduce pain in patients with distal sensory polyneuropathy (DSP) but not in those with antiretroviral toxic neuropathy (ATN) associated with HIV disease. HIV-associated neuropathy is believed to be on the rise, concomitant with the increase in the number of patients in whom the virus is being diagnosed. Patients with distal sensory peripheral neuropathy associated with HIV infection were subjected to a placebo-controlled, randomized, double-blind study to identify the benefit of lamotrigine therapy. Although both placebo- and lamotrigine-treated patients had a decrease in pain, the rate of decrease was more rapid in the lamotrigine group. Patients administered antiretrovirals and lamotrigine, however, were noted to have slower pain relief than those treated with lamotrigine without the antiretroviral agents. In a subsequent larger trial, it was found to be effective for both DSP and HIV ATN-related pain. The effect of lamotrigine as adjunctive therapy was also studied in 220 patients with a variety of NP conditions uncontrolled by monotherapy. This randomized, double-blind, placebo-controlled study evaluated the efficacy and tolerability of lamotrigine in addition to gabapentin, a TCA, and a nonopioid analgesic. The study included patients with PDN, PHN, traumatic or surgical nerve injury, incomplete spinal cord injury, TN, multiple sclerosis, and HIV-associated peripheral neuropathy. Lamotrigine was generally well tolerated but did not demonstrate effective pain relief as evaluated by pain score or the use of rescue medication.

Lamotrigine has not been found to be effective in the treatment of chemotherapy-induced peripheral neuropathy, nor has it been found to be beneficial in treating the central pain related to multiple sclerosis.

TOPIRAMATE (TOPAMAX)

Topiramate has multiple mechanisms of action and broad use for seizure disorders. Topiramate blocks voltage-sensitive sodium channels, limits sustained repetitive firing, and binds to GABA_A receptors to enhance GABA activity through non-benzodiazepine- and non-barbiturate-related mechanisms. It increases the opening frequency of chloride ion channels in GABA_A receptors and can block α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-kainate glutamate receptors by acting as a negative modulator of glutamate at this receptor. Topiramate reduces the activity of L-type calcium channels and is a carbonic anhydrase inhibitor. Topiramate exhibits linear pharmacokinetics over its dose range and has a half-life of 19 to 25 hours. Its oral bioavailability is about 85% and it is not affected by food. Enzyme-inducing drugs may reduce the serum level of topiramate. Common side effects include paresthesias because of inhibition of carbonic anhydrase, drowsiness, fatigue, and cognitive symptoms. The incidence of nephrolithiasis was 1.5% in clinical trials, and mild weight loss is often noted. The propensity for weight reduction in some patients has led to investigation of its potential as a weight-reducing agent.

The initial dose is 50 mg at bedtime, with increases to an upper limit of 200 mg twice daily. Studies have demonstrated that pain relief begins to occur at doses of 200 mg/day. Two large trials on migraine prophylaxis with topiramate
were published in 2004, and topiramate received FDA approval for this indication. A review of multiple double-blind studies examining the efficacy of topiramate for PDN failed to show significant analgesic benefit. However, a more recent 12-week, double-blind study showed that it had greater efficacy than placebo in relieving the pain sensed by patients with PDN. Topiramate has also been studied for other painful conditions. In a double-blind, randomized, crossover trial, topiramate, 50 to 400 mg, was assessed in patients with chronic lumbar radicular pain; it resulted in an improved global pain relief score, but it did not reduce leg pain. The study was limited by frequent side effects and a high dropout rate. The exact role of topiramate has yet to be determined, and thus it may best be reserved as an adjunct for pain management with other membrane stabilizer agents. Case reports in the literature have also highlighted the use of this agent for additional forms of NP, including PHN, intercostal neuralgia, and CRPS.

**LACOSAMIDE (VIMPAT)**

Lacosamide is an effective and well-tolerated antiepileptic drug that is used as adjuvant treatment of focal-onset seizures uncontrolled by other agents. Although it has not been compared directly with other adjuvant treatment options, its different mechanism of action and favorable safety profile make this antiepileptic agent a valuable addition to the treatment options available. The primary action of lacosamide is enhancement of slow inactivation of voltage-gated sodium channels without any apparent interaction with fast inactivation, a mechanism that differs from that of other sodium channel–blocking membrane stabilizers. In addition to treatment of epilepsy, lacosamide has been found to be beneficial in the treatment of PDN. Evidence of the efficacy of lacosamide in patients with PDN has been found in the results of a phase II trial and phase III trials. In a later trial, the primary end point of pain reduction was not reached.

**GLOBAL ANESTHETICS**

**LIDOCAINE**

Local anesthetics are used in NP states to block the aberrant firing of abnormal nerves, although they also block normally conducting (non-nociceptive) nerves. As a group, they are effective in the treatment of PHN, TN, radiculopathies, and peripheral neuropathies.

**GABAergic MEDICATIONS**

**VALPROIC ACID (DEPAKOTE)**

First synthesized in 1882, valproate became available in the 1960s as an antiepileptic agent and received FDA approval in 1978 as an immediate-release formulation. The drug has a broad spectrum of use for seizure disorders, including absence seizures, and is now also used extensively by psychiatrists for mood disorders. The exact molecular mechanisms responsible for its clinical effects are unknown. Catabolism of GABA is inhibited and the synaptic release of GABA is increased. There are conflicting reports in the literature regarding the efficacy of this agent for NP, although studies have demonstrated that it is effective as migraine therapy at dosages of 750 mg/day for a period of 3 months. In an RCT it was found to be mildly beneficial in the treatment of PDN and had a relatively high NNT of 7. Side effects include gastrointestinal upset, somnolence, and dizziness. The exact role of valproic acid in the armamentarium of the pain practitioner is yet to be elucidated.

**DIAZEPAM (VALIUM), LORAZEPAM (ATIVAN), CLONAZEPAM (KLONOPIN)**

Benzodiazepines, such as diazepam, lorazepam, and clonazepam, facilitate the actions of GABA in the CNS as a result of their binding to the GABA_A receptor. The side effects of drowsiness and ataxia and the development of tolerance to the antiseizure effect limit the usefulness of benzodiazepines for chronic use. Clonazepam is also used for chronic facial pain and has had some success in small clinical trials. A randomized, double-blind trial of a benzodiazepine for pain compared lorazepam with amitriptyline for PHN, but lorazepam was found to be less effective.

Although benzodiazepines are frequently prescribed for multiple pain syndromes, there is little, if any evidence of their benefit as pain therapy, and they are more commonly associated with adverse events. Recently, use of the benzodiazepine clonazepam was evaluated for the treatment of neuropathic radicular pain in an randomized controlled trial (RCT) and found to have no benefit beyond placebo.

**LOCAL ANESTHETICS**

Local anesthetics are used in NP states to block the aberrant firing of abnormal nerves, although they also block normally conducting (non-nociceptive) nerves. As a group, they are effective in the treatment of PHN, TN, radiculopathies, and peripheral neuropathies.

**LIDOCAINE**

The typical dose of lidocaine is 1 to 5 mg/kg intravenously. Side effects include dizziness, blurred vision, and seizures, which typically occur at a plasma level of 10 mg/mL. Given that lidocaine is an antiarrhythmic, bradycardia and cardiac depression (present at a 20- to 25-mg/mL plasma concentration) are potential risks with this agent; therefore, electrocardiographic studies are indicated for long-term or high-dosage use of lidocaine. This therapy is severely limited by the method of medication delivery, and its most likely utility is as a diagnostic test for a disease process (e.g., erythromelalgia) or as therapy with mexiletine.

A patch formulation of 5% lidocaine (Lidoderm) is available in a topical preparation. Approved by the FDA for PHN, it has also proved to be of benefit in patients with various other types of NP, including PDN, post-thoracotomy pain, intercostal neuralgia, and meralgia paresthetica. The eutectic mixture of local anesthetics (EMLA)—composed of prilocaine and lidocaine—has also been advocated for use as a topical local anesthetic. This agent is sometimes used as an adjunct for venipuncture in the pediatric population, but care must be taken with the amount of EMLA cream given to patients to avoid toxicity. Prilocaine is readily metabolized to O-toluidine, which can lead to methemoglobinemia. However, if dosages of prilocaine are kept below 600 mg, clinical methemoglobinemia is less likely to develop. These topical formulations are discussed at greater length in Chapter 42.
**MEXILETINE**

Mexiletine is an antiarrhythmic and, for pain relief, can be considered an oral analogue of lidocaine. Pain physicians may provide intravenous lidocaine for pain management, with monitoring of dose and effect. After receiving a dose of intravenously administered drug, treatment may readily be converted to oral mexiletine. The standard starting dose is 75 to 150 mg/day with a target of 300 to 450 mg/day.

Mexiletine can be used for PDN, thalamic stroke pain, spasticity, allodynia, and myotonia, although its effects are minimal. It has been used successfully in patients with the rare Na1.7 mutation causing erythromelalgia. Common side effects, including somnolence, irritability, blurred vision, and nausea and vomiting, severely limit the utility of this medication. Patients are also at risk for the development of blood dyscrasias, and blood tests should be obtained on a regular basis.

**MAGNESIUM**

Research has recently been performed to evaluate antagonists of the N-methyl-D-aspartate (NMDA) receptor, including the membrane-stabilizing effect of magnesium. In a study of seven patients with PHN, intravenous infusion of 30 mg/kg of magnesium sulfate over a 30-minute period was found to be more effective in relieving pain than an intravenous infusion of saline. Significant limitations with this therapy include the method of medication delivery (intravenous) and lethargy and muscle flaccidity following its use. Further, RCTs with alternative formulations need to be conducted to establish its role in the treatment of pain.

**LEVETIRACETAM (KEPPRA)**

Levetiracetam is a newer anticonvulsant that was approved in 1999 as adjunctive therapy for partial seizures in adults. It appears that inhibition of voltage-gated sodium channels or T-type calcium channels is not involved in the anti-convulsant effects of levetiracetam, which does not appear to have direct GABAergic receptor effects. The mechanism of action of levetiracetam thus does not involve modulation of the four main systems. The starting dose of levetiracetam is 500 mg twice daily, and it may be increased to a recommended 3000 mg/day in divided doses. Dosages of up to 5000 mg/day have been assessed for the treatment of NP. Its linear pharmacokinetics results in predictable effects as the dosage is increased. Levetiracetam is not metabolized by the cytochrome P-450 system and thus does not have significant drug interactions. Adverse effects include asthenia, dizziness, somnolence, and headache. The drug has a number of favorable characteristics and has therefore been investigated for adjuvant use in areas such as pain. Unfortunately, in a number of well-conducted RCTs, it was found to be ineffective in the treatment of NP secondary to spinal cord injury, polynuropathic, and postmastectomy pain.

**CONCLUSION**

There are now a wide variety of neuronal membrane-stabilizing medications available for the treatment of NP conditions. The majority of RCTs to determine the effectiveness of these agents have involved select NP conditions such as PDN and PHN, with extrapolation of these results to other neuropathic conditions. As the science of pain medicine has advanced, studies have begun to examine less common NP conditions and the efficacy of these agents. Conditions such as chemotherapy-induced neuropathy and HIV-associated neuropathy have proved to be exceptions to the common belief that all NP responds to the standard group of membrane-stabilizing agents, and this reinforces the understanding that nerve-related pain may have similar symptoms or pain qualities but may not respond to the same treatments.

**KEY POINTS**

- Multimodal medical management of cancer- and non–cancer-related pain can involve the use of nonopioid medications, as well as opioid medications.
- The NNT is the number of patients needed to be treated with a particular drug to obtain one patient with a defined degree of relief.
- Drugs with a low NNT/NNH ratio are superior to drugs with a high NNT/NNH ratio.
- Calcium channel modulators that are used for the treatment of neuropsychiatric pain, such as gabapentin and pregabalin, bind to the α2δ subunit of L-type voltage-gated calcium channels and result in decreased release of glutamate, norepinephrine, and substance P.
- The combination of low doses of gabapentin with low doses of morphine or nortriptyline provides significantly greater analgesia with lower side effects than those agents used alone.
- Recently, use of the benzodiazepine diazepam was evaluated for the treatment of neuropsychiatric radicular pain in a randomized, controlled trial and was found to have no benefit beyond placebo.
- Levetiracetam was found to be ineffective in the treatment of neuropathic pain secondary to spinal cord injury, polyneuropathy, and mastectomy.

552.e2 REFERENCES

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a diverse group of chemically unrelated compounds that are classified together based on their therapeutic property of possessing anti-inflammatory action (Fig. 40.1). NSAIDs are the most widely prescribed drugs for the treatment of acute and chronic pain, and they account for about 6 to 7 billion dollars in sales worldwide.

Extracts from the bark and leaves of willow, myrtle, and other plants have therapeutic effects because of the presence of salicylic acid and were first used for the treatment of fever in 1763 by Edward Stone. In 1829, Henri Leroux in France obtained a compound of salicylic acid (known as salicin) in crystalline form and succeeded in splitting it to obtain the acid in its pure state. Professor Hermann Kolbe in Germany discovered the compound’s chemical structure and succeeded in synthesizing it in 1859. Sodium salicylate was first used for the treatment of rheumatic fever in 1875. Bayer Pharmaceutical started manufacturing aspirin (acetylsalicylic acid) by 1914 and currently sells about 11 billion tablets annually. Shortly after aspirin was manufactured, other drugs with diverse chemical structures but similar anti-inflammatory, anti-inflammatory, and analgesic properties were discovered; these drugs were grouped together as NSAIDs. John R. Vane elucidated the mechanism of NSAIDs in 1971 and shared the Nobel Prize in Physiology and Medicine with Sune Bergström and Bengt Samuelsson in 1982.

MECHANISM OF ACTION

PROSTAGLANDIN SYNTHESIS AND PHARMACOLOGY

Von Euler coined the term prostaglandin (PG) to describe an extract from semen that contracted uterine smooth muscle. Although PGs are derived from arachidonic acid and other polyunsaturated fatty acids, the 20-carbon polyunsaturated essential fatty acid (arachidonic acid) is the major source in mammalian tissues. PGs derived from arachidonic acid (prostaglandin E₂ [PGE₂], thromboxane, and prostacyclin) contain two double bonds. Analogous compounds synthesized from eicosatrienoic (linoleic) and eicosapentaenoic acids contain one less or more double bond in the side chains (PGE₁, PGE₃, respectively). The various groups of PGs, thromboxanes, hydroxy acids, and leukotrienes that retain the 20-carbon unsaturated fatty acid structure are collectively known as eicosanoids. The three fatty acid precursors (eicosapentaenoic acid) are derived directly or indirectly from dietary fat and are esterified into cell membranes. Their release, usually as a result of trauma, is the major stimulus for eicosanoid production because PGs cannot be stored and are released as soon they are synthesized. Disruption of the cell membrane leads to the release of phospholipid, which is converted to arachidonic acid by the action of phospholipase A₂. Arachidonic acid in turn acts as a substrate for cyclooxygenase (COX). COX-catalyzed peroxidation of arachidonic acid results in a cyclic structure, whereas peroxidation catalyzed by lipoxygenase produces straight-chain hydroxy-peroxy acids, which can then be converted to hydroxy acids (Fig. 40.2).

PGs are also involved in the pyretic response. After injection of pyrogens, there is a rise in PG levels in cerebrospinal fluid (CSF) that is prevented by pretreatment with aspirin. It is of interest that acetaminophen, which is antipyretic but not anti-inflammatory, blocks brain PG synthetase. Prostanoids do not generally activate nociceptors directly but sensitize them to mechanical stimuli and chemical mediators of nociception, such as Bradykinin. PGE₂ is the predominant eicosanoid released from the endothelial cells of small blood vessels and a key mediator of both peripheral and central pain sensitization. Because PGE₂ is the prostanoid most associated with inflammatory responses, the formation of PGE₂ at inflammatory sites is often considered an indicator of local COX activity, and suppression of PGE₂ is an indicator of a decreased inflammatory process. Production of PGE₂ is slow in onset and of long duration in response to inflammation. It is currently recognized that COX is encoded by two genes. Although the isomerization of PGH₂ into PGE₂ has been well characterized biochemically and pharmacologically, the enzyme responsible, PGE synthase, has been purified and cloned only rather recently. This enzyme is one of the membrane-associated proteins in the eicosanoid and glutathione metabolism superfamily, which consists of six proteins with divergent functions.

COX-1 AND COX-2 SELECTIVITY

The existence of a COX isofrom that is positively and negatively regulated by cytokines and glucocorticoids, respectively,
Figure 40.1 Structures of several different nonsteroidal anti-inflammatory drugs revealing the wide variation in chemical structures of the compounds that are grouped into this one therapeutic class.

Figure 40.2 Pathway for the formation of prostaglandins. COX, cyclooxygenase; CRTH2, chemoattractant receptor-homologous molecule; DP, PGD receptor; EP1, EP2, EP3, EP4, PGE receptors; FPα, PGF receptor α; FPβ, PGF receptor β; IP, PGI receptor; PG, prostaglandin; TPα, TXA2 receptor α; TPβ, TXA2 receptor β; TXA2, thromboxane A2.
was long suspected, but it was only in the early 1990s that an inducible COX isoenzyme (COX-2) was successfully cloned.\(^\text{15}\) The identification of two COX isoforms, COX-1 and COX-2, has generated intense effort to characterize the relative contribution of each isoform to prostanoid production in specific situations. The development of isoform-specific antagonists has been extremely useful, first as experimental tools and, more recently, for clinical therapy.

Both COX-1 and COX-2 isoenzymes are composed of three independent folding units: (1) an epidermal growth factor–like domain, (2) a membrane-binding moiety, and (3) an active enzymatic domain that consists of a long hydrophobic channel.\(^\text{16}\) Despite their remarkable structural similarity, the two COX isoforms have different gene expression profiles, distinct kinetic properties, and different interactions with phospholipase A\(_2\) and synthases.\(^\text{17}\) The genes for COX-1 and COX-2 are located on human chromosomes 9 and 1, respectively.\(^\text{18}\) Whereas COX-1 represents a housekeeping gene that lacks a TATA box, the promoter of the immediate-early gene COX-2 contains a TATA box and binding sites for several transcription factors, including the nuclear factor κB (NF-κB), the nuclear factor for interleukin-6 (IL-6) expression (NF-IL-6), and the cyclic adenosine monophosphate (cAMP) response element–binding protein.\(^\text{19}\)

COX-1 is expressed constitutively and produces prostanoids that fine-tune physiologic processes requiring instantaneous or continuous regulation (e.g., hemostasis).\(^\text{16}\) COX-2 expression is usually low but can be induced by numerous factors, including neurotransmitters, growth factors, proinflammatory cytokines, lipopolysaccharide, calcium, phospholipids, and small-peptide hormones.\(^\text{20}\) However, there are exceptions to the original constitutive versus inducible theory of COX expression. COX-1 expression can be induced in some stress conditions, such as nerve injury, whereas many tissues, including the central nervous system (CNS) and kidney, constitutively express COX-2.\(^\text{20}\) In the spinal cord there are detectable basal levels of both COX-1 and COX-2, which might enable immediate reactions to release of transmitter that result in prostanoid production.\(^\text{21}\)

It has been suggested that there is another COX enzyme formed as a splice variant of COX-1, known as COX-3.\(^\text{22}\) Canine COX-3 expressed by transfected insect cells can be inhibited by therapeutic concentrations of analgesic or antipyretic drugs, such as acetaminophen, phenacetin, aspirin, and dipyrone. However, it has been reported that this COX-1 variant (COX-3) is not expressed in humans, \(^\text{23}\) rats, or mice because the corresponding additional intron 1 sequence in the mRNA transcript spans 94 (human) or 98 (rat and mouse) nucleotides, thus shifting the coding sequence out of frame.\(^\text{24,25}\)

PERIPHERAL AND CENTRAL INDUCTION OF COX-2

The original hypothesis formulated by Vane in his Nobel Prize–winning work on the mechanism of action of NSAIDs was that these compounds inhibit prostanoid production in the periphery, thereby preventing a sensitizing action of PGE\(_2\) on the peripheral terminals of sensory fibers.\(^\text{26}\) More recently, peripheral inflammation has also been shown to induce a widespread increase in COX-2 and PGE\(_2\) synthase expression in the CNS. The proinflammatory cytokine IL-\(\beta\) is upregulated at the site of inflammation and plays a major role in inducing COX-2 in local inflammatory cells by activating NF-κB.\(^\text{28}\) IL-\(\beta\) is also responsible for induction of COX-2 in the CNS in response to peripheral inflammation, but this is not the result of neural activity arising from sensory fibers innervating the inflamed tissue or the result of systemic IL-\(\beta\) in plasma. Instead, peripheral inflammation produces some other signaling molecule that enters the circulation, crosses the blood-brain barrier, and acts to elevate IL-\(\beta\) levels, which leads to COX-2 expression in neurons and non-neuronal cells in many different areas of the spinal cord.\(^\text{4,29}\) An elevation in COX-2 also occurs at many levels in the brain and spinal cord, mainly in the endothelial cells of the brain vasculature.\(^\text{30}\)

Thus, there appear to be two forms of input from peripheral inflamed tissue to the CNS. The first is mediated by electrical activity in sensitized nerve fibers innervating the inflamed area, which signals the location of the inflamed tissue, as well as the onset, duration, and nature of any stimuli applied to this tissue.\(^\text{26}\) This input is sensitive to peripherally acting COX-2 inhibitors and neural blockade with local anesthetics, such as occurs with epidural anesthesia.\(^\text{31}\) The second is a humoral signal originating from the inflamed tissue that acts to produce widespread induction of COX-2 in the CNS. This input is not affected by regional anesthesia\(^\text{29,32}\) and can be blocked only by centrally acting COX-2 inhibitors.\(^\text{29,31}\) This implies that patients undergoing neuraxial anesthesia for surgery also need a centrally acting COX-2 inhibitor for optimal reduction of postoperative pain and the postoperative stress response.\(^\text{31}\)

It is therefore clear that the permeability of the blood-brain barrier to currently used NSAIDs and COX-2 inhibitors is important.\(^\text{33,34}\) Inhibitors of COX-2 that penetrate the blood-brain barrier more effectively might represent more efficient painkillers and could also act to reduce many of the more diffuse aspects of inflammatory pain, such as generalized aches and pains, depression, and loss of appetite, which are key aspects in determining the quality-of-life response to treatment.\(^\text{35}\) The main process whereby a drug passes from the bloodstream to the CNS is passive diffusion, for which lipophilicity and ionization are critical determinants of transfer.\(^\text{36}\) CSF represents a convenient sampling point for drugs that enter the CNS; however, there are very few NSAIDs for which CSF pharmacokinetics has been defined. For example, the CSF-to-plasma concentration ratio of oxyphenbutazone has been determined to be 0.0074 (0.7%). This ratio is close to the free fraction of oxyphenbutazone in plasma, which is about 0.5%. The high lipid solubility of indomethacin allows it to cross into CSF rapidly and equilibrate with the free plasma concentration.\(^\text{38}\) Similar results have been noted with ketoprofen.\(^\text{39}\)

PROSTANOID RECEPTORS: EXPRESSION, REGULATION, AND FUNCTION

The first prostanoid receptor to be isolated and cloned was the thromboxane A\(_2\) (TXA\(_2\)) receptor,\(^\text{40}\) a guanine (G) protein–coupled receptor with seven transmembrane domains. Homology screening of complementary DNA (cDNA) libraries has resulted in the isolation and identification of seven other prostanoid receptors that had been predicted pharmacologically: the PGD receptor (DP), four PGE receptors (EP\(_1\), EP\(_2\), EP\(_3\), and EP\(_4\)), the PGF receptor (FP), and the PGI receptor (IP). Prostanoid receptors are expressed
in many tissues and cell types. Among the EP receptors, EP₃ and EP₄ are the most widely distributed, whereas the distribution of EP₁ and EP₂ is restricted to the kidney, stomach, and uterus, as well as to neuronal and non-neuronal cells in the nervous system.⁴¹ EP₁, EP₃, and EP₄ mRNA is expressed in primary sensory neurons in the dorsal root and trigeminal ganglia,⁴² thus suggesting involvement in PGE₂-mediated peripheral sensitization. Inflammation affects the level of expression of many prostanoid receptor subtypes. Further studies are needed to determine which of the EP receptors are involved in analgesia and their respective antagonists.

Inhibition of PG biosynthesis may only partly explain the therapeutic effects of NSAIDs.⁴³ Another postulated mechanism includes interactions with the adenylate cyclase system. Indomethacin and some other NSAIDs inhibit phosphodiesterase, thereby elevating the intracellular concentration of cAMP.⁴⁴

### PHARMACOKINETICS

NSAIDs are weak acids with pKₐ values typically lower than 5. Because weak acids will be 99% ionized 2 pH units above their pKₐ, these anti-inflammatory agents will be present in the body mostly in the ionized form.

#### GENERAL FACTORS AFFECTING NSAID PHARMACOKINETICS

Although NSAIDs differ in their individual pharmacokinetic properties, some general factors affecting NSAID pharmacokinetics can enable clinicians to select among the different agents available.

**ABSORPTION**

Most NSAIDs are absorbed rapidly following oral administration, and peak plasma concentrations are generally reached within 2 to 3 hours after administration. Slow-release dosage forms have been developed to maintain active plasma levels for prolonged periods. Factors affecting gastric emptying may have a profound effect on the time course of the clinical effect of the NSAID administered. The extent of drug absorption from the gastrointestinal (GI) tract is more important than the rate.⁴⁵ The rectal route of administration has been used to minimize GI side effects, which are a common feature of these agents. In general, the rate and extent of NSAID absorption are comparable for the rectal and oral routes.⁴⁶

**DISTRIBUTION**

All NSAIDs are lipid soluble, weakly acidic, and highly bound to plasma proteins, with the exception of aspirin. In most cases, less than 1% of the total plasma concentration is in the unbound form. Albumin is the major binding protein for NSAIDs. Disease conditions that cause hypoalbuminemia will result in an increased free fraction of NSAIDs in plasma, thus affecting the distribution and elimination of these agents.⁴⁷ Most NSAIDs have distribution volumes between 0.1 and 0.15 L/kg.

In inflammatory joint diseases, the effect of an NSAID is related to its level in the affected synovial fluid. This level correlates closely with the concentration of drug at the active site because there is simple transport of drugs across the synovial membrane.⁴⁸,⁴⁹ The amount of drug in synovial fluid is dependent on the level of albumin in the joint, which is lower than in plasma.⁵⁰

**ELIMINATION**

Hepatic biotransformation is the main elimination pathway for most NSAIDs.⁵¹ Most are metabolized by cytochrome P-450–mediated oxidation, glucuronide conjugation, or both. Renal excretion of nonmetabolized drug is a minor elimination pathway for most NSAIDs and accounts for less than 10% of the administered dose. Some NSAID metabolites are also excreted to a significant extent in bile.

### PATHOPHYSIOLOGIC CONDITIONS AFFECTING NSAID KINETICS

Renal failure and hepatic disease are common disorders that affect the kinetics of NSAIDs.

**RENA L FAILURE**

Renal failure has a variety of influences on drug kinetics, not only by reducing the renal excretion of drugs and metabolites normally excreted in urine but also by affecting the absorption, distribution, and biotransformation of drugs.

**Absorption and Distribution**

Absorption of NSAIDs is not impaired in patients with renal failure. However, the plasma protein binding of many acidic compounds such as the NSAIDs is impaired in those with renal failure.⁵² The result is an increase in the volume of distribution of the unbound fraction of the drug in plasma.

**Elimination**

An increase in the unbound fraction of the drug in plasma may lead to an increase in total plasma clearance of the NSAID. The clearance of NSAIDs (e.g., diflunisal, ketoprofen, naproxen, indoprofen, benoxaprofen, tiaprofenic acid) for which the formation of acyl glucuronides is a major elimination pathway is significantly reduced in patients with renal failure.⁵³ The effect of renal failure on the oral clearance of several other NSAIDs (e.g., ibuprofen, fenbufen, isoxicam, piroxicam) is small.⁵⁴ Most of these compounds are metabolized by oxidative pathways. All NSAIDs are highly bound to plasma proteins, and hemodialysis will probably not result in increased elimination of these agents. No dosage adjustments are therefore necessary for patients being administered NSAIDs who are undergoing hemodialysis.⁵⁴

### HEPATIC DISEASE

Impaired liver function can affect the disposition of NSAIDs.

**Absorption and Distribution**

Most NSAIDs are low-clearance drugs, and liver disease should theoretically not be expected to interfere with the oral bioavailability of these agents. Because the liver is the major organ for the synthesis of albumin, the major binding protein for NSAIDs in plasma, it would be expected that hepatic dysfunction could lead to alterations in the unbound drug fraction present in plasma.
Aspirin inhibits the biosynthesis of PGs by irreversible acetylation and consequent inactivation of COX. This is in contrast to the action of newer NSAIDs, which are reversible inhibitors of the COX enzyme.\textsuperscript{57} Although most cells can synthesize new COX, platelets cannot; thus, the acetylation of their microsomal enzyme lasts for the life of the platelet (10 to 14 days). The ability of aspirin to acetylate proteins may be one reason for its superiority over other salicylate derivatives as an anti-inflammatory agent. Of all the NSAIDs, only aspirin has been associated with Reye’s syndrome, a combination of seizures, coma, and sometimes death related to the use of aspirin during a viral illness in children.\textsuperscript{58}

**DIFLUNISAL**

Diflunisal is potentially better tolerated in the GI system because it is not metabolized to salicylic acid in plasma, based on a study comparing diflunisal, 250 and 500 mg twice daily, with aspirin, 600 mg four times daily.\textsuperscript{59} It has a short half-life relative to aspirin and causes less inhibition of platelets than aspirin does.\textsuperscript{60}

**CHOLINE MAGNESIUM TRISALICYLATE AND SALSALATE**

Both are nonacetylated salicylates that have minimal effect on platelet function and less effect on the GI mucosa than their acetylated counterparts do. They produce similar analgesia and blood levels of salicylate as those of the acetylated class.\textsuperscript{61}

**ACETAMINOPHEN**

Acetaminophen is a $\text{p}$-aminophenol derivative with analgesic and antipyretic properties comparable to those of aspirin. Antipyresis probably occurs because of direct action on the hypothalamic heat-regulating centers via the inhibiting action of endogenous pyrogen.\textsuperscript{62} Recently, it has been hypothesized that acetaminophen may be acting via the serotonergic pathway to provide analgesia.\textsuperscript{63} Though equipotent to aspirin in inhibiting central PG synthesis, acetaminophen exhibits no significant peripheral PG synthetase inhibition. Doses of 650 mg have been shown to be more effective than doses of 300 mg, but little additional benefit is seen at doses higher than 1000 mg, thus indicating a possible ceiling effect.\textsuperscript{64}

Acetaminophen has few side effects in the usual dosage range; no significant GI toxicity or functional changes in platelets occur. It is almost entirely metabolized in the liver, and the minor metabolites are responsible for the hepatotoxicity seen with overdose.\textsuperscript{65} Inducers of the cytochrome P-450 enzyme system in the liver (e.g., alcohol) increase the formation of metabolites and therefore increase hepatotoxicity. In certain patients (chronic ethanol users, patients suffering from malnutrition, and fasting patients), repeating therapeutic or slightly excessive doses may precipitate hepatotoxicity. A dosage of 2600 to 3200 mg/day may represent a safer chronic daily dosage, and dosing should not exceed 4 g/day.\textsuperscript{66} Toxic doses may be a function of baseline glutathione levels and other dose-related factors. Acetaminophen is completely and rapidly absorbed following the oral route. Peak serum concentrations are achieved within 2 hours of a therapeutic dose; therapeutic serum concentrations are 10 to 20 $\mu$g/mL.\textsuperscript{67} About 90% of acetaminophen is hepatically metabolized to sulfate and glucuronide conjugates for renal excretion, with a small amount being secreted unchanged in urine.\textsuperscript{68}
The bioavailability of rectally administered acetaminophen is variable. It is approximately 80% that of tablets, and the rate of absorption is slower, with the maximum plasma concentration being achieved about 2 to 3 hours after administration.\textsuperscript{69} Doses of 40 to 60 mg/kg of rectal acetaminophen have been shown to have an opioid-sparing effect in postoperative pain models.\textsuperscript{70} Propacetamol, an injectable prodrug of paracetamol, is completely hydrolyzed within 6 minutes of administration, and 1 g of propacetamol yields 0.5 g of paracetamol. Injectable paracetamol has been shown to reduce opioid consumption by about 35\% to 45\%.\textsuperscript{71} in postoperative pain studies.\textsuperscript{72} In a study examining the analgesic serum concentrations of paracetamol, it was demonstrated that a ceiling effect of paracetamol may be present at intravenous doses of 5 mg/kg, which corresponds to a serum concentration of 14 mg/mL.\textsuperscript{73} Recently, an intravenous form of acetaminophen has become available. One gram of injectable acetaminophen is equivalent to 2 g of propacetamol and has a lower incidence of pain at the injection site.\textsuperscript{74} Intravenous acetaminophen has been demonstrated to be an effective adjunctive analgesic after orthopedic, ear-nose-throat, and dental surgery.\textsuperscript{75-77} Intravenous acetaminophen also provided analgesia superior to that with oral acetaminophen after cardiac surgery.\textsuperscript{78}

**ACETIC ACID DERIVATIVES**

This group of NSAIDs contains two subclasses, pyrrole acetic acids (indomethacin, sulindac, tolmetin, ketorolac, etodolac) and phenylacetic acids (diclofenac, bromfenac).

**INDOMETHACIN**

Indomethacin has good oral and rectal absorption, although the extent of absorption varies widely among patients. There is also large interpatient variability in its elimination half-life as a result of extensive enterohepatic recirculation of the drug. It is highly bound to albumin. Metabolism involves demethylation and deacetylation in the liver, with subsequent excretion of inactive metabolites and unchanged drug in bile and urine.\textsuperscript{79} Its clinical application is somewhat limited by a relatively high incidence of side effects (primarily gastritis and renal dysfunction), but it is used in patients with acute gouty arthritis and osteoarthritis.

**SULINDAC**

Sulindac was developed as the result of a search for a drug similar to indomethacin but with lower toxicity. The GI toxicity associated with sulindac may be lower because it is an inactive prodrug that is converted after absorption by liver demethylation and deacetylation in the liver, with subsequent excretion of inactive metabolites and unchanged drug in bile and urine.\textsuperscript{80} It is eliminated from plasma, predominantly by excretion in bile, but is subject to enterohepatic circulation. Peak plasma levels of 0.1 to 0.2 mg/100 mL occur 2 to 3 hours after an oral dose of 200 mg. Steady-state plasma levels of the sulfide are reached after 4 to 5 days of therapy with 200 mg twice daily by mouth. It is available in 150- and 200-mg tablets and administered twice daily for the treatment of gouty arthritis, osteoarthritis, and various inflammatory diseases.\textsuperscript{82}

Huskinson and Scott\textsuperscript{82} reported that only 25% of patients have GI problems with sulindac; constipation is common. Sulindac seems to have less effect on the CNS than indomethacin does, possibly because it has an indene nucleus, rather than the indole nucleus present in indomethacin and serotonin, an important mediator in the CNS.

**TOLMETIN AND ETODOLAC**

Both these drugs have fewer side effects than other NSAIDs do. Tolmetin is available in 100- and 200-mg tablets and has a half-life of 60 minutes. It is excreted in urine partly unchanged, partly conjugated, and as an inactive dicarboxylic acid metabolite. Tolmetin can cause edema because of sodium retention and abnormal liver function, both of which are reversible on discontinuation of this NSAID.

Etodolac is an acidic compound with a $pK_a$ of 4.65. It is manufactured as tablets and capsules, with a normal dosage ranging from 1 to 1.2 g daily. Clinical doses of 200 to 300 mg twice daily for the relief of low back or shoulder pain have been equated to analgesia with naproxen, 500 mg twice daily.\textsuperscript{84} From large clinical trials it has been found that the incidence of abdominal pain and dyspepsia is similar to that with several other NSAIDs and GI ulceration develops in less than 0.3% of patients.\textsuperscript{85} Dyspepsia occurs in 10% of patients taking etodolac, with a somewhat lower incidence of abdominal pain.

**KETOROLAC**

Ketorolac is currently the most commonly used parenteral NSAID in the United States. Although indomethacin has been available as an injectable form for years, it was used only in low dosages for the treatment of patent ductus arteriosus. Ketorolac is almost entirely bound to plasma proteins (more than 99\%), which results in a small apparent volume of distribution, and it is extensively metabolized by conjugation and excreted via the kidney.\textsuperscript{86} Its analgesic effect occurs within 30 minutes, its maximum effect takes place in 1 to 2 hours, and it has a duration of analgesia of 4 to 6 hours.\textsuperscript{87} Ketorolac has been demonstrated to be efficacious in treating postoperative pain in several studies, both as a single agent and as an adjunct to opioids.\textsuperscript{88-90} There is evidence that ketorolac may be acting at the CNS in addition to its peripheral mode of action.\textsuperscript{30} Dental surgery studies with ketorolac have also indicated that it acts centrally,\textsuperscript{91} but measurement of drug levels in CSF has demonstrated poor penetration of the compound from plasma.\textsuperscript{92}

Oral ketorolac was approved for use in the United States approximately 3 years after the parenteral form and has an efficacy similar to that of naproxen and ibuprofen.\textsuperscript{93} However, the parenteral form can be administered at single doses of 30 mg intravenously or up to 60 mg intramuscularly. A 30-mg dose can be repeated intravenously or intramuscularly every 6 hours. The oral dose is limited to 10 to 20 mg. Ketorolac should not be used for more than 5 days because of GI toxicity. Since there have been reports of deaths caused by GI and operative site bleeding, the drug’s license was suspended in Germany and France. In response to these adverse events, the drug’s manufacturer recommended reducing the dose of ketorolac from 150 to 120 mg/day.\textsuperscript{87} The European Committee for Proprietary Medicinal Products has recommended a further maximal daily dose reduction to 60 mg for older patients and 90 mg for younger adults. Recent studies have examined the efficacy of this drug when administered intranasally.\textsuperscript{95,96} The intranasal route of administration may offer the added
advantage of better brain penetration via the olfactory route and might provide higher levels of the drug in the CNS and CSF, with minimal GI side effects.

**DICLOFENAC**

Diclofenac has a carboxylic acid functional group and is rapidly and completely absorbed after oral administration. Oral preparations include diclofenac potassium, which is rapidly absorbed in the stomach, and enteric-coated diclofenac sodium, which resists dissolution at low pH and is released in the duodenum. A parenteral form has been used in Europe, with one study showing it to be effective in reducing opioid requirements and reducing pain after thoracotomy.57

Diclofenac sodium has also been tested in clinical trials in a gel form for relief of pain from superficial burns, with good success.98 A Cochrane collaborative meta-analysis showed that diclofenac was effective in treating postoperative pain, with a dose-response relationship demonstrating increasing efficacy of diclofenac at 25-, 50-, and 100-mg doses.99

Diclofenac binds extensively to plasma albumin.100 Substantial concentrations of the drug are attained in synovial fluid, which may be one of the sites of action of diclofenac.101 Concentration-effect relationships have been established for total bound, unbound, and synovial fluid diclofenac concentrations.102 Diclofenac is eliminated following biotransformation to glucuronon conjugated and sulfate metabolites, which are excreted in urine, and very little drug is eliminated unchanged.

Diclofenac differs from other NSAIDs in that it has a high first-pass effect and hence lower oral bioavailability. Diclofenac may also be associated with a significantly higher incidence of hepatotoxicity than other NSAIDs. The excretion of conjugates may be related to renal function. Accumulation of conjugates occurs in patients with end-stage renal disease; however, no accumulation is apparent on comparison of younger and older adults.103 Dosage adjustments in older adults, children, or patients with various disease states (e.g., hepatic disease, rheumatoid arthritis) may not be required. Significant drug-drug interactions have been demonstrated with aspirin, lithium, digoxin, methotrexate, cyclosporine, cholestyramine, and colestipol.104

**PROPIONIC ACID DERIVATIVES**

This class of compounds includes ibuprofen, fenoprofen, ketoprofen, flurbiprofen, and naproxen. A newer drug in this class is oxaprozin, which has received attention because of its once-daily dosage regimen, but it has no distinct advantage over other NSAIDs.105

**IBUPROFEN**

Ibuprofen is well absorbed, and peak plasma levels of 15 to 20 µg/mL are achieved about 1 to 2 hours after a single dose. Its half-life is about 3.5 hours. An intravenous form of ibuprofen has been developed, and an 800-mg intravenous dose is well tolerated and results in faster and higher peak drug levels but a similar total bioavailability and elimination profile as oral dosing.106 The drug is metabolized mostly in the liver, with less than 10% excreted unchanged in urine and bile.107 Ibuprofen at a dose of 1200 mg/day produces effective analgesia in arthritis patients. At the high end of the recommended dosage, 2400 mg/day, it produces GI side effects, of which nausea and dyspepsia are predominant. Renal side effects of ibuprofen appear to be dose-dependent and have not been reported at the recommended over-the-counter drug dosage (0.2 to 0.8 g/day). Even at anti-inflammatory dosages (>1.6 g/day), renal side effects are almost exclusively encountered in patients with low intravascular volume and low cardiac output, particularly in older adults.108 Ibuprofen antagonizes the irreversible platelet inhibition induced by aspirin. Therefore, treatment of patients at increased cardiovascular risk with ibuprofen may limit the cardioprotective effects of aspirin.109

**KETOPROFEN**

Ketoprofen is available in oral form and reaches its peak plasma level in 0.5 to 2 hours. Its half-life is 2.4 hours, with an analgesic duration of 4 to 6 hours.110 The maximum recommended dosage is 300 mg/day. Pharmacokinetic data indicate that plasma levels of ketoprofen with oral administration (100 mg) are higher than when applied via a patch. Ketoprofen, 100 mg, has been tried as a patch to directly deliver the compound to the site of injury. Because the patch facilitates delivery of ketoprofen over a 24-hour period, the drug remains continually present in the tissue adjacent to the site of application. High tissue but low plasma ketoprofen concentrations mean that although tissue concentrations are high enough to exert a therapeutic effect, plasma concentrations remain low enough to minimize systemic adverse events.111

**FENOPROFEN**

The calcium derivative of fenoprofen is more commonly used; it is well absorbed and achieves a peak plasma level of 20 to 50 µg/mL 2 hours after a single oral dose, with a plasma half-life of 2 to 3 hours.112 The drug is available as 500-mg capsules, and the recommended dosage is 2.4 g/day. Steady-state plasma levels are reached within the first 24 hours of therapy. Fenoprofen is well tolerated in comparison to aspirin and causes minimal occult GI bleeding; nevertheless, dyspepsia remains its most common side effect. Most of the drug is excreted as glucuronide in urine.

**NAPROXEN**

Naproxen is well absorbed in the upper GI tract and is highly bound to plasma albumin. Because of its long half-life of 13 hours, it is suitable for twice-daily administration.113 Equilibrium is reached in about 3 days. Excretion is almost entirely in urine, mainly as an inactive glucuronide metabolite. Naproxen is available as 250-, 375-, and 500-mg tablets and has been used for the treatment of arthritis and other inflammatory diseases, with efficacy superior to that of aspirin.114 It causes less GI irritation than aspirin does. Naproxen increases bleeding time by inhibiting platelet aggregation. When given during pregnancy, it can cross the placenta in 20 minutes and cause neonatal jaundice.

**OXAPROZIN**

Oxaprozin is effective in the management of adult rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, soft tissue disorders, and postoperative dental pain. It has high oral bioavailability (95%), with peak plasma concentrations being achieved 3 to 5 hours after dosing.113 It is metabolized in the liver by oxidative and conjugative pathways and readily
eliminated by the renal and fecal routes. The strong analgesic qualities of oxaprozin are particularly useful for painful musculoskeletal conditions because, for example, it inhibits COX-1 and COX-2 isoenzymes, inhibits nuclear translocation of NF-κB and metalloproteinases, and modulates the endogenous cannabinoid system. In a randomized study of patients with refractory shoulder pain, oxaprozin, 1200 mg once daily, was superior to three doses per day of diclofenac (50 mg) in reducing pain and improving quality of life.

Oxaprozin can diffuse easily into inflamed synovial tissue after oral administration. Though discovered more than 20 years ago, it is now under intensive investigation because of its unusual pharmacodynamic properties. Other than being a nonselective COX inhibitor, the drug is capable of inhibiting both anandamide hydrolyase in neurons, with consequent potent analgesic activity, and NF-κB activation in inflammatory cells. Moreover, oxaprozin induces apoptosis of activated monocytes in a dose-dependent manner. Because the monocyte, macrophage, and NF-κB pathways are crucial for the synthesis of proinflammatory and histotoxic mediators in inflamed joints, oxaprozin appears to have pharmacodynamic properties exceeding those presently assumed as markers of classic NSAIDs.

OXICAM DERIVATIVES

The only NSAID in this class in clinical use is piroxicam. Unlike other NSAIDs, the peak serum concentration following oral dosing is attained more slowly, with a duration of 5.5 hours. It is notable for its long elimination half-life, 48.5 hours, so up to 1 week may be needed to achieve steady-state blood concentrations, although it does also allow once-daily dosing.

PYRAZOLONE DERIVATIVES

The only drug in clinical use in this class is phenylbutazone. Although phenylbutazone is a very effective anti-inflammatory and analgesic, its clinical use has been severely limited because of an association with aplastic anemia and agranulocytosis.

ANTHRANILIC ACID DERIVATIVES

These NSAIDs are unique because they block PG synthesis and the tissue response to PGs. Mefenamic acid has been associated with severe pancytopenia and many other side effects. Therefore, it cannot be used for longer than 1 week. Meclofenamate has a high incidence of GI toxicity and is also not a first-line drug. It is well absorbed orally; peak plasma levels are reached after 2 hours, with a half-life of about 4 to 6 hours.

NAPHTHYLALKANONES

This newer class of NSAIDs is most noted for its nonacidic chemical structure, similar to naproxen but unlike that of other clinically used NSAIDs. The only clinically available NSAID in this class is nabumetone. Studies have shown that its use results in fewer gastric lesions than occur with aspirin, naproxen, or ibuprofen. Also, dosages of 1 g/day for 7 days in volunteers resulted in no changes in bleeding time. Only 35% of the drug is converted to its active form after oral administration. None of the parent drug can be measured in plasma after oral administration because of the rapid biotransformation that occurs during the first-pass effect, which makes nabumetone a prodrug.

MELOXICAM

Meloxicam is a relatively new NSAID approved for the treatment of osteoarthritis in the United States. It has also been evaluated for the treatment of rheumatoid arthritis, ankylosing spondylitis, and acute rheumatic pain. Meloxicam has been shown to be COX-2 preferential, particularly at its lowest therapeutic dose, and to exert an anti-inflammatory action by inhibiting prostanoid synthesis in inflammatory cells. Because it is COX-2 preferential, it would be expected to have less GI toxicity than nonselective NSAIDs do. In clinical trials of meloxicam for osteoarthritis, it was found to be as effective as piroxicam, diclofenac, and naproxen, with fewer GI symptoms and a lower incidence of perforation, obstruction, and bleeding.

Meloxicam has a plasma half-life of approximately 20 hours and is convenient for once-daily administration in 7.5- and 15-mg tablets. Neither moderate renal nor hepatic insufficiency has significantly altered the pharmacokinetics of meloxicam in short-term studies; however, it should not be used in patients with renal failure. Furthermore, dose adjustment is not required in older adults. Drug interaction studies have demonstrated that meloxicam interacts with some medications, including cholestyramine, lithium, and some inhibitors of cytochrome P-450 2C9 and 3A4. Consequently, increased clinical vigilance should be maintained when co-prescribing some medications with meloxicam. No interactions have been observed following the concomitant administration of food, antacid, aspirin, β-acetyldigoxin, methotrexate, warfarin, or furosemide.

Concentration-dependent therapeutic and toxicologic effects have yet to be extensively elucidated for meloxicam. Its pharmacokinetic profile is characterized by prolonged, almost complete absorption, and the drug is more than 99.5% bound to plasma proteins. Meloxicam is metabolized to four biologically inactive main metabolites, which are excreted in urine and feces. Steady-state plasma concentrations are achieved within 3 to 5 days. The pharmacokinetic parameters of meloxicam are linear over the dose range of 7.5 to 30 mg, and bioequivalence has been shown for a number of different formulations.

COX-2 INHIBITORS

COX-2-specific inhibitors were developed with the aim of reducing the incidence of serious GI adverse effects associated with the administration of traditional NSAIDs, the assumption being that these side effects were mediated by COX-1. Assessment of COX-1 and COX-2 selectivity in vitro in whole-blood assays (Table 40.2) of the cellular capacity to produce prostanoids has shown that selectivity is a continuous variable of COX inhibitors.

The initial COX-2 inhibitors approved by the U.S. Food and Drug Administration (FDA) were celecoxib and rofecoxib. Overall, a meta-analysis of clinical studies evaluating COX-2 inhibitors versus traditional NSAIDs for postoperative
pain has shown that the analgesic efficacy of COX-2 inhibitors 0 to 6 hours postoperatively is similar to or better than that of ibuprofen. The initial clinical trials using COX-2 inhibitors for the management of pain evaluated efficacy in the immediate postoperative period and demonstrated a reduction in postoperative opioid consumption. A meta-analysis examined the advantage of multimodal analgesia with acetaminophen, with NSAIDs, and when COX-2 inhibitors were added to patient-controlled analgesia with morphine. The results suggested that all the analgesic agents provide an opioid-sparing effect (25% to 55%). The use of nonselective NSAIDs was associated with a decrease in the incidence of postoperative nausea, vomiting, and sedation. In addition, the use of COX-2 inhibitors or acetaminophen did not decrease the incidence of opioid-related adverse events when compared with placebo. Clinical trials of COX-2 inhibitors used during the preoperative period and into the postoperative period (2 weeks) for patients of COX-2 inhibitors used during the preoperative period and, the postoperative period (2 weeks) for patients undergoing both major surgery and minimally invasive surgery have demonstrated improved clinical outcomes. Perioperative administration of COX-2 inhibitors for total joint arthroplasty has been shown to result in a reduction in perioperative pain and improvement in outcomes without the added risk of increased perioperative bleeding.

It was recently demonstrated that perioperative administration of oral COX-2 inhibitors can reduce CSF PGE2 levels in humans during the perioperative period, which has resulted in improved outcomes following hip replacement surgery. In addition to the effect on CSF PGE2, COX-2 inhibitors were able to modulate the level of CSF IL-6. The exact mechanism responsible for the reduction in interleukin level has yet to be determined but is probably related to the PGE2 pathway.

**CELECOXIB**

Celecoxib was the first COX-2 inhibitor approved by the FDA (December 1998). It has now been approved for the relief of pain from osteoarthritis, rheumatoid arthritis, acute pain, dysmenorrhea, and familial adenomatous polyposis. It has good selectivity for the COX-2 enzyme (see Table 40.2). Celecoxib is available in 100-, 200-, and 400-mg capsules, with a maximum recommended dosage of 400 mg/day for chronic pain. The dose recommended for the management of acute pain is 400 mg followed by 200 mg within the first 24 hours. If celecoxib is administered with aluminum- or magnesium-containing antacids, plasma levels of celecoxib are reduced. Peak plasma levels occur 3 hours after oral administration, and the drug crosses into CSF. Celecoxib is 97% protein bound, with an apparent volume of distribution of 400 L. It is metabolized via cytochrome P450 2C9 and eliminated predominantly by the liver. It is not indicated for pediatric use and is a category C drug for pregnancy. The drug has a half-life of about 11 hours. Adverse events noted in the various clinical trials include headache, edema, dyspepsia, diarrhea, nausea, and sinusitis. It is contraindicated in patients with sulfonamide allergy or known hypersensitivity to aspirin or other NSAIDs. Because celecoxib does not interfere with platelet function, it can be administered perioperatively as a multimodal analgesic without increasing the risk for bleeding. The incidence of NSAID gastropathy may also be lower with celecoxib than with nonselective NSAIDs.

**ROFECOXIB**

Rofecoxib is a selective COX-2 inhibitor indicated for use in patients with osteoarthritis, rheumatoid arthritis, dysmenorrhea, and acute pain. The drug is administered orally, its bioavailability is 93%, and 87% of the absorbed dose is bound to plasma proteins. The metabolism of rofecoxib in the liver yields metabolites that have no COX-1 or COX-2 activity. Though metabolized by the liver, adjustment in dosage for patients with liver disease is not necessary. The metabolites are predominately eliminated from the body in urine. Analgesic efficacy occurs 0.7 to 1.5 hours after oral dosing and continues for more than 24 hours. Steady-state plasma concentrations of rofecoxib are achieved after 4 days, a function of its 17-hour half-life. It is supplied in 12.5-, 25-, and 50-mg tablets, including a suspension (5 mL contains 12.5 mg/5 mL or 25 mg/5 mL).

When compared with other NSAIDs, rofecoxib has less effect on the GI mucosa and therefore has less likelihood of GI complications; adverse events reported with rofecoxib include dyspepsia, peripheral edema, and hypertension. Because rofecoxib has no effect on platelet aggregation and has minimal interaction with warfarin, it has been used extensively in the perioperative arena as a preemptive analgesic for various types of surgeries. Larger clinical trials and long-term follow-up studies undertaken to demonstrate the efficacy of this compound in the prevention of cancer have demonstrated an increased incidence of cardiovascular events, which prompted voluntary withdrawal of rofecoxib by the manufacturer in 2004 (see more detailed discussion later).

**VALDECOXIB AND PARECOXIB**

Valdecoxib is a derivative of isoxazole and binds noncovalently to COX-2 to form a tight and relatively stable enzyme-inhibitor complex. It is a potent inhibitor of PGE2 production in humans. Valdecoxib and its metabolites are also the active moieties of a parenteral COX-2 inhibitor, parecoxib sodium. Valdecoxib has good oral bioavailability (83%) and a minimal first-pass effect. It achieves its maximal plasma concentration in 3 hours, with an elimination half-life of about 8 to
11 hours. It is metabolized by the liver via the cytochrome P450 3A4 isoenzyme. About 70% of the dose is excreted in urine as metabolites. Valdecoxib has been approved for use in patients with osteoarthritis (10 mg), rheumatoid arthritis (10 mg), and acute pain (up to 40 mg). Several clinical studies have demonstrated the efficacy of valdecoxib in patients undergoing oral surgery and major orthopedic surgery at doses of 40 mg. Common adverse events reported include GI and renal toxicity. Clinical studies in high-risk cardiac patients in which a significantly increased incidence of major cardiovascular adverse events and increased risk for serious skin reactions (e.g., toxic epidermal necrolysis, Stevens-Johnson syndrome, erythema multiforme) were demonstrated led to withdrawal of this COX-2 inhibitor from the U.S. market in 2005.

New COX-2 inhibitors that are in clinical use in Europe include etoricoxib and lumiracoxib. However, these drugs have not yet been approved by the FDA. Concerns about their cardiovascular risk profile are as yet unresolved.

ETORICOXIB

Etoricoxib (MK-663) is a dipyridinyl derivative that contains a phenyl group attached to the central ring. Etoricoxib is highly selective for COX-2 (IC50 ratio, 344; see Table 40.2), with substantial distribution into tissue and 92% bound to plasma. It is distributed rapidly, with the peak concentration being reached within 1 to 2 hours, and has an elimination half-life of approximately 22 hours. Etoricoxib is metabolized via cytochrome P-450-dependent oxidation, which results in prolonged elimination in patients with liver disease. The highest recommended daily dosage for chronic use is 60 to 90 mg; for acute pain, the dose is 120 mg.

Clinical trials of etoricoxib have demonstrated its analgesic efficacy for various types of arthritis, acute dental pain, dysmenorrhea, and chronic pain conditions such as back pain. Adverse effects include GI, renal, and cardiovascular manifestations. There is a 40% reduction in the relative risk for GI side effects with etoricoxib in comparison to other NSAIDs.

LUMIRACOXIB

Lumiracoxib is structurally distinct from other COX-2 inhibitors; it is a phenylacetic acid derivative with a short mean plasma half-life of 4 hours, but it provides analgesic efficacy for 24 hours with a single dose. It is 99% protein bound, with a volume of distribution of 13 L and a bioavailability of 74% after oral administration. Lumiracoxib has been found to bind and interact with the COX-2 enzyme via a mechanism different from that of other COX-2-selective inhibitors and carboxylic-containing nonselective COX inhibitors. The carboxylate group of lumiracoxib forms hydrogen bonds with the catalytic Tyr385 and with Ser530 on COX-2 rather than with the larger hydrophobic side pocket or with Arg120. Lumiracoxib is highly selective for COX-2 (see Table 40.2). It has been shown clinically to provide analgesia for the treatment of knee osteoarthritis, acute pain after dental surgery, and pain after major joint replacement surgery. Like other COX-2 inhibitors, lumiracoxib has been shown to have a reduced incidence of GI side effects. In a large controlled study (TARGET study) including 18,325 patients, lumiracoxib, 400 mg daily, was shown to cause fewer gastric ulcers than other NSAIDs do; no increase in cardiovascular risk was demonstrated in this study.

COMBINATION DRUGS

To enhance the efficacy and safety of NSAID analgesia, drugs have been formulated in combination with NSAIDs. Formulations of ibuprofen-containing hydrocodone are available, and diclofenac has also been formulated in combination with misoprostol. Although such combinations are more convenient, there is no evidence that they are any more effective or safer than when administered separately. Caffeine, long sold in combination with acetaminophen and aspirin in over-the-counter analgesic preparations, has also been studied in combination with ibuprofen. The effect of the added analgesia from caffeine is measurable but not substantial. The enhanced NSAID analgesia seen in combination with caffeine probably does not result from alterations in absorption or distribution of the NSAID.

An oxycodone-ibuprofen combination, 5 mg/400 mg, is manufactured as Combunox. It is an oral fixed-dose combination tablet with analgesic, anti-inflammatory, and antipyretic properties. It is approved in the United States for short-term use (up to 7 days) in the management of acute, moderate, and severe pain and is the first and only fixed-dose combination of ibuprofen and oxycodone. A single dose of oxycodone-ibuprofen (5 mg/400 mg) provided better analgesia than did low-dose oxycodone or ibuprofen administered alone in most trials. It is generally well tolerated after single or multiple doses, and short-term use is not expected to produce any of the serious adverse effects typically associated with the long-term use of opioids or NSAIDs.

ADVERSE EFFECTS OF NSAIDS

The clinical utility of NSAIDs has been limited greatly by concerns of adverse effects. Such concerns have included inhibition of platelet function and renal and GI effects. Recently, concerns about bone healing and cardiovascular risk have become prominent.

HEMATOLOGIC EFFECTS

Arachidonic acid is converted into the PG endoperoxides PGG2 and PGH2 by the action of COX (see Fig. 40.2). These endoperoxides in turn are converted to TXA2 in platelets by the action of TXA2 synthase, but in vascular endothelium they are converted to PGI2 by the action of PGI2 synthase. TXA2 functions as a platelet activator and vasoconstrictor, whereas PGI2 is a platelet inhibitor and vasodilator. Furthermore, activated platelets divert some of their endoperoxides to vascular cells (“endoperoxide steal”) to provide more substrate for PGI2 formation. Platelet activity, therefore, is the result of a constant balance between the effects of PGI2 in the endothelium and TXA2 in platelets. Platelets are especially vulnerable to COX inhibition because unlike most other cells, they cannot regenerate this enzyme. Presumably, this reflects the inability of platelets to synthesize proteins independently. Thus aspirin, which irreversibly acetylates the COX enzyme, causes inhibition of platelet aggregation for the life span of the platelet, which is 7 to 10 days. In contrast, nonselective NSAIDs reversibly inhibit the COX enzyme and thus cause a transient reduction in the formation of TXA2 and inhibition of platelet activation, which
resolves after most of the drug is eliminated.\textsuperscript{167} A single dose of 300 to 900 mg of ibuprofen can inhibit platelet aggregation for 2 hours after administration, but the effect is largely dissipated by 24 hours.\textsuperscript{167,168} Similarly, both sulindac and diclofenac also cause a short-term (<24 hours) reduction in platelet aggregation. The antiplatelet effects of long-acting NSAIDs such as piroxicam, however, can last for several days after use of the drug is discontinued.\textsuperscript{169}

Studies have shown variable clinical effects of NSAIDs on perioperative bleeding. Most of the studies that have found an association between NSAID use and blood loss have included surgeries with relatively high unsutured tissue surfaces, such as tonsillectomy and total joint replacement. In one study of patients undergoing total hip replacement surgery, those who received NSAIDs had more intraoperative and postoperative blood loss than did those who did not.\textsuperscript{170} A meta-analysis of clinical trials of NSAID use for tonsillectomy showed an increase in post-tonsillectomy bleeding.\textsuperscript{171} Studies have noted more complications in patients given NSAIDs with half-lives longer than 6 hours and when NSAIDs are administered before surgical control of bleeding. Many studies of perioperative NSAIDs have not demonstrated an increased risk for bleeding. No difference was found in clinical blood loss during total hip replacement or transurethral resection of the prostate in patients taking diclofenac versus those taking placebo.\textsuperscript{172,173} A study of ketorolac, 60 mg, administered during anorectal surgery did not find any association with intraoperative or postoperative bleeding.\textsuperscript{174} A meta-analysis of the perioperative use of NSAIDs in patients undergoing a variety of surgical procedures revealed a slight, but statistically significant, risk for “any bleeding” (1.7% vs. 0.2%), as well as “severe bleeding” (1.7% vs. 0%), associated with the perioperative use of nonselective NSAIDs.\textsuperscript{175}

Finally, most NSAIDs potentiate the anticoagulant activity of warfarin by displacing the protein-bound drug or by inhibiting its metabolism by hepatic microsomal enzymes.\textsuperscript{167} Thus, they should be used with caution in patients taking oral anticoagulants, especially older patients, who can have a significant increase in bleeding and hospitalization when the two are used in combination.\textsuperscript{176}

**CARDIOVASCULAR EFFECTS**

NSAIDs and COX-2 inhibitors may cause an increased incidence of serious cardiovascular thrombotic events, myocardial infarction, and stroke.\textsuperscript{177} This effect has been noted most markedly with COX-2 inhibitors. Unbalanced biosynthesis of PGI\(_2\) and TXA\(_2\) seems to play a role in athrogenesis and thrombosis. It is postulated that prolonged administration of COX-2 inhibitors, which inhibit PGI\(_2\), may lead to several adverse effects, including a rise in blood pressure, initiation and early development of atherosclerosis, and architectural and functional responses of blood vessels to such stress. These changes may predispose individuals to an exaggerated thrombotic response on rupture of atherosclerotic plaque.\textsuperscript{178} Aspirin and traditional NSAIDs suppress the activities of COX-1 and COX-2 and therefore reduce both TXA\(_2\) and PGI\(_2\) levels. In contrast, COX-2 inhibitors suppress the production of PGI\(_2\) without affecting TXA\(_2\) synthesis.\textsuperscript{179} These mechanisms may be responsible for the increased incidence of acute myocardial infarction observed with prolonged use of COX-2 inhibitors.\textsuperscript{180}

A fivefold increase in the incidence of myocardial infarction was noted in the Vioxx Gastrointestinal Outcome Research (VIGOR) study.\textsuperscript{181} This study involved the use of rofecoxib, 50 mg daily, for a median of 9 months in a high-risk rheumatoid arthritis patient population in which the use of aspirin was precluded.\textsuperscript{182} Similarly, the Adenoma Polyp Prevention on Vioxx (APPROVe) study, which evaluated a 25-mg daily dose of rofecoxib in patients with a history of colorectal adenoma, demonstrated a 1.7-fold increase in the risk for myocardial infarction and cerebrovascular events associated with rofecoxib that became apparent after 18 months of therapy.\textsuperscript{183} Epidemiologic database studies, which reflected actual drug use and included higher-risk patients, also found a correlation between normal- or high-dose rofecoxib use and adverse cardiovascular outcomes.\textsuperscript{142,183} The drug manufacturer voluntarily withdrew rofecoxib from the world market on September 30, 2004.

Subsequently, on December 17, 2004, the Adenoma Prevention with Celecoxib (APC) trial was halted because of an increased occurrence of cardiovascular events. The APC trial compared the efficacy of celecoxib (200 or 400 mg twice daily) with that of placebo for 33 months in preventing colorectal adenoma.\textsuperscript{183} Celecoxib was associated with a dose-related 2.3- to 3.4-fold increase in serious adverse cardiovascular events, which became apparent after 12 months of treatment. However, two other large long-term placebo-controlled studies had different results. The Prevention of Spontaneous Adenomatous Polyps (PreSAP) trial,\textsuperscript{184} which included patients taking 400 mg of celecoxib daily or placebo for an average of 32 months, found no difference in risk for cardiovascular events. The Alzheimer’s Disease Anti-Inflammatory Prevention Trial (ADAPT)\textsuperscript{185} found no increased risk with celecoxib, 200 mg daily, but noted a statistically significant increase in cardiovascular risk with naproxen.\textsuperscript{186}

Valdecoxib and the parenteral prodrug parecoxib have also been associated with the potential risk for adverse postoperative cardiovascular events, including an increase in cerebrovascular events (2.9% vs. 0.7%) and myocardial infarction (1.6% vs. 0.7%), after the administration of a supramaximal dose (40 mg twice daily) for 14 days following coronary artery bypass graft surgery.\textsuperscript{187} However, no increases in cardiovascular events were observed with therapeutic dosing of parecoxib followed by valdecoxib for general and orthopedic surgery.\textsuperscript{146,148,149}

A joint meeting of the FDA’s Arthritis Advisory Committee and the Drug Safety and Risk Management Advisory Committee was convened in February 2005 to discuss the safety of COX-2 inhibitors and nonspecific NSAIDs. These committees jointly reaffirmed that COX-2 inhibitors are important treatment options for pain management and that the preponderance of data demonstrates that the cardiovascular risk associated with celecoxib is similar to that associated with commonly used older nonspecific NSAIDs.\textsuperscript{177} The rationale behind this conclusion is that COX-2 inhibitors collectively increase cardiovascular risk when compared with placebo but not when compared with nonselective NSAIDs. It was noted that rigorous scientific studies are needed to characterize the longer-term cardiovascular risks associated with these analgesics.

Subsequently, on April 7, 2005, the FDA announced a series of changes applicable to the entire class of NSAIDs.
These included an FDA boxed warning for the potential increased risk for cardiovascular events and GI bleeding associated with all prescription NSAIDs, including celecoxib. The manufacturers were asked to revise their labeling to include a medication guide for patients to help make them aware of the potential for cardiovascular and GI adverse events. In addition, the FDA requested that the manufacturers of all over-the-counter NSAIDs revise their labels to include more specific information about the potential cardiovascular and GI risks and include information to assist consumers in the safe use of these drugs. Finally, the FDA concluded that the overall risk-benefit profile of valdecoxib is unfavorable and requested that the manufacturer voluntarily withdraw valdecoxib from the market.

The FDA noted that all NSAIDs can lead to the new onset of hypertension or worsening of preexisting disease, which may contribute to an increased incidence of cardiovascular events.177

Follow-up studies have demonstrated concerns about cardiovascular safety for a wide variety of NSAIDs (Table 40.3). A systematic review of 51 observational studies involving more than 3 million patients found that several NSAIDs of various categories were associated with a significantly increased risk for cardiovascular events: rofecoxib with a 45% increase in cardiovascular events, diclofenac with a 40% risk that increased at higher doses, indomethacin with a 30% increased risk, meloxicam with a 20% increased risk, and ibuprofen with elevated risk at higher but not at lower doses. Naproxen at any dose had the least association with adverse cardiovascular events.188,189

deductive analysis of the cardiovascular risk associated with each NSAID and enable the most appropriate selection to be made for patients with cardiovascular disease in whom NSAIDs cannot be avoided entirely.

BONE HEALING

Another concern regarding the perioperative use of NSAIDs is the possible deleterious effect on osteogenesis and spinal fusion.192 PGs have been known for many years to have potent effects on bone metabolism, including osteoblastic and osteoclastic activity, as well as being essential for bone repair.193 The exact mechanism by which NSAIDs impair spinal fusion has not yet been elucidated. It has been hypothesized that the effect may be mediated by inhibition of the inflammatory process with a concomitant reduction in blood flow in the early period of osteogenesis, decreased mesenchymal cell proliferation, or inhibition of calcification of the bone matrix.194 Many investigators have recommended that NSAIDs not be used in the multimodal management of acute pain for patients undergoing spinal fusion surgery.192-195 Although the data are conflicting, a large body of literature derived from laboratory animal studies has suggested that COX-2 inhibitors delay or inhibit bone healing.193,194 However, in these studies COX-2 inhibitors were administered over a period of several weeks to months at doses higher than those approved for acute pain.

Another Cochrane database study pooled the results of 11 cohort and case-control trials involving fracture, osteotomy, and spine fusion in patients with NSAID exposure and nonunion as an outcome. In the initial analysis of the pooled data of the 11 studies, the OR for nonunion with NSAID exposure was 3 (confidence interval [CI] = 1.6 to 5.6). However, when only higher-quality studies were considered, which included primarily spine fusion patients, no significant outcome was detected.196

Another study evaluated 9995 patients with humeral shaft fractures, including 105 with nonunion. A total of 10.3% were exposed to NSAIDs within 90 days of their index fracture. NSAID exposure within the first 90 days was significantly associated with nonunion (OR = 3.7, CI = 2.4 to 5.6). When the data for each of the three 30-day periods were placed in the same multivariate model, only the period from 61 to 90 days showed a relationship between NSAID use and nonunion. A similar relationship was demonstrated for opioids and nonunion during this period. These results suggest that painful nonhealing fractures may be the cause of NSAID use rather than the result.197

A small study investigating the utility of indomethacin in preventing heterotopic ossification in patients with long-bone fractures undergoing hip replacement noted a higher risk for nonunion in the indomethacin group (26%) than in the radiation therapy group (7%).

Conversely, a recent study compared the efficacy and safety of etoricoxib with tramadol in patients undergoing hallux valgus repair. Etoricoxib provided superior pain relief and patient recovery scores without any effect on quality of bone or wound healing.199
These conflicting results indicate that large randomized prospective trials are needed to better delineate causality and determine risk. Given the relatively low incidence of nonunion, large cohorts will be needed.

**TENDON AND SOFT TISSUE HEALING**

Several animal investigations have raised questions regarding the effect of NSAIDs on soft tissue healing. Lower tensile strength was noted in healing of the Achilles tendon in rats treated with indomethacin or parecoxib than in controls. In another study of rodent patellar tendon healing, both traditional and COX-2–selective NSAIDs impaired healing, with the COX-2–selective medications having the most dramatic effect. In a small randomized controlled trial of marathon runners, ibuprofen was shown to decrease patellar tendon PGE₂ levels and impair load-induced adaptive collagen synthesis in the patellar tendon when compared with placebo. Further investigations delineating the clinical relevance of these findings are needed.

**ALLERGY, HYPERSENSITIVITY, AND ASTHMA**

All NSAIDs, including acetylsalicylic acid, may induce hypersensitivity reactions, which are of two general types. Both may be related to inhibition of PG synthesis. The two types of hypersensitivity reactions are (1) the syndrome of asthmatic attacks in patients with vasomotor rhinitis, nasal polypsis, and bronchial asthma and (2) the syndrome of urticaria and angioedema. PGE₂ is a bronchodilator. It stabilizes histamine stores in mastocytes and thus helps inhibit the inflammatory response. In a susceptible person, the result of inhibition of PG biosynthesis may be spontaneous degranulation of mastocytes, with release of histamine into the respiratory tract and skin leading to bronchoconstriction and asthma, as well as urticaria.

Recent data have demonstrated that acetaminophen can deplete pulmonary antioxidant levels, which can result in an increased risk for newly diagnosed asthma. Previous research has demonstrated that acetaminophen may be associated with an increased risk for newly diagnosed asthma if used for 14 days or more per month. Increasing use of acetaminophen may be associated with an increased prevalence of asthma and chronic obstructive pulmonary disease.

**GASTROINTESTINAL EFFECTS**

The first evidence that aspirin could damage the stomach was reported in 1938 based on gastroscopic observations. In the 1950s and 1960s, case-control studies indicated that melena was associated with NSAID use. NSAIDs cause hemorrhagic gastric erosions in the corpus and antrum of the stomach. The mortality rate attributed to NSAID-related GI toxic effects is 0.22% per year, with an annual relative risk of 4.21. It has been estimated that 16,500 NSAID-related deaths occur per year as a result of gastric complications, similar to the number of deaths annually from acquired immunodeficiency syndrome (16,685) and higher than the deaths caused by multiple myeloma and asthma. Some risk factors identified for the development of NSAID-induced ulcers include advanced age; history of ulcer; concomitant use of corticosteroids; higher doses of NSAIDs, including the use of more than one NSAID; concomitant administration of anticoagulants; serious systemic disorder; cigarette smoking; consumption of alcohol; and concomitant infection with *Helicobacter pylori*.

NSAIDs cause ulceration in the stomach by their topical irritant effect on the epithelium and their ability to suppress PG synthesis. The ability of NSAIDs to cause gastric damage correlates with the time and dose dependency for PG suppression in the stomach. Inhibition of PG synthesis leads to a reduction in the ability of the gastric mucosa to defend itself against luminal irritants; bicarbonate secretions, blood flow, and epithelial cell turnover are influenced by PGs. Another feature of NSAIDs that probably contributes to gastric bleeding from preexisting ulcers is their effect on platelet aggregation through the suppression of thromboxane synthesis. Mediators in the pathway whereby decreased PG levels cause gastric irritation and damage have been extensively studied.

NSAID-induced enteropathy has been documented in the small intestine and colon, although the exact mechanism is not fully understood. Various preventive strategies have been developed to reduce NSAID gastroenteropathy. Enteric-coated and slow-release formulations of NSAIDs have been ineffective in preventing the gastric side effects seen with NSAID consumption. Other agents used for the prevention of ulcer formation with NSAIDs include sulcrate (controversy exists about its efficacy), histamine 2 (H₂) receptor antagonists (famotidine), proton pump inhibitors (omeprazole), and PGs (misoprostol).

NSAID gastric-induced complications led to the development of COX-2 inhibitors. These agents have shown promise in reducing NSAID-associated gastropathy. In the SUCCESS-I study, celecoxib was compared with nonspecific NSAIDs in 13,274 patients with osteoarthritis. Patients were randomly assigned to either celecoxib, 100 or 200 mg twice daily, or nonselective NSAID therapy (diclofenac, 50 mg twice daily, or naproxen, 500 mg twice daily) for 12 weeks. The study revealed that both dosages of celecoxib were as effective as the nonselective NSAIDs in treating osteoarthritis. However, significantly more gastric ulcer–related complications occurred in the nonselective NSAID group of patients (0.8/100 patient-years) than in the celecoxib group (0.1/100 patient-years) (OR = 7.02, \( P = 0.008 \)). The results of the SUCCESS-I study are different from those of the Celecoxib Long-term Arthritis Safety Study (CLASS), which did not demonstrate an advantage of celecoxib in reducing the incidence of upper GI ulcer complications; this was attributed by the SUCCESS-I study authors to the low dropout rate and design of the newer study.

Preferential use of COX-2 inhibitors because of their gastric enteropathy safety properties led to the increased incidence of cardiovascular effects that resulted in the withdrawal of some COX-2 inhibitors from the market. Guidelines for gastric protection when NSAIDs are needed have been suggested. For all patients, nonpharmacologic methods (e.g., lifestyle changes) should be initiated first. Topical agents should be considered. Acetaminophen can be used safely for many conditions. Nevertheless, NSAID therapy may be needed. In patients who have no cardiovascular risk factors and are at low or no risk for GI complications, monotherapy with one of the traditional nonselective NSAIDs can be prescribed (Table 40.4). In patients who do not require aspirin prophylaxis and who are at risk for NSAID-induced
GI complications, an initial approach would be to prescribe a COX-2 inhibitor or a traditional NSAID and proton pump inhibitor. In contrast, in patients with cardiovascular risk who require aspirin prophylaxis, COX-2 inhibitors should be avoided; in patients with no GI risk factors, traditional NSAIDs can be used; and if they are at risk for GI complications, a proton pump inhibitor must also be prescribed.\(^{215}\)

### RENAL TOXICITY

Aspirin and other NSAIDs cause a transient decrease in renal function. This effect may occur more often in patients with underlying renal disease.\(^{216}\) The postulated mechanism is inhibition of the renal synthesis of PG, which may be important in the autoregulation of renal blood flow. Aspirin may also block the diuretic effect of spironolactone by inhibiting its binding to the tubular cell receptor. Similarly, NSAIDs may alter a patient’s responses to thiazides or loop diuretics. Fluid retention and edema have been observed in some patients taking NSAIDs.

The renal profile of traditional NSAIDs and COX-2 inhibitors may be described by the following: sodium retention is mediated by COX-2 inhibition, and changes in the glomerular filtration rate are caused by inhibition of COX-1 and COX-2. All NSAIDs, including COX-2 inhibitors, are associated with hypertension and edema.\(^{217}\) Most cases resolve with continuation of therapy, with resolution generally occurring over a period of 1 to 8 weeks. Risk factors for NSAID-induced renal toxicity include chronic NSAID use, multiple NSAID use, dehydration, volume depletion, congestive heart failure, vascular disease, hyperreninemia, shock, sepsis, systemic lupus erythematosus, hepatic disease, sodium depletion, nephrotic syndrome, diuresis, concomitant drug therapy (e.g., diuretics, angiotensin-converting enzyme inhibitors, β-blockers, potassium supplements), and age 60 years or older.\(^{216}\)

### HEPATIC TOXICITY

Aspirin is clearly hepatotoxic in certain situations, and this effect is not dose dependent. However, the effect is reversible when use of the drug is discontinued.\(^{218}\)

### CENTRAL NERVOUS SYSTEM EFFECTS

Direct toxic reactions are of several types. Symptoms of the ear in the form of tinnitus or deafness are usually an early warning of toxicity. Toxic manifestations are directly related to free drug levels, which vary inversely with albumin levels; the adverse event is typically reversed when the dose is reduced or discontinued. The most frequently implicated class of drugs in hypersensitivity-induced aseptic meningitis is the NSAIDs. Four NSAIDs—ibuprofen, sulindac, tolmetin, and naproxen—have been implicated in drug-induced aseptic meningitis. Patients typically complain of fever, headache, and stiff neck, which generally commence within weeks of beginning therapy.\(^{219}\)

### USE IN SPECIFIC POPULATIONS

#### PREGNANT AND LACTATING WOMEN

When administered to pregnant women, salicylates may reach substantial levels in the fetus. Birth defects have not been reported to occur in regular users; however, experimental evidence has shown that it is teratogenic in monkeys.\(^{220}\) Aspirin taken at term may delay the onset of labor for 3 to 10 days, and it has been associated with increased bruising of the newborn child, particularly when instrumentation is necessary. Administration of aspirin or indomethacin at term to delay the onset of labor has been reported to cause serious pulmonary vascular disease in the newborn infant.

#### PEDIATRIC USE

NSAIDs are often used “off label” in pediatric populations.\(^{221}\) In the United States and Canada, NSAIDs approved for children include ibuprofen, naproxen, tolmetin, aspirin, and choline magnesium salicylate. In the United Kingdom, diclofenac, indomethacin, piroxicam, and mefenamic acid are also approved for use in children. Review of the available pharmacokinetic data before use of any NSAID not approved for pediatric populations is suggested to minimize adverse effects and maximize efficacy.\(^{222}\) GI toxicity from NSAIDs does occur in children, but estimates of frequency vary. In a large retrospective study of 702 children examined for gastropathy, only 5 (10 events) were documented with gastric ulcers or gastritis.\(^{222}\) Other toxicities related to NSAID use in children are renal (rare) and skin reactions, which are all reversible.\(^{223}\)

Oral administration of ibuprofen (15 mg/kg) every 4 to 6 hours at a fixed dose and the option of using opioid at an adjustable dose could be beneficial for the relief of pain in pediatric patients. When oral administration is not possible, rectal ibuprofen (40 mg/kg/day) or indomethacin is useful.\(^{221}\) In situations in which the oral or rectal route is not optimal, intravenous ketorolac, 0.5 mg/kg, followed by repeated doses every 6 hours to a maximum of 60 mg/day, can be used.\(^{224}\) Ketorolac can be of great benefit in pediatric patients with sickle cell crisis, but renal function in these patients needs to be monitored closely.

Oral acetaminophen at doses of 15 mg/kg every 4 to 6 hours is an effective analgesic for children; when the oral route is not available, acetaminophen suppositories may be used. Absorption of rectal acetaminophen is slow and sometimes erratic.\(^ {225}\) Studies have suggested that an initial dose of 40 mg/kg followed by 20 mg/kg every 6 hours may be needed to maintain therapeutic blood levels.\(^ {226}\) An

intravenous formulation of acetaminophen is now available that is well tolerated and effective at a dose of 15 mg/kg.227

**OLDER ADULTS**

Absorption of NSAIDs is not affected by the diminished active transport systems in the GI tract of older adult patients because most of the absorption of these compounds occurs via passive diffusion.228 Changes in body composition, such as a decrease in albumin levels in older adult patients, might be expected to increase the toxicity of highly protein-bound compounds; however, such compounds seldom produce clinically important effects if hepatic and renal function is normal.229

Piroxicam and ibuprofen have been shown to have longer plasma half-lives in older women and men, respectively.230,231 These drugs also undergo biotransformation largely by oxidation. There is evidence that drugs undergoing biotransformation by phase II reactions are more slowly eliminated, as may be the case with naproxen and ketoprofen.232,233 Acute renal failure may occur, especially in older adult patients, when the renin-angiotensin system is activated and a PG inhibitor is prescribed.233

Older patients are subject to a number of diseases for which they receive multiple medications. Drug-drug interaction is therefore a serious issue. Some important examples include the interaction of NSAIDs such as phenylbutazone or azaprozone with warfarin, which can lead to an enhanced anticoagulation effect.234 Indomethacin nullifies the hypotensive effects of atenolol, propranolol, prazosin, captopril, and thiazide diuretics. It also blunts the diuretic response of furosemide, triamterene, and spironolactone. Phenylbutazone and oxyphenbutazone increase the rate of synthesis of the cytochrome P-450 enzyme, thereby reducing the hydroxylation activity of tolbutamide; thus, the plasma half-life of this agent is prolonged, which can result in hypoglycemia. Azaprozone also enhances the hypoglycemic action of tolbutamide. Salicylate in therapeutic doses has been shown to enhance the effects of oral hypoglycemic agents, especially chlorpropamide.

**CONCLUSION**

NSAIDs have been a mainstay of acute and chronic pain management for decades and will continue to play this role in the foreseeable future.235,236 A deeper understanding of their complex effects on the PG pathways in normal and disease states will be necessary to tailor these drugs for best efficacy and safety. Their effects are widespread and encompass all organ systems in both health and disease. Further investigation of the effects of NSAIDs on this complex balance is essential. This will allow physicians to apply the risk-benefit ratio to each individual.

A greater variety of modes of administration are now available. Intranasal and intravenous forms are available for patients who cannot take oral medications. Transdermal preparations may allow drugs to be delivered directly to tissues while limiting systemic effects.

Despite recent setbacks with the withdrawal of newer, more selective NSAIDs from the market because of safety concerns, continued development of anti-inflammatory drugs that are capable of targeting specific points of the PG pathway is necessary to optimize pain management.

**KEY POINTS**

- Prostanoids are arachidonic acid derivatives that are essential to the central and peripheral inflammatory response. The phospholipid released as a result of disruption of cell membranes is converted by phospholipase A<sub>2</sub> to arachidonic acid.
- Cyclooxygenase (COX) catalyzes the conversion of arachidonic acid to prostanoids by the addition of molecular oxygen. The prostanoid most prominently associated with the inflammatory response is prostaglandin E<sub>2</sub>.
- COX-1 and COX-2 are two different isoforms of COX that have very different functions. COX-1 is primarily expressed constitutively. It serves to maintain homeostasis, stimulate angiogenesis, regulate gastric pH, and regulate platelet reactivity, as well as other functions. COX-2 is a highly inducible enzyme importantly associated with the inflammatory response. The relative effects of anti-inflammatory drugs on COX-1 and COX-2 have important implications for the efficacy and safety of these drugs.
- Peripheral inflammation leads to induction of COX-2 and expression of prostaglandin E synthase in the central nervous system by both neural and humoral components. The humoral component can be blocked only by centrally acting COX-2 inhibitors.
- Most nonsteroidal anti-inflammatory drugs (NSAIDs) currently available can be broadly classified as salicylates (e.g., aspirin), acetaminophen, acetic acid derivatives (e.g., indomethacin), propionic acid derivatives (e.g., ibuprofen), and COX-2 inhibitors.
- Unlike other NSAIDs, acetaminophen inhibits prostaglandin synthesis in the central nervous system, but not in peripheral tissues.
- The utility of all NSAIDs is limited by concerns of adverse events, including effects on the gastric mucosa, renal function, platelet reactivity, bone and tissue healing, cardiovascular risk, and interactions with other patient medications.
- Selective COX-2 inhibitors were developed to reduce some of the adverse effects of COX-1 inhibition, such as GI ulcers and platelet inhibition. However, serious concerns have arisen about increased cardiovascular risk with these medications. This led to withdrawal of several of the newer COX-2–selective medications from the market.
- A thorough and individualized assessment of the potential benefits and adverse effects for each patient is critical to successful use of these drugs.
- Areas for future investigation include novel methods of drug delivery, drugs with specific targets on the prostaglandin pathway, central versus peripheral sites of action, epidemiologic studies on drug safety, and nonanalgesic uses, including prophylaxis for cancer, cardiovascular disease, and dementia.

Skeletal Muscle Relaxants

Kenneth C. Jackson, II | Charles E. Argoff | Andrew Dubin

The term *skeletal muscle relaxant* is often used to describe a diverse group of medications commonly used in the treatment of back pain (Table 41.1). Medications commonly referred to as skeletal muscle relaxants include carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine. All these agents are labeled by the U.S. Food and Drug Administration (FDA) with an indication for the relief of discomfort associated with an acute, painful, musculoskeletal condition. Oral baclofen and tizanidine are also commonly used to treat acute musculoskeletal conditions and are considered by many clinicians as muscle relaxants, despite the lack of an FDA-approved indication in this regard. Baclofen and tizanidine do have FDA indications for the treatment of spasticity caused by upper motor neuron syndromes including multiple sclerosis, spinal cord disease, or injury. Benzodiazepines, principally diazepam, are also commonly used and indicated for adjunctive relief of skeletal muscle spasm and are often considered in discussions regarding skeletal muscle relaxants.

In discussing this broad class of medications, it becomes difficult to cull out the actual intended therapeutic outcomes. These agents are typically prescribed during the initial presentation of acute low back pain problem, often the result of a soft tissue mechanical injury. The injury normally occurs to the muscles, ligaments, or tendons, structures around the lumbar spine. The presentations may include local pain and tenderness, muscle spasm, and limited range of motion. Muscle spasm is often the most difficult to define and is the subject of controversy among some clinicians. Muscle spasm can be described as a vicious pain-spasm-pain cycle that protects compromised tissues and structures. Secondary to these pain impulses, an involuntary reflex muscle contraction at the site of injury can occur, which in turn can lead to local ischemic injury. This can further facilitate the pain-spasm-pain paradigm. Muscle spasm phenomena may be considered a variation of a myofascial pain presentation.

**MECHANISM OF ACTION**

In considering this discussion of muscle spasm pathophysiology, the problem with defining the activity of the skeletal muscle relaxants becomes manifest. The exact mechanism of action for these various agents has not been fully elucidated. It is generally accepted that skeletal muscle relaxants have the ability to depress polysynaptic reflexes within the dorsal horn via a variety of mechanisms (Box 41.1), which in turn may relax skeletal muscle tissue in an indirect manner. In animal studies, these agents exert their muscle-relaxing effects by inhibiting interneuronal activity and blocking polysynaptic neurons in the spinal cord and descending reticular formation in the brain. Interesting to note is that sedating agents also depress polysynaptic reflexes, making it difficult to determine whether skeletal muscle relaxants produce their clinical activity via sedation or a change in the pain-spasm-pain cycle.

**INDICATIONS FOR USE**

Despite the common use of skeletal muscle relaxants, relatively little data exist to elucidate their role in the treatment of back pain, especially chronic back pain. None of the agents discussed in this chapter have an indication for use in the setting of chronic back pain. In one survey of skeletal muscle relaxant use in the United States, muscle relaxants, although indicated for short-term treatment, are most often prescribed on a long-term basis. In general, skeletal muscle relaxants, excluding baclofen and tizanidine, maintain FDA labeling as adjuncts for treatment of short-term acute low back pain (LBP) and are commonly used to treat muscle spasms and associated pain for periods of 1 to 3 weeks. This time frame coincides with how long many patients may expect it will take to recover from an initial acute low back insult. In this context, it may be difficult to discern the role of these agents, other than the palliative analgesic quality that they may provide for patients. Skeletal muscle relaxant selection depends on an evaluation of adverse effects, contraindications, patient tolerability, and clinical experience. This discussion will also include a brief review of the clinical use of botulinum toxin as a treatment for musculoskeletal pain.

**SPECIFIC DRUGS**

**CARISOPRODOL (SOMA)**

Carisoprodol is available as a 250-mg or 350-mg tablet and in combination with aspirin (soma compound) and with aspirin and codeine (soma compound with codeine). Carisoprodol dosing should not exceed four doses in a 24-hour period (Table 41.2). Similar to other muscle relaxants, carisoprodol has additive sedative effects when taken with alcohol or other central nervous system (CNS) depressants.

Carisoprodol is converted in the liver to meprobamate (Miltown), an intravenous (IV) controlled substance. Meprobamate is well known to produce phenomena that result in physical and psychological dependence. Substance abuse is problematic with carisoprodol, probably as a consequence of meprobamate formation. Several states within the United States have begun listing carisoprodol as a controlled substance in their state formularies. However,
carisoprodol is not considered a controlled substance at the federal level. Because of the dependence potential, carisoprodol use should be avoided. It should also be cautiously tapered as opposed to immediately discontinued following long-term use.

**CHLORZOXAZONE (PARAFLEX, PARAFON FORTE DSC)**

Chlorzoxazone is available as 250- and 500-mg tablets, taken up to four times daily. It has been suggested that chlorzoxazone may be less effective than the other skeletal muscle relaxants. It does not have any significant drug-drug interactions, but it does have a significant adverse effect profile that includes a rare idiosyncratic hepatocellular reaction. The role of this agent is unclear, considering the potential lack of efficacy and significant toxicity profile.

**CYCLOBENZAPRINE (FLEXERIL)**

Cyclobenzaprine is available as 5- and 10-mg tablets, with recommended dosing of up to three times daily. Cyclobenzaprine is more structurally and pharmacologically related to the tricyclic antidepressants than to the CNS depressant skeletal muscle relaxants. As with other skeletal muscle relaxants,
cyclobenzaprine does not have activity directly on muscle tissue, with animal data suggesting that this agent acts primarily in the brainstem. The net result of this action is a reduction in tonic somatic motor activity.19 Although no human evidence exists to support this mechanism, the newer 5-mg dose has yielded similar clinical efficacy with less sedation than the more sedating 10-mg dose.20 In the future, this may prove to be an important distinction with the CNS depressant agents. In an open-label study of patients with acute neck or low back pain associated with muscle spasm who were randomized to be treated for 7 days with cyclobenzaprine 5 mg PO three times daily alone or cyclobenzaprine 5 mg PO three times daily in combination with ibuprofen, at doses of 400 mg PO three times daily or 800 mg three times daily, no significant treatment differences were found among these groups.21

Because of the structural relationship to tricyclic antidepressants (TCAs), clinicians must be cognizant of the anticholinergic side effects, such as dry mouth, urinary retention, dizziness, hypotension, and constipation, seen with cyclobenzaprine. Use of cyclobenzaprine is contraindicated in the setting of arrhythmias, congestive heart failure, hypothyroidism, acute glaucoma, narrow angle glaucoma, or during the acute recovery phase of a myocardial infarction. One report suggested that coadministration with pro-serotonergic agents such as selective serotonin reuptake inhibitors (SSRIs) may predispose patients to life-threatening serotonin syndrome.22

Cyclobenzaprine labeling suggests that concomitant use with tramadol may place patients at higher risk for developing seizures.19 Attendant use of cyclobenzaprine with monoamine oxidase inhibitors or use within 14 days after their discontinuation is contraindicated. It can also enhance the effects of agents with CNS depressant activity. Older adults appear to have a higher risk for CNS-related adverse reactions, such as hallucinations and confusion, when using cyclobenzaprine. Withdrawal symptoms have been noted with the discontinuation of chronic cyclobenzaprine use. Use of a medication taper may be warranted for chronic-use patients.

**METAXALONE (SKELAXIN)**

Metaxalone is available as a 400- and 800-mg tablet and has a recommended maximal dose of 800 mg three or four times daily. Metaxalone does not have any significant drug-drug interactions and appears to have a fairly benign side effect profile, although fatalities attributed to the use of metaxalone have been reported.23,24 Hemolytic anemia, leukopenia, and impaired liver function have been seen with the use of metaxalone, but they are uncommon. Metaxalone is contraindicated in patients who have severe renal or hepatic impairment. It is known to cause an elevation in the cephalin flocculation test, necessitating serial liver function assessments. Metaxalone can also produce a false-positive result for Benedict’s test. In this scenario, alternatives to urine glucose testing may be necessary.25 Although FDA approved since the 1980s, there are few published placebo-controlled studies comparing metaxalone with placebo for the treatment of musculoskeletal pain.26

**METHOCARBAMOL (ROBAXIN, ROBAXISAL)**

Methocarbamol is available in oral and parenteral forms for IV or intramuscular use. However, many complications have arisen with the injectable form, including pain, sloughing of the skin, and thrombophlebitis. The injectable form should be used cautiously in patients with known latex hypersensitivity. The oral dosage form of the medication is marketed as a 500- and 750-mg tablet, with a recommended daily dosage range of 4000 to 4500 mg as three or four divided doses daily. For difficult situations, the dose for the first 24 to 48 hours can be up to 6 to 8 g/day. Methocarbamol is also combined with aspirin and marketed as Robaxisal. Similar to metaxalone, although FDA approved in the 1980s, there are few published placebo-controlled studies comparing methocarbamol with placebo for the treatment of musculoskeletal pain.27

**ORPHENADRINE CITRATE (NORFLEX, NORGESIC, NORGESIC FORTE)**

Orphenadrine is a direct descendant of diphenhydramine and thus exhibits antihistaminic and anticholinergic properties. Like methocarbamol, orphenadrine is available in a parenteral dosage formulation. There have been reports of severe adverse reactions with parenteral use (e.g., anaphylactoid reaction), making this formulation difficult to use. Orphenadrine is available as a 100-mg tablet (Norflex) and in combination with aspirin (Norgesic) and caffeine (Norgesic Forte).

Orphenadrine use with propoxyphene (removed from the U.S. market in 2011) may cause confusion, anxiety, and tremors, perhaps because of additive effects. Orphenadrine’s anticholinergic actions have been noted to produce significant adverse effects at high dosages, such as tachycardia, palpitations, urinary retention, and blurred vision.28 Given its significant anticholinergic profile, orphenadrine use is contraindicated in patients with underlying neuromuscular junction defects such as myasthenia gravis and Lambert Eaton syndrome.

**DIAZEPAM (VALIUM)**

This is the most commonly prescribed and referenced benzodiazepine for the treatment of muscle spasms.29 Diazepam demonstrates hypnotic, anxiolytic, antiepileptic, and antispasmodic properties. With respect to muscle relaxation, gamma-aminobutyric acid (GABA)—mediated presynaptic inhibition at the spinal level is thought to be the main mechanism of action for diazepam. Sedation and abuse potential are the main concerns with this agent; therefore, it should not be used as a first-line muscle relaxant agent. It is important to taper this agent slowly after long-term use to avoid any withdrawal symptoms. Diazepam is available in a wide range of dosages, and each patient should be treated on an individual basis. The recommended dosage range for musculoskeletal pain is 2 to 10 mg four times daily. Coadministration of the benzodiazepine class of medications with opioids, as they are commonly prescribed, can lead to significant morbidity in the form of respiratory depression and mortality from respiratory failure.

**BACLOFEN (LIORESAL)**

Baclofen is chemically related to GABA and produces its effects by inhibiting monosynaptic and polysynaptic transmission along the spinal cord. This drug is mainly used for
spasticity associated with CNS disorders (multiple sclerosis [MS], spinal cord lesions). Studies have shown baclofen to have superior efficacy when compared with diazepam. Baclofen is unique in that it can be administered intrathecally in cases of severe spasticity and for patients who do not tolerate or have failed oral therapy. It has also found a niche in the treatment of trigeminal neuralgia because of a more favorable side effect profile. Baclofen is available in 10- and 20-mg tablets, with a therapeutic range of 40 to 80 mg daily. The medication should be started at 5 mg three times daily and tapered up to a therapeutic level of 5 mg every 3 to 5 days. It should be tapered slowly after long-term use to avoid a withdrawal reaction, rebound phenomena, and potential withdrawal seizures that can occur with sudden cessation. It should be used with caution in older patients and patients with renal impairment.

**TIZANIDINE (ZANAFLEX)**

Tizanidine (Zanaflex) is a short-acting inhibitor of excitatory (presynaptic) motor neurons at the spinal and supraspinal levels, producing agonistic activity at the noradrenergic α2 receptors. This activity results in the inhibition of neurotransmitter release from spinal interneurons and the concomitant inhibition of facilitatory spinal pathways that enhance muscle movement. Tizanidine is related chemically to clonidine, but it has significantly lower anti-hypertensive effects. The main adverse effect for most patients is sedation. Currently, tizanidine is FDA approved for the management of increased muscle tone associated with spasticity resulting from CNS disorders, such as multiple sclerosis or spinal cord injury. There are published studies on the use of tizanidine in the setting of back pain or muscle spasm, either alone or in combination with ibuprofen, as well as a report of effective use for myofascial pain.

In a multicenter placebo-controlled study evaluating the efficacy and safety of tizanidine for the treatment of low back pain, tizanidine was found to provide more pain relief and less restriction of movement compared with placebo. Drowsiness was the most common side effect, but this adverse effect may actually be desired in patients with nighttime exacerbations of their pain. In a separate study, 105 patients with acute low back pain were given tizanidine 4 mg PO three times daily in conjunction with ibuprofen 400 mg PO three times daily, or ibuprofen 400 mg PO three times daily with placebo. The study results suggested that the tizanidine-ibuprofen combination is more effective for the treatment of moderate or severe acute low back pain than ibuprofen only. Tizanidine is available as 2- and 4-mg tablets; treatment should be instituted with a 4-mg single dose, increasing by 2- to 4-mg increments up to a therapeutic dose. The maximum daily dose should not exceed 36 mg.

Tizanidine should be used with caution in the setting of renal impairment. Tizanidine clearance decreases by 50% in patients with creatinine clearance lower than 25 mL/min. Coadministration with alcohol can increase the area under the curve (AUC) of tizanidine by approximately 20% and increase the maximum concentration (Cmax) by approximately 15%. Use with oral contraceptives can decrease the clearance of tizanidine and place patients at higher risk for sedating adverse effects.

**BOTULINUM TOXINS (BOTOX-ONABOTULINUMTOXINA, DYSPORT-ABOBOTULINUMTOXINA, XEOMIN-INCOBOTULINUMTOXINA AND MYOBLOC-RIMABOTULINUMTOXINB)**

Botulinum toxin is a potent neurotoxin produced by the gram-positive anaerobic bacterium *Clostridium botulinum*. Of the seven known immunologically distinct serotypes of botulinum toxin (A to G), only types A and B have been developed for routine commercial use. Historically, the toxin’s primary mechanism of action has been linked to its ability to inhibit the release of acetylcholine from cholinergic nerve terminals. However, it is now appreciated that these neurotoxins may also inhibit the release of glutamate, substance P, and calcitonin gene-related peptide. These effects may strongly contribute to the analgesic effects of these toxins.

Botulinum toxin has been studied in a number of chronic pain conditions associated with painful muscle spasm, including cervicogenic headache, temporomandibular joint disorders, craniofacial dystonia syndromes, chronic myofascial pain, and chronic low back pain.

The potential benefit of the use of botulinum toxin for the treatment of cervicogenic headache associated with “whiplash” injuries has been noted. In 1997, Hobson and Gladish reported that botulinum toxin type A (onabotulinumtoxinA) injections could be effective in reducing cervicogenic headache resulting from cervical whiplash-type injuries.

In a randomized, double-blind, placebo-controlled study, Freund and Schwartz found that the botulinum toxin type A–treated patients (onabotulinumtoxinA) demonstrate significant greater improvement from baseline with respect to pain reduction and cervical range of motion. Mixed results have been observed in evaluating the effect of botulinum toxin injection on temporomandibular joint and other orofacial-related pain. In an open-label study completed by Freund and Schwartz, patients with temporomandibular joint dysfunction believed to be related to myofascial dysfunction were treated with a total of 200 units of botulinum toxin A (onabotulinumtoxinA) (masseter and temporalis muscles injected), with most patients experiencing pain reduction as well as improvements in jaw function. Von Lindern and colleagues’ study of patients with chronic facial pain associated with muscular hyperactivity also demonstrated improvement in botulinum toxin type A (onabotulinumtoxinA)–treated patients. However, in a placebo-controlled crossover trial evaluating botulinum toxin type A (onabotulinumtoxinA) in patients with chronic moderate to severe orofacial pain of muscular origin, no statistically significant differences were seen between placebo and active treatment.

There have been several published evaluations of the use of botulinum toxin for the treatment of myofascial pain in the cervicothoracic regions. In a small crossover trial (N = 6), patients whose cervical myofascial trigger points were injected with botulinum toxin type A (onabotulinumtoxinA) had an average of 30% pain reduction. In a separate study, Wheeler and associates completed a randomized, double-blind, prospective, placebo-controlled study in 35 patients with chronic cervical myofascial pain who were injected with either 50 or 100 units of botulinum toxin type A (onabotulinumtoxinA) or normal saline. No clear benefit was found in the botulinum toxin–treated patients. Porta, in a single-blinded study,
evaluated the potential difference between “conventional” lidocaine-methylprednisolone trigger point injections and botulinum toxin type A injections (onabotulinumtoxinA) for myofascial pain treatment and concluded that although each group received benefit, the duration of benefit was longer in the botulinum toxin–treated group.

Botulinum toxin injections have also been studied in the treatment of chronic low back pain. In one study, 31 patients with chronic low back pain were randomized to be treated with 200 units of botulinum toxin A (onabotulinumtoxinA) into five sites (L1-5 or L2-S1, 40 units/site) or placebo injections. Pain and disability were measured at 3 and 8 weeks following injection using the visual analog scale and the Oswestry Low Back Pain and Disability Questionnaire. At 3 and 8 weeks, the pain reduction experienced by the botulinum toxin–treated group was greater than that experienced by the placebo group, and at 8 weeks there was less disability in the botulinum toxin–treated group compared with placebo.46 A report evaluating the use of botulinum toxin type A (abobotulinumtoxinA) for the relief of upper back myofascial pain syndrome concluded that several secondary parameters, such as physicians’ global assessment and patients’ global assessment, significantly favored abobotulinumtoxinA over placebo at weeks 8 and 12.47 The precise role of botulinum toxin injection therapy in the management of conditions associated with chronic muscle spasm remains to be determined.

CONCLUSION

Available clinical data indicate that skeletal muscle relaxants are more effective than placebo with respect to relieving acute low back pain.9 Most of this information is dated, however, with study designs and analyses that would not be acceptable if this research were conducted today. In general, no data support any one agent being more efficacious than another. Some reports have suggested that chlorzoxazone may be less effective than other agents, which puts into question the viability of using this agent.8,48

Most clinical guidelines list skeletal muscle relaxants as optional agents for use individually or in combination with an NSAID. The Agency for Health Care Policy and Research (AHCPR) guidelines, published in 1995, specifically noted that skeletal muscle relaxants alone or in combination with an NSAID are no more effective than using an NSAID alone.49 This conclusion has been supported in systematic reviews by van Tulder and colleagues.8,48 Skeletal muscle relaxants have been shown to be more effective than placebo for patients with acute LBP with respect to outcomes such as short-term pain relief, global efficacy, and improvement of physical outcomes.50,53 But there remains no quality evidence that allows for a direct comparison of skeletal muscle relaxants with NSAIDs. Most clinicians and researchers agree that skeletal muscle relaxants may be of benefit to patients with acute low back pain by reducing the duration of their discomfort and accelerating recovery. A meta-analysis of cyclobenzaprine use in acute low back pain by Browning and associates concluded that despite limitations in the available evidence, the combination of an NSAID with cyclobenzaprine appears to be warranted.54 It is probably best to consider the use of skeletal muscle relaxants as an adjunct or alternative to NSAIDs, especially in cases in which NSAID toxicity is a concern or when NSAID monotherapy proves suboptimal. Two Cochrane reviews concluded that there is little evidence to support the use of muscle relaxants for the management of pain associated either with inflammatory arthritis or rheumatoid arthritis.55,56

Skeletal muscle relaxants have CNS depressant effects and should be used with caution, particularly for patients with concomitant use of alcohol, anxiolytics, opioid analgesics, or other sedating medications. There is strong evidence that skeletal muscle relaxants are associated with higher risks for total adverse effects, especially those related to the central nervous system.8,9,48 The most common and consistent adverse effects noted with the central nervous system were drowsiness and dizziness.25 The benzodiazepines-muscle relaxants such as diazepam and sedative-muscle relaxants such as carisoprodol are highly addictive and should never be used as first-line agents.

Thus, skeletal muscle relaxants remain an enigmatic collection of agents with an ill-defined role in the treatment of chronic back pain. This is partly because of the nature of their discovery and early clinical applications that predate more modern research approaches. Considering the many issues currently facing clinicians (e.g., adverse effects of NSAIDs), it will become necessary to re-evaluate the role and use of skeletal muscle relaxants in the future.

KEY POINTS

• Muscle relaxants may treat muscle spasticity in two manners. First, they can modify the stretch reflex arc, either by reducing the excitatory signals or by augmenting the inhibitory interneurons. This decreases activation of the alpha motor neuron. Second, they can disrupt the excitation-contraction coupling that produces muscle contraction.

• Cyclobenzaprine is a centrally acting skeletal muscle relaxant that is structurally related to tricyclic antidepressants; it acts primarily at the level of the brainstem.

• Baclofen, as a GABAb agonist, causes hyperpolarization and thus decreases the release of excitatory neurotransmitters in the brain and spinal cord. It causes less sedation than benzodiazepines and may reduce pain by decreasing substance P release.

• Skeletal muscle relaxants have been shown to be more effective than placebo for patients with acute LBP with respect to outcomes, such as short-term pain relief, global efficacy, and improvement of physical outcomes.

• Botulinum toxin type A (onabotulinumtoxinA) injections could be effective in reducing cervicogenic headache resulting from cervical whiplash-type injuries.

• Carisoprodol is converted in the liver to meprobamate (Miltown), an intravenous (IV) controlled substance. Meprobamate is well known to produce phenomena that result in physical and psychological dependence.
SUGGESTED READINGS

The references for this chapter can be found at www.expertconsult.com.
In contrast to the use of a systemic analgesic, use of a topical analgesic may result in relief of pain without the requirement for notable systemic absorption. A topical analgesic is not a transdermal analgesic. For example, the mechanism of action of transdermal nitroglycerin or fentanyl and clonidine patches is systemic, which requires systemic absorption through the skin, as well as a systemic concentration of the specific drug. A topical analgesic requires neither systemic absorption nor a significant systemic concentration to be clinically effective. A topical analgesic is an analgesic that is applied locally and directly to the painful areas, with the primary site of action being local to the site of application. As noted previously, it is not a “transdermal analgesic,” which unlike a topical analgesic, requires a systemic analgesic concentration for its analgesic action. This is not a trivial distinction: analgesics have been inappropriately considered “topical” agents even when formal pharmacologic studies to demonstrate a lack of systemic activity or systemic drug concentration (or both) had not been completed, and at other times, true topical agents have been incorrectly described as transdermal agents. As discussed in this chapter, topical analgesics have been studied and are used for acute pain, as well as for a variety of types of chronic neuropathic and non-neuropathic pain. Different topical analgesics are associated with different mechanisms of action, a point to be considered when choosing a topical analgesic for a patient with chronic pain. Of great interest is the recent observation (described in greater detail later in this chapter) that although a topical analgesic’s primary mechanism of action may occur locally and within the peripheral nervous system (PNS), the effect of a topical analgesic can be detected in the central nervous system (CNS) by functional neuroimaging.

**BACKGROUND**

Undoubtedly, pain cannot be ultimately experienced in the absence of relevant brain activity; however, we have also appreciated for many years the importance of PNS activity, including provision of input to the CNS, in initiating and maintaining acute and some chronic painful conditions. There are specific painful conditions, such as central post-stroke pain and spinal cord injury pain, in which the pain mechanisms lie within the CNS and do not respond to topical analgesics. Many common chronic pain syndromes, including post-herpetic neuralgia (PHN), chronic low back pain (CLBP), and osteoarthritis (OA), probably result from mechanisms involving both the PNS and CNS.

If pain cannot be experienced without brain activation, how can a topical analgesic whose primary mechanism of action is largely within the PNS be helpful? A topical analgesic may interrupt, depending on the specific analgesic, certain mechanisms of pain transmission and by doing so may actually lead to a reduction in central pain mechanisms and thus pain as well. In other words, acknowledging that the experience of pain cannot occur without the brain, less pain may be experienced if use of a topical analgesic leads to reduced activation of PNS mechanisms, which if activated would facilitate transmission of pain signals to the CNS for central processing. This chapter reviews the use of topical analgesics for the treatment of various painful conditions and provides an update of previously published similar reviews.1-3

The potential clinical benefit of any analgesic—or for that matter any medical treatment—is diminished by its adverse effect profile, toxicities, and drug-drug interactions. When considering the use of a topical analgesic, the risk for and severity of significant adverse effects and drug-drug interactions are often less than those for the same analgesic administered systemically.1 Consider, for example, the treatment of OA with a nonsteroidal anti-inflammatory drug (NSAID). If one can successfully treat someone with a topical NSAID versus a systemic NSAID, this may be helpful in reducing the risk for systemic side effects typically associated with NSAIDs. Rash and unpleasant skin sensations may occur with the use of a topical analgesic, but neither is typically experienced.5 Among the topical analgesics currently approved by the Food and Drug Administration (FDA) (see Box 42.1), the 5% lidocaine patch (Lidoderm) has been studied widely. Several studies of the 5% lidocaine patch have been designed to evaluate its safety and tolerability. For example, the outcome of one study assessing the tolerability and safety of 24-hr/day use of four 5% lidocaine patches demonstrated that there were no significant systemic side effects and that plasma lidocaine levels remained below those known to be associated with cardiac abnormalities. In this study, the safety and tolerability were similar if the subject used the patch for 12 or for 24 hr/day.6 In a multicenter open-label study, patients with a history of CLBP from a variety of causes were treated safely with four 5% lidocaine patches every 24 hours for extended periods.5 In each of these reports, no significant dermal reactions were experienced.5,7

Dermal sensitivity is a potential side effect of all topical analgesics; however, other adverse effects may be experienced as a result of the use of a specific topical analgesic that may be more related to the specific medication in the specific topical analgesic. An example is capsaicin. After the topical application of capsaicin, severe burning at the site of application commonly occurs. This particular side effect may in fact not infrequently lead to reduced clinical
effectiveness of this specific topical analgesic. Capsaicin, when applied topically in its currently available forms, does not result in significant systemic accumulation or in any life-threatening outcomes, and the incidence of burning may decrease with repeated use; however, frequent occurrence of this side effect may negatively affect treatment adherence and consequently the patient’s ability to benefit from its use. The 8% capsaicin patch (Qutenza), approved by the FDA for the treatment of PHN, was generally well tolerated in clinical trials even though burning did occur. In contrast to over-the-counter preparations of capsaicin that may need to be applied multiple times daily, the 8% capsaicin patch is applied for a single hour and may result in effective outcomes for 12 weeks or longer.

It is generally acknowledged that a patient being treated for chronic pain may also have other medical comorbid conditions that would be treated with pharmacologic therapies as well. Recognizing that drug-drug interactions are minimized with topical analgesics may be clinically relevant when managing a patient who has been prescribed systemic medications concurrently for comorbid medical conditions. Recently published guidelines regarding the pharmacologic management of persistent pain in older adults emphasize this point in their recommendations. A clinical example would be a 79-year-old woman being treated for hyperlipidemia, hypertension, coronary artery disease, and type 2 diabetes mellitus and OA. She requires analgesics for the chronic pain associated with her OA and is already taking four oral systemic medications on a daily basis for the other chronic medical conditions. A trial of the use of a topical medication for her may offer several advantages over a systemic medication because of reduced drug-drug interactions, assuming that she achieves adequate pain relief. Since the topical analgesics available typically do not involve dose titration and many systemic agents do, this may provide an additional potential benefit for a patient.

The prescriber must recognize the difference between topical analgesics that are prescribed as commercially available, FDA-approved agents and those that are touted as “topical” agents by various compounding pharmacies but in fact have not been proved to be such following appropriate testing. Commercially available FDA-approved topical analgesics must have demonstrated to the FDA consistent manufacturing standards and quality control, in contrast to those manufactured and sold by a specialized compounding pharmacy. The reader should keep in mind that the so-called topical analgesics that may be made by a compounding pharmacy may consist of a combination of substances, such as a local anesthetic, NSAID, and antidepressant combined together in a chemical base, that are not commercially available. FDA-approved topical products. There is no current general requirement for compounding pharmacies to demonstrate manufacturing consistency, and this is an important point for a prescriber to recognize. Even though for many compounding pharmacies there is no documentation of quality control or preparation consistency such as would be required for an FDA-approved product, these products are commonly prescribed. In a survey of members of the American Society of Regional Anesthesia and Pain Medicine, 27% of the respondents reported prescribing such an agent, and 47% of the respondents noted a positive impression suggesting that they thought that patients responded well to the preparation. Of interest is continued commercial development of new topical analgesic preparations. Recently, three topical NSAIDs and the 8% capsaicin preparation have been approved by the FDA. Topical preparations containing opioids, local anesthetics, antidepressants, glutamate receptor antagonists, α-adrenergic receptor agonists, adenosine, cannabinoids, cholinergic receptor agonists, gabapentinoids, prostanoids, bradykinin, adenosine triphosphate, biogenic amines, and nerve growth factor are each at various stages of clinical development.

As one would expect for an oral systemic analgesic, the mechanism of action of a specific topical analgesic depends on the chemical entity or entities in the specific agent, and this may be considered when choosing a particular agent for a patient. The mechanism of action of the topical agent capsaicin, for example, appears to be through agonist activity at the transient receptor potential vanilloid 1 (TRPV1) on Aβ and C fibers. As a result of this activity at the TRPV1 receptor, release of substance P and calcitonin gene-related peptide takes place, and it is hypothesized that reduced peripheral as well as central excitability with resulting less pain through reduced affective input occurs because of the depletion of substance P in C fibers associated with the application of topical capsaicin. The results of both human nerve biopsy and animal studies demonstrate nerve fiber degeneration in the skin underneath the site of capsaicin application. Such nerve fiber degeneration associated with the application of capsaicin has been suggested to be one of the mechanisms through which its use results in pain relief. The mechanism of action of a topical NSAID, in contrast to capsaicin, is probably associated with inhibition of prostaglandin synthesis and the resulting anti-inflammatory effect. Keeping in mind that the extent of anti-inflammatory effect is not consistently proportional to the pain relief experienced, perhaps other mechanisms of action might be considered. It may be worthwhile to consider the potential benefit of an agent with more than one mechanism of action. For example, the antinociceptive effects of topical morphine may be enhanced by a topical cannabinoid as demonstrated in a study in rats in which the radiant tail flick test was used. Local anesthetic agents are known to suppress the activity of peripheral sodium channels within sensory afferents and subsequent pain transmission; however, other mechanisms of action are under investigation. It has been noted that decreased expression of mRNA for specific sodium channel subtypes may occur following local anesthetic use. Several local anesthetic-containing topical analgesics are currently available commercially, including the 5% lidocaine patch, EMLA cream (eutectic mixture of local anesthetics, 2.5% lidocaine/2.5% prilocaine), and the Styre patch (lidocaine, 70 mg/tetracaine, 70 mg). Of these
three agents, only the 5% lidocaine patch is associated with an analgesic effect without creating anesthetic skin, whereas use of EMLA cream or the FDA-approved Synera patch may create both analgesia and anesthesia. This difference among the preparations is useful to apply in specific clinical settings, such as venipuncture, lumbar puncture, intramuscular injections, and circumcision, for which creating both anesthesia and analgesia would be helpful. Choosing which topical analgesic to use clearly depends on the clinical setting in which the medication is being used. At least for the 5% lidocaine patch, it has been noted that application of the patch itself, by protecting allodynic skin from being stimulated, may reduce the allodynia experienced by those afflicted by neuropathic pain states such as PHN.1

One novel area of topical analgesic development involves the use of tricyclic antidepressants as topical analgesics. Certain tricyclic antidepressants such as amitriptyline and doxepin have been demonstrated to block sodium channels, and the potential clinical benefit of this mechanism when such an agent is topically applied is being actively investigated at this time.19,20 One commercially available topical antidepressant, doxepin hydrochloride (Zonalon) cream, is currently approved by the FDA for the short-term treatment of adult patients with pruritus associated with atopic dermatitis or lichen simplex chronicus. Of interest have been reports of use of this agent in an “off-label” manner as a topical analgesic.21 Other topical agents, including topical opioids, glutamate receptor antagonists, and cannabinoids, have potential as topical analgesics as well. Certain studies of some of these agents are discussed in the following sections.

**USE OF TOPICAL ANALGESICS FOR SPECIFIC CLINICAL CONDITIONS (SEE BOX 42.2)**

### NEUROPATHIC PAIN

The use of specific topical analgesics for the management of neuropathic pain has been established by a number of clinical trials, and more than one published review of the management of neuropathic pain has emphasized their efficacy.32-34

### LOCAL ANESTHETICS

The first medication to receive FDA approval for the treatment of PHN was in fact the 5% lidocaine patch. The clinical trials that led to the FDA approval of this preparation for the management of PHN demonstrated that when compared with patients treated with placebo patches, patients who were treated with 5% lidocaine patches experienced statistically significantly more pain reduction in a safe and well-tolerated manner:25,26 A phase IV open-label study involving PHN patients was completed to evaluate whether treatment of PHN with the 5% lidocaine patch affected various quality-of-life measures. A study of 332 patients with PHN used the Brief Pain Inventory (BPI), a validated pain assessment tool. During the study period, enrolled patients were able to use up to three 5% lidocaine patches 12 hours each day, and the BPI was completed daily for 4 weeks. Sixty-one percent (204/332) of the subjects enrolled noted decreased pain intensity by the end of the first week of the study. A reduction in pain intensity was noted by the second week of patch use in more than 40% of the 128 subjects who had not experienced pain relief by the end of the first week of the study. Overall, 70% of enrolled patients experienced improvement by the study’s conclusion.27 In another open-label study, treatment with the 5% lidocaine patch was compared with treatment with pregabalin (Lyrica) for PHN. The study results demonstrated that the 5% lidocaine patch was at least as effective as pregabalin for pain relief in PHN patients. Among the study’s most interesting results was that for patients who had not responded to either the 5% lidocaine patch or pregabalin alone, using these agents in combination resulted in greater benefit, and the combination was well tolerated by these patients.28 This observation is particularly important to note when managing patients with PHN.

In addition to PHN, use of the 5% lidocaine patch for the management of other neuropathic pain states has been evaluated in various studies. A study conducted in Europe, a randomized, double-blind, placebo-controlled trial evaluated the analgesic efficacy of the 5% lidocaine patch for the treatment of “focal” neuropathic pain syndromes.29 The painful conditions included in the study were mononeuropathies, intercostal neuralgia, and lioinguinal neuralgia. The results of this study demonstrated that adding the 5% lidocaine patch to other pharmacotherapeutic regimens could reduce ongoing pain and allodynia as quickly as within the first 8 hours following application in some patients, as well as in other patients over a period of 7 days.29 A smaller open-label study of 16 patients with various chronic neuropathic pain conditions (post-thoracotomy pain, complex regional pain syndrome, postamputation pain, painful diabetic neuropathy, meralgia paresthetica, postmastectomy pain, neuroma-related pain) demonstrated that the 5% lidocaine patch provided pain relief without significant side effects in 81% of these patients.30 It is worthy to note that according to the study’s authors, patients enrolled in this study, before use of the 5% lidocaine patch, had experienced suboptimal outcomes with numerous other agents commonly prescribed for the treatment of neuropathic pain. Several other non-controlled studies of patients with painful diabetic neuropathy who were treated with the 5% lidocaine patch have been completed. These studies allowed patients to use as many as four 5% lidocaine patches for as long as 18 hr/day. Viewing these studies as a group, the majority of enrolled subjects reported pain reduction and good tolerability of this medication.31,32 An additional study, a 3-week single-center, open-label study of the 5% lidocaine patch in patients with painful idiopathic sensory polyneuropathy, noted significant improvements in both pain and quality-of-life measures.33

In addition to measuring any changes in pain intensity or function (or both) in patients treated with the 5% lidocaine

patch, changes in pain quality in patients with PHN have been studied as well. Changes in the quality of pain in patients with PHN treated with the 5% lidocaine patch versus placebo were evaluated in a multicenter, randomized, vehicle-controlled study of 150 PHN patients. Reduced intensity of certain neuropathic pain qualities according to the Neuropathic Pain Scale was more likely to occur in patients treated with the 5% lidocaine patch than in those given the placebo patch (up to three patches for 12 hours each day). Also of interest was that certain types of neuropathic pain (deep, sharp, and burning) that were reduced had previously been assumed to not be related to PNS but to CNS mechanisms. In their discussion of the study’s results, the authors proposed that given the localized primary PNS mechanism of action of the 5% lidocaine patch, peripheral mechanisms of neuropathic pain might also be important in the development of these neuropathic pain qualities. The results of a functional brain magnetic resonance imaging study of patients with PHN treated with the 5% lidocaine patch for various lengths of time demonstrated that the brain activity occurring with the spontaneous pain of PHN appeared to be modulated in a manner related to the length of application of this medication, thus suggesting again that a peripherally acting agent may have an impact on CNS pain mechanisms.

Another local anesthetic preparation that is currently commercially available is EMLA cream. Its FDA-approved indication is as a topical anesthetic for use on normal intact skin for analgesia, but it is not FDA-approved for any specific neuropathic pain disorder. Several studies of EMLA cream for the treatment of PHN have been completed, with mixed results. The results of a randomized, controlled study of PHN patients treated with EMLA cream or placebo cream did not demonstrate a significant difference in treatment outcome between the two groups. The results of two uncontrolled studies were more favorable and suggested that use of EMLA cream could relieve the pain associated with PHN.

CAPSAICIN

Even though there has been interest in using capsaicin for a number of neuropathic pain disorders such as diabetic neuropathy, painful human immunodeficiency virus (HIV)-related neuropathy, PHN, and postmastectomy pain, many of the older studies had yielded disappointing results, perhaps partly as a result of the weakness of past available strengths of capsaicin (0.025% and 0.075%), as well as poor toleration of the treatment, poor treatment adherence, and the resulting insufficient pain relief. However, in contrast, the results of a higher-strength capsaicin preparation demonstrated better analgesia. In one reported study of patients with painful HIV neuropathy treated with 7.5% topical capsaicin cream, the patients experienced notable pain relief, but to be able to tolerate this medication, concurrent treatment with epidural anesthesia was required. At the 2004 Annual Scientific Meeting of the American Academy of Neurology, two open-label studies, one involving patients with PHN and one involving patients with painful HIV-associated distal symmetrical polyneuropathy, reported notable pain relief in the majority of patients following the single application of a high-concentration (8%) capsaicin patch. The duration of pain relief lasted as long as 48 weeks (PHN).

A review of the published randomized trials on the use of topical capsaicin for the treatment of either neuropathic or musculoskeletal pain syndromes concluded that “although topically applied capsaicin has moderate to poor efficacy in the treatment of chronic musculoskeletal or neuropathic pain, it may be useful as an adjunct or sole therapy for a small number of patients who are unresponsive to, or intolerant of, other treatments.” Recently, the 8% capsaicin patch (Qutenza) received FDA approval for the treatment of PHN. In studies leading to its FDA approval, it was shown to be more effective in reducing pain intensity than was an active, lower-concentration capsaicin product that served as placebo, and it was generally well tolerated. It has also been studied for other neuropathic pain states such as painful HIV neuropathy, with a favorable outcome as well.

The results of a novel study comparing the pain-reducing effect of a topical preparation containing 3.3% doxepin alone or a topical preparation containing 3.3% doxepin combined with 0.075% capsaicin versus placebo in patients with a variety of chronic neuropathic pain problems indicated that each treatment provided similar pain-reducing effects and that each was superior to placebo.

OTHER AGENTS

Interest in the use of topical tricyclic antidepressants for the treatment of neuropathic pain has resulted in multiple clinical trials, including the trial on topical doxepin described earlier. For several such trials, the topical preparation examined was a combination of 2% amitriptyline and 1% ketamine. One of these studies, a double-blind, randomized, placebo-controlled study involving 92 patients with diabetic neuropathy, PHN, or postsurgical or post-traumatic neuropathic pain, resulted in no difference in analgesic benefit among any of the four treatment groups (placebo, 2% amitriptyline alone, 1% ketamine alone, or a combination of 2% amitriptyline and 1% ketamine). The results of an open-label study completed by similar investigators involving 28 patients with neuropathic pain for 6 to 12 months treated with the combination topical analgesic 2% amitriptyline and 1% ketamine demonstrated that the average reduction in pain was 34%. Another open-label study by similar investigators using the same type of preparation also demonstrated encouraging results. Noncontrolled trials evaluating the use of topical ketamine, one in PHN patients and one in patients with complex regional pain syndrome type 1, each concluded that topical ketamine may be an effective topical analgesic; however, serum ketamine levels were not measured in either study, and thus it is not clear how truly “topical” the ketamine preparations were. There is one report suggesting that topical application of geranium oil may provide temporary relief of PHN.

SOFT TISSUE INJURIES AND OSTEOARTHRITIS

Common musculoskeletal pain conditions include soft tissue injuries and OA. Since 2007, the FDA has approved three topical NSAIDs, including 1% diclofenac sodium gel (1% Voltaren gel), the 1.3% diclofenac epolamine topical patch (Flector patch), and 1.5% diclofenac topical solution (Pennsaid). Each of these FDA-approved topical NSAIDs has different indications. Diclofenac sodium 1% gel (1% Voltaren gel) is FDA-approved for treating pain associated
with OA in joints that can be managed with topical treatment, such as the knees and hands. The diclofenac epolamine topical patch (Flector patch) is FDA-approved for the topical treatment of acute pain from minor strains, sprains, and contusions. The diclofenac sodium topical solution (Pennsaid) is FDA-approved for treatment of the signs and symptoms of OA of the knee.56

NONSTEROIDAL ANTi-INFLAMMATORY DRUGS

The use of other topical NSAIDs has been studied most notably outside the United States. For example, a topical ketoprofen patch (100 mg) was found to be superior to placebo in reducing pain intensity following 7 days of treatment in a 2-week randomized, placebo-controlled study of 163 patients with pain from an ankle sprain.57 In a separate study, a comparable topical ketoprofen preparation was evaluated in patients with tendinitis in a randomized, double-blind, placebo-controlled study. Subjects treated with the active medication fared better than the placebo-treated group did, and except for the skin irritation experienced by some, the treatment was otherwise well tolerated.58 Ketoprofen gel has been reported to be helpful when used as an adjunct to physical therapy, with benefit reported in a child with Sever’s disease, a not uncommon source of heel pain in growing children.59 A randomized, controlled study of use of a diclofenac patch in 120 individuals experiencing acute pain after a “blunt” injury demonstrated that it was not only well tolerated but also reduced pain intensity greater than did placebo treatment.60 Treatment of acute sports injury-related pain with a diclofenac patch has also been studied. Two studies, one not controlled and the other a multicenter randomized, controlled study, noted that a diclofenac patch was found to be well tolerated and effective in patients with acute sports injuries. Patients experienced an average of 60% pain relief in the open-label study.61,62 Additional NSAIDs have also been studied, and in a noncontrolled study of patients described as experiencing “soft tissue pain,” the reported results indicated that topical flurbiprofen was associated with greater pain reduction than oral diclofenac was and that fewer adverse effects occurred when the topical preparation was used.63 This study is one of very few that actually compared a topical NSAID with an oral agent—an important study design for comparing not only efficacy but also adverse events. In another controlled study, use of topical ibuprofen cream for the management of acute ankle sprains was found to be superior to placebo in reducing pain.64 In a controlled study of ketoprofen gel for the management of acute soft tissue pain, it was found to be more effective than placebo in providing pain relief.65 A topical formulation of 5% ibuprofen gel was examined in a placebo-controlled study in patients with painful soft tissue injuries. Patients received either 5% ibuprofen gel or placebo gel for a maximum of 7 days. Pain intensity levels, as well as limitations in physical activity, were assessed daily. A significant reduction ($P < 0.001$) in pain intensity plus improvement in physical activities was experienced by the patients who received the 5% ibuprofen gel versus placebo.66 A second study with similar patient types completed by the same investigators demonstrated similar results.67 Also of interest is a recent Cochrane database review in which it was concluded that topical NSAIDs can provide good levels of pain relief without the systemic adverse effects of oral NSAIDs in the treatment of acute musculoskeletal pain.68

The use of topical analgesics for the treatment of OA has also been studied, and in fact, multiple reviews of this subject have recently been published.69,70 A diclofenac patch preparation, studied in a randomized, double-blind, controlled study in patients with chronic pain secondary to knee OA, demonstrated that this patch may be safe and effective for this common condition.71 A randomized controlled study comparing the use of a topical diclofenac solution and oral diclofenac for the treatment of OA of the knee concluded that use of the topical diclofenac solution produced relief of symptoms that was equivalent to that of oral diclofenac and resulted in a significantly reduced incidence of diclofenac-related gastrointestinal complaints.72 A recently published long-term study with the same topical diclofenac solution confirmed its safety during the study period.73 A study of individuals with pain in the temporomandibular joint compared treatment with diclofenac solution applied topically several times daily and treatment with oral diclofenac. Even though there was no significant difference in analgesic benefit between the two groups, significantly fewer gastrointestinal side effects were experienced by the patients receiving the diclofenac topical solution.74 Other completed topical NSAID trials include a placebo-controlled trial that demonstrated efficacy of 1.16% topical diclofenac gel in patients with OA of the knee and a randomized controlled study demonstrating benefit from the application of a topical diclofenac solution versus placebo after 6 weeks of treatment in patients with painful OA of the knee.75 One meta-analysis examining the use of topical NSAIDs for the treatment of OA found evidence suggesting that topical NSAIDs are more effective than placebo during the initial 2 weeks of treatment only.76 The authors concluded that the evidence available indicates that topical NSAIDs are inferior to oral NSAIDs during the first week of treatment.77 A separate meta-analysis reviewed the evidence for the use of topical NSAIDs for chronic musculoskeletal pain and concluded that topical NSAIDs are effective and safe in treating chronic musculoskeletal conditions for 2 weeks.80 Another meta-analysis on the use of topical NSAIDs for OA suggested that of the four studies that compared a topical NSAID with placebo or vehicle in patients with OA of the knee, pain relief did occur for a longer period with the topical NSAID than with placebo but that the results were not uniform for the preparations reviewed.81

Health care professionals and especially prescribers must be aware of the fact that topical salicylates are used by patients in over-the-counter preparations. A meta-analysis reviewed the limited data available from trials of musculoskeletal and arthritic pain and concluded that topically applied rubefacients containing salicylates have moderate to poor efficacy in relieving acute and chronic pain. The authors emphasized that estimates of the efficacy of these rubefacients are currently unreliable because of a lack of appropriately designed clinical trials.82 A randomized controlled study completed in Europe with the topical NSAID etelcnac examined its effect in comparison to placebo in 237 patients with knee OA and concluded that use of topical etelcnac for the treatment of OA of the knee versus placebo is safe and effective.83 In an additional clinical trial, topical etelcnac gel was compared with oral diclofenac and
placebo in patients with knee OA. Each active treatment resulted in analgesia superior to that achieved with placebo, but as reported in the meta-analysis mentioned earlier, the incidence of gastrointestinal side effects was notably lower in the group treated with topical etenac gel than in those treated with the oral NSAID diclofenac. Additional studies have demonstrated that topical diclofenac may be effective in reducing the pain associated with various types of degenerative joint disease.

Other topical agents have been studied for these musculoskeletal pain conditions as well. Capsaicin 0.025% cream was determined to be no better than the vehicle (not active) cream in a randomized, double-blind study of 30 patients with pain in the temporomandibular joint. A randomized controlled study of a topical cream containing glucosamine sulfate, chondroitin sulfate, and camphor for OA of the knee showed a significant reduction in pain in the treatment group after 8 weeks when compared with the placebo group.

Although a published case series reported the potential benefit of “topical” morphine in the management of chronic OA-related pain, this report emphasized that morphine or its metabolites, or both, were identifiable in the urine of treated patients, thus calling into question how truly “topical” this preparation was given its systemic effects.

LOW BACK AND MYOFASCIAL PAIN

Regrettably, substantially fewer studies examining the use of topical analgesics for low back pain or myofascial pain, two very common conditions, have been published. A randomized, double-blind, placebo-controlled study comparing the use of topical capsaicin with placebo in 154 patients with CLBP resulted in 60.8% of capsaicin-treated patients versus 42.1% of placebo patients experiencing 30% pain relief after 3 weeks of treatment (P < 0.02). Unfortunately, additional studies have been published in abstract form only—two are novel (one will be mentioned) because they each involve the use of a local anesthetic for conditions not typically thought of as being responsive to this form of treatment. In one, a multicenter, open-label study involving 120 patients with acute (<6 weeks), subacute (<3 months), short-term chronic (3 to 12 months), or long-term chronic (>12 months) low back pain with four 5% lidocaine patches applied to the most painful areas in the low back region demonstrated that during the 6-week study period the majority of patients experienced moderate or a greater degree of pain relief.

OTHER USES OF TOPICAL ANALGESICS

It is important to note other painful conditions in which topical analgesics have been used even if the number of patients studied in each study was relatively small. Various types of topical analgesics, including opiates, may be helpful in reducing the pain associated with pressure ulcers or dressing changes. Controlled studies have demonstrated the benefit of EMLA cream in reducing the pain associated with circumcision and venipuncture and, in addition, in reducing the pain associated with breast cancer surgery. At least two studies have suggested that either topical ketamine or topical morphine can be used for mucositis-associated pain following chemotherapy or radiation therapy in patients with head and neck carcinoma. Topical opiates have been reported to reduce pain in two children with epidermolysis bullosa. In one report, the analgesic effect of menthol, an ingredient common in many over-the-counter analgesic preparations, is hypothesized to be the result of activation of κ-opioid receptors. Burn pain has been reported to be treated effectively with a topical loperamide preparation. Two randomized controlled studies—one involving postoperative pain (diclofenac patch) and the other involving wound pain treatment (capsicum plaster topically applied at acupuncture sites)—have been published as well.

Central neuropathic itch was treated successfully with the 5% lidocaine patch in a single case report. The results of an enriched enrollment study in which an open-label initial study led to the randomization of responders in a placebo-controlled study of the use of either 4% amitriptyline/2% ketamine cream, 2% amitriptyline/1% ketamine cream, or placebo in patients with PHN demonstrated that after 3 weeks of treatment the average daily pain intensity was lower in patients receiving the higher-concentration combination cream than in those receiving the lower concentration combination or placebo (P = 0.026 for the high-concentration cream vs. placebo). Plasma levels of either drug were detected in less than 10% of the patients receiving active treatment. An open-label study of the use of a 0.25% capsaicin topical agent in a lidocaine-containing vehicle in 25 patients with painful diabetic polyneuropathy and 7 patients with PHN demonstrated pain relief in the majority of patients who were studied. In a noncontrolled study of 23 patients with acute migraine headache, 0.1% capsaicin gel applied topically was helpful in reducing mild or moderate pain. In a randomized, double-blind study assessing 154 patients with chronic pain from lateral epicondylitis, topical glyceryl trinitrate (0.72 mg/day) was found to provide statistically significantly greater pain relief after 8 weeks when compared with placebo. In a study of 52 patients with chronic pain secondary to chronic Achilles tendinopathy, patients who had been treated with topical glyceryl trinitrate for 6 months were more likely 3 years after treatment to have less pain and more function than those who had been treated with placebo. Published reports of the use of topical phenytoin for the treatment of pain from superficial burns or chronic leg ulcers are noted as well.

CONCLUSION

The clinician should consider the use of topical analgesics for a variety of painful conditions. Of note is that the number of FDA-approved topical agents has increased. Off-label use of the available therapies must include careful consideration of the potential risks, as well the benefits of such. Given the repeated observations that topical analgesic use is generally associated with a more desirable side effect profile than are orally, transdermally, parenterally, or intrathecaally administered analgesics, this factor should be considered when developing a pain management treatment regimen for individual patients, especially when...
pharmacotherapy will be involved. Certainly, additional large, well-designed studies that include comparative trials with nontopical analgesics would be helpful to better understand the role of topical analgesics in the management of acute and chronic pain.

KEY POINTS

- In contrast to using a systemic analgesic, use of a topical analgesic is less likely to be associated with systemic side effects since the systemic concentration of a topical analgesic is likely to be lower than that with systemic administration.
- Topical analgesics are not equivalent to transdermal analgesics.
- Despite the localized, peripheral mechanism of action of a topical analgesic, there may be central nervous system effects related to the topical analgesic.
- The clinical benefit of topical analgesics for a broad range of chronic pain conditions has clearly been established.

Neuraxial Agents

Robert W. Hurley | Dustin Anderson | Steven P. Cohen

Medication delivery to the spinal cord or the dorsal nerve roots via the intrathecal or epidural route exploits the endogenous pharmacology of the neuraxis to relieve pain in patients. These methods of delivery require a certain degree of expertise and are commonly used by anesthesiologists and interventional pain management specialists. In 1885, Leonard Corning described the first neuraxial administration of a medication, first in a dog and then in a man suffering from "seminal incontinence."1 Fourteen years later, Augustus Bier (Fig. 43.1) reported the first case whereby cocaine was administered intrathecally to provide surgical anesthesia for lower limb orthopedic procedures.2 The first use of a neuraxial technique to treat chronic pain was in 1901 when Sicard administered a local anesthetic epidurally via the caudal route.3 Another significant breakthrough occurred in 1942 when Janez Marlan used a catheter to continuously administer medication for labor analgesia.4 The epidural injection of steroids for the treatment of sciatica was first described in 1953.5 Several years after the discovery of the endogenous opioid receptors and their respective agonists, Wang reported treating cancer pain with intrathecal morphine.6

This chapter focuses on the current pharmacologic agents that are administered into the epidural or intrathecal space to produce antinociception (in animals) or analgesia (in humans), as well as future potential agents. The outcomes of neuraxial anesthesia and analgesia on postsurgical morbidity, as well as long-term neuraxial analgesia either by intrathecal pump or a tunneled epidural catheter, are covered elsewhere in this text and, hence, are not addressed in this chapter.

PERIPHERAL NERVE NEUROTRANSMITTERS AND THE SPINAL CORD

A variety of mechanical, thermal, or chemical stimuli can result in the sensation of pain. Information about these painful or noxious stimuli is carried to higher brain centers by receptors and neurons that are distinct from those that carry innocuous somatic sensory information. Small-diameter A-delta and C fibers primarily transmit nociceptive information. Neurotransmission by A-delta and C fibers is accomplished via the release of numerous peptides, including substance P, calcitonin gene-related peptide, galanin, vasoactive intestinal peptide, and somatostatin into the spinal cord. The excitatory amino acid, glutamate, is also present within small-diameter primary afferents and can be released by noxious stimulation, resulting in the activation of second-order neurons in the dorsal horn of the spinal cord.7 The presynaptic nerve terminals of primary afferents in the spinal cord are potential therapeutic targets. They possess numerous receptor systems that can enhance transmission by increasing the release of excitatory amino acids and other transmitters, activating voltage-gated calcium channels and purinergic receptors, and inhibiting pathways involved in the modulation of pain, such as alpha2-adrenergic, cholinergic, serotonergic, and opioid receptors as well as gamma-aminobutyric acid (GABA) systems.8-12

Primary afferent neurons release neurotransmitters, activating postsynaptic receptors on second-order projection neurons in the spinal cord (Fig. 43.2).13 Second-order neurons in the dorsal horn possess a wide variety of neurotransmitter receptors. A subset of these receptors, including those involving substance P and the excitatory amino acid glutamate (e.g., N-methyl-D-aspartate [NMDA] and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid [AMP] kainate, mGluR), can induce depolarization of the neuron, leading to increased nociceptive transmission. Activation of other receptors such as opioid, GABAergic and serotonergic incites hyperpolarization of postsynaptic neurons, thereby inhibiting the transmission of noxious stimuli. Neurotransmission by second-order neurons on bulbar or thalamic targets is primarily through glutamate, resulting in depolarization of postsynaptic AMPA and NMDA receptor-containing neurons.14

NEURAXIAL AGENTS

Medications approved by the Food and Drug Administration (FDA) can be used for a multitude of purposes, including not only the approved indication, but for off-label indications as well. This practice is common with systemically delivered medications. Unfortunately, it has also become common practice to use medications approved for systemic use in anatomic sites that have not been tested for safety. These sites include the intrathecal or epidural compartments that can result in actual or potential risk to the spinal cord of patients.15 During 2007-2008, the journals Anesthesia & Analgesia, Anesthesiology, and Regional Anesthesiology and Pain Medicine revised their instructions to authors to address this concern and established the following policy:16

1. Is the drug approved by the FDA for this indication?
2. If the drug is not approved, is it widely used off-label (e.g., in tens of thousands of patients)? [The] editorial board concluded that if multiple textbooks indicated that the drug could be safely used in a given manner, this was a suitable surrogate demonstration that the drug was widely used for the indication.
3. If neither 1 nor 2 applies, was the study performed with an "Investigator Investigational New Drug (IND)" from the FDA or an equivalent regulatory authority?

This chapter is divided into three categories: (1) medications with FDA approval for neuraxial administration; (2) medications without FDA approval but which are commonly used; and (3) experimental medications that have neither received approval nor are in common use.

LOCAL ANESTHETICS (BOX 43.1)

The most widely used drugs for neuraxial analgesia are local anesthetics, which produce a reversible conduction blockade of impulses in peripheral and central nerves. Local anesthetics have proven to be safe and reliable in interrupting nerve impulse conduction in both peripheral and central nerves. Local anesthetics are most commonly used to provide surgical anesthesia, postoperative pain relief, and relief of cancer pain. The discussion of local anesthetic agents will be brief.

Electrical impulses in the form of action potentials are conducted along nerve fibers. The propagation of electrical impulses along nerve fibers in the form of action potentials is responsible for transmitting sensory and motor information along the nerves. Action potentials are dependent on maintaining a resting membrane potential of approximately 60 to 70 mV, which requires various pumps and channels to sustain an electrochemical gradient. The most important channel is the voltage-gated sodium channel, which allows the influx of sodium ions during the depolarization phase of the action potential, thus enabling an impulse to travel down the nerve fiber. These sodium channels are complex three-dimensional structures integrated into the membrane lipid bilayer of the nerve cells. Local anesthetic agents act by interrupting the propagation of an impulse, thereby inhibiting the nerve conduction of a painful stimulus. Local anesthetics gain access to the sodium channel from either the plasma or cytoplasmic side of the channel protein, and bind within the pore of the channel. The binding of sodium channels by local anesthetics is state dependent. The local anesthetic can bind to the channel when it is open (active), closed (inactivated), or in a resting state. However, the receptor has the highest affinity when the channel is open or closed and the lowest affinity in the resting state. These processes are not sensory specific; thus, local anesthetics are capable of blocking the transmission of all nerve fibers, not just A-delta and C fibers. Therefore, the potential for motor blockade, as well as sensory blockade, limits the use of these agents.

OPIOIDS (BOX 43.2)

Opioid analgesics exert their actions through the inhibition of target cell activity. The existence of multiple types of opioid receptors was originally proposed by Martin and colleagues. Subsequent studies using both in vitro and in vivo
pharmacologic methods, and employing alkaloid-derived and synthetic compounds, provide support for the existence of multiple opioid receptor subtypes, including mu, delta, and kappa receptors. Molecular cloning techniques have, thus far, identified three gene families that encode for these receptors. In addition, an “orphan” opioid receptor (ORL1), which shares substantial sequence homology but does not bind prototypic opioid receptor agonists with high affinity, has also been identified and structured. All of the opioid receptors belong to the GTP-binding protein superfamily of metabotropic receptors. Agonist binding to opioid receptors results in activation of inwardly rectifying potassium channels, the inhibition of N-type and L-type calcium channels, or the inhibition of adenylate cyclase activity, all processes by which neuronal excitability can be suppressed.

Whereas peripherally located opioid receptors have been identified, the predominant analgesic sites are believed to reside in the central nervous system (CNS). In the brain, these receptor sites include the brainstem, thalamus, forebrain, and mesencephalon. In the spinal cord, they include the postsynaptic receptors located on cells originating in the dorsal horn, as well as presynaptic receptors found on the spinal terminals of primary afferent fibers.

The effects of opioids are determined not only by their affinity for endogenous receptors but also by their ability to reach those receptors. The onset of analgesia is similar for intrathecal and epidural narcotics, suggesting that the penetration of neural tissue—and not the meninges—is the rate-limiting step. Intrathecal opioids exert their analgesic properties by presynaptically inhibiting the release of glutamate, substance P, and calcitonin gene-related peptide, molecules believed to be responsible for transmitting nociceptive signals across synapses. Epidurally administered opioids may operate via an additional mechanism. The systemic absorption of an epidural bolus of lipophilic opioids (e.g., fentanyl and sufentanil) is similar to that which follows an intramuscular injection and may play a role in the analgesic effects. The conflicting theories regarding how epidural lipophilic opioids exert their pain-relieving properties may be partially explained by the differing modes of administration. For example, a bolus of epidural fentanyl appears to produce analgesia mostly via spinal mechanisms, whereas uptake into the systemic circulation plays a major role in the analgesic effects produced by continuous epidural infusion. In contrast, hydrophilic opioids as morphine are more likely to diffuse across dural membranes where their primary analgesic effect is exerted through receptors in the dorsal horn.

Lipid solubility determines, in part, several other important characteristics of intrathecal opioids, including the spread of analgesia and side effects. Opioids that are highly water soluble, such as morphine, exhibit a greater degree of rostral spread when injected into the subarachnoid or epidural space than lipid-soluble compounds, so that in pain conditions requiring higher spinal levels or more extensive coverage, the degree of analgesia they confer may be superior. Conversely, because many of the adverse effects of spinal opioids, such as nausea, vomiting, and delayed respiratory depression, are the result of interaction with opioid receptors in the brain, the more water-soluble compounds are associated with a higher incidence of these problems.

Whereas the earliest studies evaluating the chronic use of intrathecal opioids were conducted in patients suffering from cancer pain, other studies have found intrathecal and epidural narcotics to be effective in nonmalignant pain as well. These conditions include not only nociceptive pain but also neuropathic pain, a heterogeneous group of disorders originally believed to be resistant to narcotics. Certain aspects of neuropathic pain, such as tactile allodynia, may be less responsive to the effects of spinal opiates. Therefore, many neuropathic conditions require adding nonopioid adjuvants to spinal opioids for successful pain relief. The caveat with the treatment of nonmalignant pain via intrathecal opioids is that these patients have a higher likelihood of complications resulting from the opioid therapy because of their normal life expectancy compared to those with cancer. Aside from the common intrathecal opioid side effects such as tolerance, constipation, sweating, nausea, and urinary retention, these patients are at risk for the development of intrathecal granulomas. Factors that are positively associated with the development of catheter tip granuloma include drug dosage, drug concentration, and the duration of intrathecal opioid therapy. In 2008, Deer and associates published recommendations for the maximum daily dose and maximum concentration of intrathecal medications (Table 43.1).

When opioids are administered directly into the cerebrospinal fluid, only a fraction of the systemic dose is required, as there are no anatomic barriers to be crossed, and vascular reuptake is slow. Not all side effects of intrathecal opioids are

dose related, but in many instances, the drastic reduction in dosage translates into reduced side effects. In fact, one of the primary indications for a trial with intrathecal or epidural narcotics is a good analgesic response to systemic opioids coupled with intractable side effects. Among the adverse opioid effects reduced by switching from oral formulations to spinal administration are sedation and constipation. Effects that may be increased include pruritus, urinary retention, and edema. The mechanisms contributing to the various adverse effects of opioids are incompletely understood but probably multifactorial and include those that are mediated via interaction with specific opioid receptors and those that are not. Undesirable effects not mediated by opioid receptors, such as CNS excitation and hyperalgesia, cannot be reversed with naloxone. The incidence of various opioid-induced side effects depends on a number of different factors including the opioid infused, route of administration and dosage, extent of disease, concurrent drug (e.g., oral opioids, adjuvants), age, concomitant medical problems, and prior exposure to opioids. The most frequent side effects of intrathecal morphine are constipation, sweating, urinary retention, nausea and vomiting, and disturbances of the libido.42-45

CALCIUM CHANNEL ANTAGONISTS (BOX 43.3)

Voltage-dependent calcium channel (VDCC) conduction plays an integral role in pain transmission. Diversity among these voltage-gated calcium channels was originally described through differences in the biophysical properties of calcium currents recorded from individual neurons. Multiple distinct voltage-gated calcium currents were observed, including the L-type responsive to dihydropyridines, the T-type responsive to ethosuximide, and the N-type and P/Q-type responsive to conotoxins. Molecular cloning has led to the identification of multiple genes encoding the calcium channels that correspond to the biophysical and pharmacologic profiles of the receptor subtypes. VDCCs are located in the plasma membrane of all excitable cells, including the neurons of the peripheral and central nervous system. These calcium channels are found in high concentrations in the dorsal horn of the spinal cord and dorsal root ganglia.46

The neuraxial administration of some VDCC modulators has been shown to produce antinociception, antiallodynia, and antihyperalgesia in animals. High threshold VDCCs, including N- and P/Q channels, are primarily found at synaptic sites involved in the release of transmitters; L-type channels are mainly observed at cell bodies and dendrites.47,48 Several VDCCs have been found to co-localize in the same neuron; therefore, antagonists to a given channel type usually block only a fraction of the VDCCs present and hence may have additive effects when combined. Finally, the relative importance of the various channel types depends on the functional status of the neuron. For instance, in acute models of nociception in uninjured naïve animals, there is a large body of evidence implicating N types, limited evidence for L types, and no evidence for P/Q types in producing antinociception. However, under conditions of persistent nociception induced in animals by chemical, inflammatory, or neuropathic stimuli, all three of these subtypes have been found to have anti-allodynic or anti-hyperalgesic properties.49,50 Although the physiologic and pharmacologic properties of VDCCs are largely determined by the molecular identity of the α1 subunit, the auxiliary subunits, including α2d1, also play a substantial role in the receptors’ characteristics. Gabapentin and pregabalin are two medications originally designed as structural analogs of GABA; however, neither drug acts as an agonist at GABA_A or GABA_B receptors, and neither drug acutely alters GABA uptake. It is likely that their analgesic effects are mediated at the α2d1 subunits of VDCCs, for which both have a substantial affinity.51,52 Intrathecal gabapentin has no effect on an animal’s nociceptive threshold in the uninjured state, but it does possess antihyperalgesic and anti-allodynic properties in animal models of chronic pain.53,54 A substantial portion of the effects exerted by gabapentin are mediated by the N-type VDCC.53,54

Ziconotide is a synthetic form of the peptide, ω-conotoxin MVIIA, which is isolated from the venom of the marine cone snail, Conus magus.55 It potently blocks N-type VDCCs in vitro and inhibits wind-up. The process of wind-up involves the activation of spinal NMDA receptors after injury, which induces a state of facilitated processing from repetitive small afferent fiber stimulation. This in turn leads to an increased response to high and low threshold stimulation and enhanced receptor field size. Ziconotide is the first member in the new drug class of selective N-type voltage-sensitive calcium channel blockers. It has been approved by the U.S. Food and Drug Administration and the European Medicines Agency for intrathecal treatment of patients with severe chronic pain that is refractory to other treatment modalities.56 Ziconotide blocks N-type calcium channels in the spinal cord and inhibits release of pain neurotransmitters from the central terminals of primary afferent neurons. By way of this mechanism, ziconotide has been found to effectively reduce pain. In a multicenter, double-blind, placebo-controlled study evaluating intrathecal ziconotide for the treatment of refractory pain in 111 patients with cancer and acquired immunodeficiency syndrome (AIDS), Staats and colleagues57 found that the treatment group obtained significantly enhanced pain relief compared to the control group (33% versus 18% improvement). The observation that there was no loss of efficacy for ziconotide in the maintenance phase is consistent with animal studies showing the absence of tolerance with calcium channel blockers. The most common side effects noted in this study were confusion, somnolence, and urinary retention; however, 97% of patients receiving ziconotide experience side effects, and 30% had serious adverse events. All side effects were reversible, with their incidence decreasing after the initial dosing period.

Common Use  
Investigational
In a randomized, double-blind, placebo-controlled trial, Wallace and colleagues demonstrated that intrathecal (IT) ziconotide provides relief in patients suffering from severe chronic nonmalignant pain who are unresponsive to conventional therapy. Patients were treated over a 6-day period and were found to respond to dosing of 0.1 µg/hr to 2.4 µg/hr. The original starting dose of 0.4 µg/hr was decreased due to a high incidence of side effects. The mean reduction in pain score from baseline was 31.2% in the treatment group compared to 6.0% in the placebo group. Patients in the treatment group reported suffering more side effects, including abnormal gait, amblyopia, dizziness, nausea, nystagmus, pain, urinary retention, and vomiting. However, Rauk and associates demonstrated that slow titration can provide comparable pain relief while minimizing the side effects experienced by patients. Wallace and colleagues showed that ziconotide could be safely given for long-term treatment of refractory pain. More than 644 patients with severe chronic pain participated in this open-label, multicenter longer-term trial. Thirty-two percent of patients receiving ziconotide for over 360 days, with a dose range between 0.048 µg/day and 240 µg/day, experienced greater than or equal to 32.7% improvement in pain scores. Although only FDA approved as single therapy (Table 43.2), emerging evidence suggests that ziconotide can be safely combined when administered intrathecally with baclofen, morphine, sufentanil, and bupivacaine. Webster and colleagues added morphine to stable IT ziconotide therapy in 25 patients, which resulted in a mean 26.3% reduction in pain and a 49.1% reduction in opioid consumption at week 4 of treatment. This study suggests a synergism between morphine and ziconotide. When IT ziconotide is combined with other drugs such as opioids and baclofen, the stability declines, which may necessitate more frequent refills.

More recently, ziconotide has been anecdotally reported to successfully treat neuropathic pain and trigeminal neuralgia. The main limitations regarding the use of IT ziconotide are its steep cost and the high incidence (> 80% in many studies) of side effects, which can include the neurologic, psychiatric, cardiovascular, gastrointestinal, and genitourinary systems. Although in some guidelines ziconotide is now considered to be a first-line treatment for chronic pain, this therapy has an extremely narrow therapeutic window with substantial side effects and should be reserved for patients for whom other agents and therapies have been exhausted.

The epidural administration of VDCC modulators has also been examined. In a double-blind study conducted in healthy cohorts, adding a low dose (5 mg) of the L-type calcium channel blocker, verapamil, to epidural bupivacaine both pre- and postsurgical incision was found to reduce postoperative analgesic requirements in patients undergoing abdominal surgery. In a case report, Filos and collaborators described a modest and short-lived analgesic benefit for epidural nimodipine in two terminal cancer patients. The authors reported significant discomfort upon administration, but with no increased incidence of sedation, mood disturbances, or hypotension.

**GAMMA-AMINOBUTYRIC ACID AGONISTS (BOX 43.4)**

Three types of GABA receptor are currently recognized: GABA_A, GABA_B, and GABA_C. Only GABA_A and GABA_B receptors are present in significant quantities within the CNS. The GABA_A receptor is a ligand-gated ion channel. Activation of this receptor by GABA results in an influx of chloride ions and stabilization of the membrane potential, which decreases neuronal excitability. The receptor possesses two binding sites for GABA, as well as sites at which barbiturates, inhalational anesthetics, neurosteroids, and benzodiazepines bind to modulate the action of GABA. The receptor itself is a pentameric arrangement of different subunits. In contrast, the GABA_B receptor is a metabotropic receptor. Activation of the GABA_B receptor by GABA results in activation of inwardly rectifying potassium channels, inhibition of calcium channels, or inhibition of adenylate cyclase activity, all of which suppress neuronal excitability.

In laboratory animals, GABA_A agonists including muscimol, isoguvacine, and midazolam have anti-allodynic and antihyperalgesic effects in chronic pain models, whereas the GABA_A antagonists, bicuculline and picrotoxin, induce allodynia and hyperalgesia in naïve rats. However, GABA_A receptors are also closely linked to large-diameter afferents and, thus, are likely involved in modulating innocuous sensations as well. Similar to GABA_A receptors, GABA_B receptors are found in greatest abundance in the superficial dorsal horn of the spinal cord. Within the GABAergic system, nociceptive transmission is primarily regulated primarily by GABA_A receptor activity. The GABA_B receptor agonist, baclofen, blocks the activity of peripheral C and A-delta nociceptive fibers. Further, in the spinal cord, GABA_B receptors are found on interneurons as well as on terminals from primary afferent neurons. GABA_B receptor agonists administered via the intrathecal or epidural route produce presynaptic inhibition, and therefore block the release of glutamate, substance P, and calcitonin gene-related peptide (CGRP) from primary afferents, and GABA from interneurons.

In naïve animals, the intrathecal administration of antagonists to either receptor increases pain behaviors, suggesting that tonic release of GABA in the spinal cord...
prevents innocuous stimuli from being perceived as noxious. In animal models of acute and persistent nociception, GABA\(_A\) agonists such as baclofen produce antinociception and anti-aldolasia, respectively, at doses in which no motor impairment is observed.\(^70,71\) In contrast, the highly selective GABA\(_A\) agonist, muscimol, was found to be effective only in animal models of persistent nociception.\(^72\) Interestingly, in the same study, midazolam, the only GABA\(_A\) agonist presently available for human use, was ineffective in either acute or persistent pain models at doses that did not produce substantial motor impairment. In summary, the results from animal studies suggest that both GABA\(_A\) and GABA\(_B\) receptor agonists could be used to treat chronic pain.

In human studies, both GABA\(_A\) and GABA\(_B\) agonists have been shown to contain analgesic effects when injected into the intrathecal or epidural space. The literature shows that the neuraxial administration of GABA\(_A\) agonists in combination with local anesthetics increases the duration of motor and sensory block, increases the time to first analgesic request, and decreases postoperative analgesic requirements. The administration of the GABA\(_A\) agonist, midazolam, via either the intrathecal or the epidural route in combination with a mixture of other analgesics, including local anesthetics and opioids, was found to reduce opioid requirements and enhance postoperative analgesia for a variety of different surgical procedures.\(^73-77\) Ghai and associates\(^78\) found that adding 20 µg/kg/hr of midazolam to a continuous postoperative epidural of 0.125% bupivacaine reduced the requirement for rescue analgesia in children following upper abdominal and flank surgery. In a meta-analysis of 13 randomized controlled trials involving 672 patients, Ho and Ismail\(^79\) found that adding midazolam to other spinal medications delayed the time to request for rescue analgesia and reduced the incident of nausea and vomiting. A prospective, randomized, double-blind study by Shadangi and associates\(^80\) involving patients undergoing elective lower abdominal, lower limb, and gynecologic procedures found that adding midazolam to bupivacaine significantly improved analgesia. One hundred patients were randomized to receive a combination of either 0.4 mL (2 mg) midazolam with 3 mL of 0.5% bupivacaine or 0.4 mL normal saline with 3 mL of 0.5% bupivacaine. The duration of sensory blockade was prolonged in the group receiving midazolam by over 25 minutes without increasing motor blockade. In a double-blind study evaluating the effects of adding intrathecal midazolam to bupivacaine in patients undergoing hemiorrhoidectomy, the addition of midazolam was found to expedite the onset of spinal analgesia in a dose-dependent manner.\(^78\) Other studies have found intrathecal midazolam to be effective in treating chronic mechanical low back pain, musculoskeletal pain, and neurogenic pain.\(^80\) In an open-label study, Prochazka and colleagues\(^81\) demonstrated the effectiveness of midazolam in the treatment of chronic low back pain and failed back surgery syndrome. Midazolam 2 to 5 mg was administered 500 times in 126 patients from 1995 to 2010. The analgesic effect lasted 9.7 weeks, with 65% of patients experiencing relief lasting 4 weeks or longer. The administration of subarachnoid midazolam was shown to be effective in treating pain associated with chronic, nonmalignant pain.\(^80\)

The safety of neuraxial administration of midazolam is controversial. Numerous animal studies have shown evidence of neurotoxicity with intrathecal midazolam. Svensson and associates\(^82\) found histologic evidence of neuronal death in the spinal cords of rats after 20 consecutive days of 100 µg intrathecal injections of midazolam. Unfortunately, the relative doses and concentrations of midazolam used in these animal studies were many times higher than those used in human studies. Malinovsky and colleagues\(^83\) reported that midazolam (1 mg/mL) produced histologic pathology that was greater than that of lidocaine or saline controls. Similar results were obtained by Erdine and colleagues,\(^84\) who found that rabbits infused with both preservative-containing and preservative-free intrathecal midazolam (300 µg daily, 1 mg/mL) over 5 days displayed vascular and other histologic spinal cord lesions on microscopic examination. Part of the controversy revolves around the pH of the medications administered. In an attempt to resolve this controversy, Bozkurt and colleagues\(^85\) administered normal saline, midazolam, and a saline vehicle control with the same acidic pH as midazolam epidurally in newborn rabbits. During electron microscopy examination on days 2 and 7, both the acidic midazolam and saline groups displayed significant pathologic spinal cord changes, such as degeneration of vacuoles, cytoplasm, and neurofilaments, disruption of myelin sheaths, lysis of cell membranes, perivascular edema, and pyknosis of nuclei. In contrast, the normal pH saline group displayed normal histology on spinal cord sectioning. More recent literature evaluating multiple doses of commercially available concentrations of midazolam in two species of animals found no histopathologic or behavior differences compared with saline controls.\(^86\) At present, the use of midazolam as a spinal analgesic is not FDA approved due to safety concerns. However, in clinical studies, there have been no reported adverse cardiovascular (hypotension or bradycardia), urologic (urinary hesitance or incontinence), or gastrointestinal (nausea or vomiting) side effects when compared to administering the local anesthetic alone.\(^13\) Prochazka and associates\(^81\) injected doses of 0.02 to 0.06 mg/kg into 14 patients with 10 administrations or more and reported that none of them displayed any clinical signs of neurotoxicity, such as bladder or bowel dysfunction, motor or sensory deficits, or new neuropathic pain. Canavero and colleagues\(^87\) reported successful intrathecal treatment of neuropathic pain with midazolam in a 60-year-old woman. They reported that intrathecal midazolam ranging from 2 to 4.6 mg successfully controlled neuropathic pain for over 6½ years. In one human study involving 1100 patients who were either administered intrathecal local anesthetic or local anesthetic and midazolam 2 mg for surgery, the authors reported no increased incidence of postoperative neurologic signs or symptoms or any other difference in complication rates between the two groups.\(^88\) Midazolam is currently considered a fifth-line neuraxial treatment for chronic pain.\(^89\)

Numerous studies support the use of neuraxial baclofen for spasticity in humans. There are multiple uncontrolled studies showing intrathecal baclofen to be effective for a variety of central pain conditions as well, including stroke, phantom limb pain, spinal cord injury, cerebral palsy, amyotrophic lateral sclerosis, and multiple sclerosis.\(^90-93\) Intrathecal baclofen has also been found to be an effective treatment for peripheral neuropathic pain conditions, such complex regional pain syndrome.\(^94-96\) In a small study by Lind and
The authors found that the addition of intrathecal baclofen in patients being treated with spinal cord stimulation for neuropathic pain improved pain scores to a greater degree than concomitant treatment with oral baclofen. The beneficial effect of intrathecal baclofen was dose dependent, peaking at 50 µg. Furthermore, at follow-up Lind and colleagues found that patients who were treated for a mean of 67 months enjoyed the same degree of pain relief, requiring only a modest (30%) dose increase. More recently, van Rijn and associates found that intrathecal baclofen provides substantial improvement in patients suffering from dystonia and in those with complex regional pain syndrome (CRPS). Thirty-six patients received a pump for continuous intrathecal baclofen for 12 months. Patients experienced a decrease in pain and disability as well as an improved quality of life. However, patients did experience a high complication rate, most often associated with pump or catheter system defects. Intrathecal baclofen administration as a therapeutic modality remains promising and would benefit from more research.

Neuraxial baclofen has also been found to be beneficial in the treatment of musculoskeletal pain. Loubser and Akman found that intrathecal baclofen reduced musculoskeletal, but not neurogenic, pain in 12 patients with chronic spinal cord injury–related pain. Based on the results of this study and the temporal disparity regarding its analgesic effects on central pain and muscle spasm, it is likely that different pain-relieving mechanisms exist for these two conditions.

At therapeutic doses, baclofen is associated with numerous adverse effects, including drowsiness, flaccidity, headache, confusion, hypotension, weight gain, constipation, nausea, urinary frequency, and sexual dysfunction. Intrathecal baclofen overdose can lead to respiratory depression, seizures, obtundation, and, if not adequately treated, death. Withdrawal from abrupt cessation of intrathecal baclofen treatment can last days to weeks, or possibly longer, and can also be life threatening. There is growing evidence to suggest that replacement with oral baclofen may not always be adequate to control the symptoms, possibly because oral baclofen does not reach the central concentrations near the range achieved with intrathecal administration. Some studies suggest that tizanidine may represent a viable option for patients with spasticity and blood pressure lability, specifically with hypertension. Currently, there is animal model evidence to support intrathecal tizanidine for neuropathic pain, but it is not approved for use in humans. Baclofen is currently considered a fourth-line treatment for chronic pain (Table 43.3).

### ADRENERGIC AGONISTS [BOX 43.5]

Adrenergic agonists have analgesic effects when applied for the management of chronic pain. Alpha-adrenergic receptors are widely distributed throughout the body and consist of two clinically significant classes: alpha_2 and alpha_3. Alpha_2 receptors are found in the smooth muscle cells of the peripheral vasculature and play an essential role in the regulation of systemic vascular resistance; they have no known significant role in analgesia. Alpha_2 receptors however, are present throughout the peripheral and central nervous system and play a substantial role in modulating pain signals. There are several known subunits of the alpha-receptor: 2a, 2b, and 2c. Clonidine binds to pre- and postsynaptic alpha_2 receptors in the dorsal horn. Activation of these receptors depresses presynaptic C-fiber transmitter release and hyperpolarizes the postsynaptic membrane through the G_i-coupled potassium channel. A different physiologic effect transpires, depending on the particular alpha subunit involved. The neuronal responses can be either inhibitory or excitatory. For example, the 2b subtype produces hemodynamic responses (primarily hypotension), whereas the 2a receptor is responsible for analgesia.

The mechanism of action of neuraxial alpha_2 agonists is similar to that for opioids in that they can exert effects on presynaptic and postsynaptic neurons. On the presynaptic neuron, they bind to alpha_2 receptors of primary afferent neurons, resulting in hyperpolarization and depressed release of neurotransmitters involved in pain transmission. On postsynaptic neurons, alpha_2 agonists hyperpolarize the cell by increasing the transmission of potassium through G_i-coupled potassium channels. Among the alpha-adrenergic agonists used for analgesia, clonidine remains the prototypical nonselective alpha_2 agonist, partly because it has been the most studied (Table 43.4). Clonidine is a nonselective agonist that produces antinociception via interaction with the alpha_2a receptor. However, it also produces substantial hemodynamic side effects due to its interaction with the 2b receptor. A newer agent, dexmedetomidine, is a selective alpha_2a receptor agonist that contains analgesic and sedative properties, with less respiratory depression and fewer cardiovascular effects.

which may contribute to their analgesic effects. In addition to their antinociceptive properties, alpha2 agonists can produce dose-dependent sedation, presumably by inhibitory mechanisms involving the brainstem.116,117

Alpha2 agonists have been administered intrathecally in humans since 1985. The antihypertensive medication, clonidine, is the most studied alpha2 agonist for neuraxial use. Although it is FDA approved for epidural use only in cancer pain, clinical reports have shown it to be effective intrathecally and epidurally for nonmalignant pain as well.118,119 Intrathecal clonidine has been reported to provide significant analgesia in combination with opioids for neuropathic pain and cancer pain, and it has been used in the pediatric population for these reasons.119 Clonidine has not consistently been shown to be effective as a single agent, but studies have shown it to prolong and enhance the effects of spinal and epidural anesthesia when coadministered with local anesthetics.120-122 When added to opioids, clonidine can extend the duration of pain relief for labor analgesia and postoperative pain.123-125 However, for acute pain, the evidence that adding clonidine to an epidural or intrathecal opioid is more effective than either analgesic alone is weak and inconsistent. Neuraxial clonidine has shown efficacy in treating central pain and spasticity after spinal cord injury.126 Studies show that dexmedetomidine prolongs local anesthetic motor and sensory blockade when compared to opioids.125,126 Alpha2 receptor agonists may also be suitable for patients suffering from neuropathic pain. In a randomized, placebo-controlled trial evaluating epidural clonidine in refractory reflex sympathetic dystrophy, Rauck and colleagues found that 300 µg of clonidine was equally effective but associated with less side effects than 700 µg.

Wu and collaborators compared preoperative epidural clonidine followed by patient-controlled epidural analgesia (PCEA) with clonidine, morphine, and ropivacaine to a control group who received preoperative epidural saline followed by PCEA with morphine and ropivacaine in 40 patients scheduled for elective colorectal surgery. Patients in the clonidine group exhibited longer PCEA trigger times, lower pain scores at rest and while coughing, less morphine consumption, and a faster return of bowel function throughout the 72-hour postoperative period compared with patients in the control group. Interestingly, the concentration of certain proinflammatory cytokines was also decreased in the clonidine group 12 and 24 hours following surgery. The most common side effects of neuraxial clonidine are sedation, hypotension, nausea and vomiting, and bradycardia. Hypotension and bradycardia are likely the result of alpha2 effects on preganglionic fibers in the thoracic spinal cord. Sedation results from their action exerted at supraspinal sites.

The interest in dexmedetomidine has grown in recent years because of its decreased cardiovascular and respiratory effects. Kanazi and colleagues showed, in a prospective, double-blind study, that 60 patients undergoing transurethral resection of prostate or bladder tumor under spinal anesthesia experienced a prolonged duration of motor and sensory blockade, with no increase in adverse hemodynamic effects or level of sedation. Patients were randomized to three groups receiving either dexmedetomidine (3 µg) or clonidine (30 µg) added to bupivacaine or bupivacaine alone. These results suggest that low-dose dexmedetomidine has similar analgesic efficacy to clonidine.

Clonidine has been studied extensively in animals and has produced no evidence of neurotoxicity.129 The number of studies involving human exposure continues to grow, and these studies have not revealed any clinical evidence of neurotoxicity. Clonidine, therefore, appears to be a drug that can be administered safely in humans via the spinal route.

### GLUTAMATERGIC RECEPTOR ANTAGONISTS

#### BOX 43.6 Intrathecal Glutamatergic Medications

Similar to GABAergic and cholinergic receptors, glutamatergic receptors are divided into the G-protein-coupled (metabotropic) receptors (mGluR) and ion channel (ionotropic) receptors, which include NMDA, AMPA, and kainite receptors. The NMDA receptors contain ion channels permeable to calcium, sodium, and potassium. The NMDA ion channel is somewhat unique in that ambient concentrations of magnesium block NMDA responses in a use- and voltage-dependent manner. In addition to the glutamate binding site, the NMDA receptor has binding sites for glycine, which functions as an obligatory co-agonist, phencyclidine-like compounds, and endogenous protons and polyamines. Endogenous protons inhibit NMDA receptors via their interactions with an extracellular proton sensor on one of the receptor’s subunits. Endogenous polyamines such as spermine and spermidine bind at a separate site but shield this proton receptor, thereby potentiating NMDA receptor activity. The AMPA and kainate receptors function as ion channels that are permeable to sodium and potassium. Activation of the ionotropic receptor results in depolarization and neuronal excitation. Metabotropic glutamate receptors are divided into three groups. Group I receptors are positively coupled to phosphatidylinositol hydrolysis, and activation of these receptors ultimately increases intracellular calcium levels. The second and third groups of mGluRs are similar to opioid receptors in that they are negatively coupled to adenylate cyclase; hence, activation of these receptors results in neuronal inhibition.

In animal studies, intrathecally applied, selective agonists at the NMDA, AMPA, kainite, and group I mGlu receptors produce spontaneous pain behavior in naive animals, and allodynia and hyperalgesia in neuropathic and inflammatory models of persistent pain. Antagonists to these receptors can reverse these nociceptive responses.

For humans, there are no AMPA, kainite, or mGluR agonists or antagonists available for clinical use. As such, the
most studied glutamate modulators are the NMDA receptor antagonists. Perhaps the most studied NMDA antagonist for neuraxial use is ketamine, a noncompetitive NMDA antagonist that has been administered both epidurally and intrathecally in humans for acute and chronic pain relief. Following tissue injury, the activation of spinal NMDA receptors induces a state of facilitated processing from repetitive small afferent fiber stimulation, leading to an increased response to high and low threshold stimulation and enhanced receptor field size. This process, known as “wind-up,” is thought to be responsible for phenomena such as allodynia and hyperalgesia.132

In a case report by Kristensen and colleagues,133 the spinal administration of CPP (3-[2-carboxypiperazin-4-yl]propyl-1-phosphonic acid), a competitive NMDA antagonist, was noted to suppress wind-up, but not spontaneous pain or allodynia in a patient with a peripheral nerve injury. Four hours after the last injection of CPP, psychomimetic side effects developed that were attributed to the rostral spread of medication. In combination with intrathecal morphine or other analgesic agents in patients suffering from cancer pain, the addition of intrathecal ketamine was shown to enhance the analgesic effects of opioids and other drugs while reducing the development of tolerance.134 In two case studies, Selda and colleagues135 found that adding low doses of epidural ketamine to morphine and bupivacaine improved analgesia while minimizing the side effects in patient suffering from terminal cancer with neuropathic components of pain. Bion136 reported that hyperbaric intrathecal ketamine mixed with epinephrine provided adequate short-term anesthesia in young soldiers undergoing field surgery. More recently, Murali Krishna and coworkers76 demonstrated that a combination of low doses of intrathecal ketamine and midazolam with bupivacaine improved postoperative analgesia in patients undergoing orthopaedic surgery. However, an open-label study by Hawksworth and Serpell137 conducted in 10 male patients undergoing prostate surgery found that the high frequency of psychomimetic disturbances, the short duration of action, and the high incidence of incomplete anesthesia precluded its use as a sole anesthetic agent. Similar findings were reported by Kathirvel and colleagues138 in a prospective study involving 30 healthy women undergoing a brachytherapy application for cervical cancer. The authors found that although the addition of 25 mg of ketamine had local anesthetic-sparing effects, it neither extended postoperative analgesia nor reduced the postoperative analgesic requirements. Compared to the patients who received bupivacaine alone, those who received bupivacaine and ketamine experienced an increased incidence of nausea, vomiting, sedation, dizziness, and “strange feelings.” In an interesting case report, the long-term intrathecal administration of the S(+)-ketamine enantiomer was found to be effective in a patient with severe neuropathic cancer pain refractory to conventional therapy.139 This study reported no adverse side effects and found low plasma concentrations of ketamine after the third week of treatment.

Epidurally administered ketamine has been found to be a clinically more viable treatment than intrathecal delivery, with a lower incidence of dysphoric and other adverse effects. In a randomized clinical study performed by Sethi and coworkers,140 low-dose ketamine was added to the epidural mixture patients undergoing major upper abdominal surgery. Ketamine added to bupivacaine in postoperative PCEA was found to provide better pain control with less opioid use. In addition, patients experienced significantly less nausea, vomiting, and pruritus. More recently, Amr demonstrated in a large randomized, double-blind, controlled trial that ketamine administered epidurally with steroids and a local anesthetic provided superior pain relief in 200 patients suffering from lumbar radiculopathy from disk herniation than steroids and a local anesthetic alone. Patients receiving ketamine by injections reported significantly decreased pain scores lasting up to 12 months postinjection, though six patients in the ketamine group experienced short-lasting delusions immediately after injection.141 In a study involving patients undergoing hepatic resection, the combination of epidural ketamine and morphine was found to provide superior pain relief compared to morphine alone. In elderly patients, the epidural ketamine dose was reduced by 33% (20 mg versus 30 mg).142 There were no reports of psychomimetic effects, neurologic findings, or any other complications in this study. In a study by Himmelseher and colleagues143 assessing the impact of adding S(+) ketamine to epidural anesthesia with ropivacaine in patients undergoing knee arthroplasty, the combination group experienced significantly longer pain relief than patients receiving the local anesthetic alone. A review of 13 randomized controlled studies involving 584 children reported that patients receiving 0.25 to 0.5 mg/kg ketamine via caudal administration extended the time needed for rescue medication by about 5 hours. Furthermore, these findings held true irrespective of the local anesthetic dose.144 One of the theoretic advantages of ketamine for chronic pain is that it is not associated with tolerance.

Not all studies have found epidural ketamine to be beneficial. Lauretti and colleagues145 found no benefit to adding epidural ketamine to clonidine in 56 patients undergoing orthopedic surgical procedures. The 24-hour postoperative pain scores, time to first rescue medication, and quality of analgesia were similar in the clonidine, ketamine, and ketamine-clonidine combination groups. In a double-blind study by Weir and associates,146 the authors found that adding ketamine to epidural bupivacaine for knee replacement surgery failed to prolong postoperative analgesia or reduce analgesic requirements, but it did result in significantly more side effects. The majority of the existing literature demonstrates that epidural ketamine in doses ranging from 0.5 to 1 mg/kg is well tolerated in patients of all age groups and is most effective when combined with opioids or local anesthetics.

The potential neurotoxicity of intrathecal ketamine remains a subject of controversy. In most countries, racemic formulations (50% S(+) and 50% R(−)-ketamine) are available either preservative-free or with preservatives, such as benzethonium chloride and chlorobutanol. Compared to the racemic mixture, the S(+) enantiomer has a fourfold greater affinity for NMDA receptor, and consequently possesses 2 to 3 times the analgesic potency. Karpinski and colleagues147 reported that a terminal cancer patient who received a 3-week intrathecal infusion of racemic ketamine was found to have subpial vacuolar myelopathy on autopsy; a similar finding was reported by Stotz and coworkers.148 On postmortem examination of a terminal cancer patient who received a 7-day trial of intrathecal ketamine, focal...
lymphocytic vasculitis close to the catheter injection site was noted. Subarachnoid S(+)–ketamine is a matter of much debate, as the results regarding its toxicity are contradictory. Although no human studies of preservative-free racemic or pure S(+)–ketamine have examined the histopathologic effects in humans, preservative-free racemic ketamine has been shown to be without apparent neurotoxic effects after repeated administration in pigs.\(^{149}\) However, S(+)–ketamine without preservative injected into dogs resulted in significant histologic abnormalities, including gliosis, axonal edema, central chromatolysis, lymphocyte infiltration, and fibrous thickening of the dura mater. Similar findings have been reported in rat models and rabbits.\(^{150,151}\) At present, ketamine is not FDA approved for neuraxial use in the United States and is considered experimental or only for use in palliative care.

**CYCLOOXYGENASE INHIBITORS (BOX 43.7)**

Research was conducted with animal models that implicated the cyclooxygenase isoenzymes, COX-1 and COX-2, as playing a role in the development and maintenance of spinal neuropathic pain.\(^{152}\) In the spinal cord, prostaglandin E2 (PGE\(_2\)) acts presynaptically to increase the release of glutamate from primary afferent C fibers and postsynaptically to directly excite dorsal horn neurons by activation of nonselective cation currents.\(^{153-155}\) Both effects promote the development and maintenance of central sensitization and enhanced pain states. The intrathecal administration of nonsteroidal anti-inflammatory drugs (NSAIDs) prevents the development of hyperalgesia and inhibits the release of PGE\(_2\).\(^{153,156}\) In an animal experiment using a peripheral nerve injury model, the nonselective COX inhibitor ketorolac provided significantly longer antinociception than the COX-2 selective NSAID, NS-398 (6 days versus 2 hours).\(^{157}\) These findings are consistent with recent experiments showing potent antinociceptive effects without neurotoxicity following intrathecal ketorolac administration.\(^{158}\) In a study by Parris and colleagues\(^{159}\) investigating intrathecal ketorolac and morphine in an animal model of neuropathic pain, the authors demonstrated that both drugs possess antinociceptive properties, with morphine being more potent than ketorolac for all outcome measures except cold allodynia, in which the effects of the two drugs were found to be similar.

Despite the promising evidence produced in animal studies, several well-designed studies have failed to demonstrate the efficacy of intrathecal ketorolac in clinical or experimental pain. Eisenach and associates\(^{160}\) tested the efficacy of intrathecal ketorolac in a randomized controlled, chronic pain study involving patients suffering primarily low back and lower extremity pain with a combination of somatic and neuropathic components. This study failed to demonstrate a difference between patients receiving ketorolac intrathecally compared with saline. In a second clinical study, Eisenach and collaborators\(^{161}\) found that 2 mg of intrathecal ketorolac combined with 15 mg bupivacaine failed to prolong postoperative analgesia when compared with normal saline. These results are disappointing and imply that intrathecal ketorolac are of limited utility for alleviating pain in humans. However, these studies included a small number of subjects, and more studies involving larger numbers of subjects are needed before conclusions can be made about the effectiveness of intrathecal ketorolac. Two studies examined the analgesic effects of intrathecal aspirin in patients with chronic refractory pain.\(^{162,163}\) In a large study conducted in 60 cancer patients with intractable pain, a single intrathecal dose of isobaric lysine acetylsalicylate (doses ranged from 120 to 720 mg) resulted in excellent pain relief in 78% of cases, with the duration of analgesia lasting from 3 weeks to 1 month on average. Neuraxial ketorolac is not FDA approved and is considered investigational or only for use in palliative care.

**CHOLINERGIC AGONISTS (BOX 43.8)**

Cholinergic receptors are divided into the G-protein-coupled (metabotropic) receptors (i.e., the muscarinic subtype) and ion channel (ionotropic) receptors (i.e., the nicotinic subtype). Pharmacologic molecular cloning studies have led to the classification of muscarinic acetylcholine receptors (mAChRs) in central and peripheral tissues into five distinct subtypes: M1, M2, M3, M4, and M5. Studies of radioligand binding and analysis of mRNA have demonstrated the existence of M1, M2, M3, and M4 receptors in the spinal cord. Neuronal nicotinic acetylcholine receptors (nAChRs) are pentameric ligand-gated ion channels, and molecular cloning has identified nine alpha and three beta subunits. These subunits assemble to form functional receptors in heteromeric combinations or as homopentamers. Receptor subunit composition underlies the differences in functional properties, and there is considerable variation in subunit expression throughout the spinal cord.

In animal models, the spinal administration of muscarinic cholinergic agonists results in antinociception, an effect that is reversed by muscarinic antagonists.\(^{164,165}\) In contrast, the intrathecal administration of nicotinic agonists results in

The authors found that the combination prolonged the initial analgesic effect of the spinal component of the CSE and decreased the requirement for local anesthesia. Furthermore, the investigators were able to demonstrate that this combination prolonged the initial analgesic effect of the spinal component of the CSE and provided a subsequent local anesthetic-sparing effect.

Neostigmine has also been coadministered for caudal analgesia in children with bupivacaine\textsuperscript{178-181} or ropivacaine,\textsuperscript{182} where it was reported to provide prolonged analgesia without any adverse effects. This benefit was demonstrated in a double-blind, randomized, prospective study by Karaaslan and coworkers,\textsuperscript{183} whereby 60 male patients between the ages of 5 months and 5 years undergoing genitourinary surgery were allocated randomly to one of three groups. One group received caudal 0.25% levobupivacaine (1 mL/kg) alone (note that levobupivacaine is no longer available in the United States). The next two groups of patients received neostigmine (2 and 4 µg/kg, respectively) together with levobupivacaine. Both groups receiving intrathecal neostigmine combined with levobupivacaine showed decreased pain scores postoperatively, a longer duration of analgesia, and lower analgesic consumption compared with the group administered levobupivacaine alone. There was no difference in analgesic efficacy between groups receiving different doses of neostigmine, nor were the adverse effects different among the three groups.\textsuperscript{183} The benefit of combining neostigmine with local anesthetics is not limited to levobupivacaine. Batra and colleagues\textsuperscript{184} demonstrated that combining neostigmine at a dose of 0.75 µg/kg with bupivacaine significantly extends spinal anesthesia duration, reduces postoperative pain scores, and decreases the need for rescue analgesia in infants undergoing lower abdominal and urogenital procedures. The study showed no benefit by increasing the dose to 1 µg/kg. Animal studies have shown that the coadministration of neostigmine does not decrease the neurotoxicity of lidocaine.\textsuperscript{185}

The combination of neostigmine with morphine via the epidural route has been shown to decrease the incidence of postoperative urine retention and prolong analgesia.\textsuperscript{186} The synergistic effect of combining neuraxial neostigmine with local anesthetics was confirmed in a randomized double-blind study by Kumar and colleagues,\textsuperscript{179} which assessed the addition of neostigmine, ketamine, and midazolam to bupivacaine in 80 children administered a single-shot caudal injection for inguinal hernia repair. The duration of complete analgesia was significantly longer in the neostigmine-bupivacaine group than in patients who received midazolam-bupivacaine, ketamine-bupivacaine, and bupivacaine alone. In addition to enhancing sensory blockade, combining neostigmine with an assortment of other intrathecal medications may also prolong muscle weakness and increase sedation.\textsuperscript{187} The most commonly encountered side effects of neostigmine are nausea, vomiting, and, at doses exceeding 150 µg, sedation and leg weakness. At low doses, neostigmine is devoid of significant hemodynamic effects, but at higher doses (750 µg), increases in blood pressure, heart rate, respiratory rate, and anxiety may occur.

The epidural administration of neostigmine alone, or in combination with local anesthetics or opioids, has been found to effectively decrease postoperative pain. In contrast to intrathecally administered neostigmine, neostigmine...
administered via the epidural route enhances opioid and local anesthetic analgesia without increasing the incidence of nausea. In a prospective, randomized, double-blind study, Caliskan and collaborators demonstrated that patients who received 1 µg/kg of neostigmine in addition to 20 mL of bupivacaine experienced faster restoration of bowel sounds and a shortened duration of postoperative ileus after abdominal aortic surgery compared to patients receiving 20 mL of bupivacaine and an equal volume of normal saline. In the first of a two-phase randomized controlled study evaluating bolus (40 and 80 mcg) epidural neostigmine in women scheduled for elective cesarean section, Ross and colleagues found that epidural neostigmine boluses did not alter baseline fetal heart rate, induce contractions, or produce nausea. In the second, randomized phase comparing patient controlled epidural analgesia with either bupivacaine alone (1.25 mg/mL) or bupivacaine combined with neostigmine (4 mcg/mL), those who received the combination treatment had a 19% decrease in bupivacaine requirements. In parturients receiving treatment for longer than 4 hours, the decrease was 25%. Similar to a previous study, those patients who received combination did experience a slight increase in sedation.

Unfortunately, there are few studies evaluating the long-term use of neuraxial neostigmine for chronic pain. Laureretti and coworkers found that the epidural administration of a low dose of neostigmine (100 µg) in combination with morphine was associated with improved analgesia when compared to opioid treatment alone in terminal cancer patients followed for 20 days. This improvement was not associated with an increased incidence of adverse effects. Neostigmine is considered investigational or only for use in palliative care of terminal patients without further options and full consent of the patient.

**OTHER EXPERIMENTAL NEURAXIAL AGENTS**

**ADENOSINE AGONISTS**

Extracellular adenosine and adenosine tri-phosphate (ATP) have been proposed as neurotransmitters. Adenosine is thought to modulate the transmission of nociceptive information by its action at peripheral, spinal, and supraspinal receptor sites. These receptors are divided into two groups: purinergic 1 (P1) and purinergic 2 (P2) receptors at which adenosine and ATP act, respectively. These receptors can be further subdivided into adenosine A1, A2a, A2b, and A3 receptors, all of which are metabotropic, and ATP P2X and P2Y receptors, which are ionotropic and metabotropic, respectively.

Numerous studies in animals have demonstrated that the spinal or systemic administration of adenosine and adenosine analogs inhibit pain behavior in response to noxious stimuli in acute and chronic models of nociception. Neuromuscularly administered A1 receptor agonists produce antinociceptive properties in a number of acute, inflammatory, and neuropathic pain models. In contrast, the spinal administration of ATP results in pronociceptive behaviors and a decrease in nociceptive thresholds through the activation of the P2X receptor. Activation of spinal P2X receptors results in antinociception, although this effect is subordinate to the pronociceptive properties of the P2X receptor.

In a phase I clinical safety study published in 1998 by Rane and colleagues, intrathecal injection of adenosine in 12 healthy volunteers reduced areas of secondary allodynia after skin inflammation and decreased forearm ischemic tourniquet pain, but it had no effect on the cold-pressor test. No adverse side effects were noted, although one patient who received a 2000 µg injection (ranges tested were from 500 µg to 2000 µg) experienced transient low back pain. In a case report on a patient with neuropathic leg pain and tactile allodynia, a single intrathecal injection of the A1 agonist, R-phenylisopropyl adenosine (R-PIA), provided relief of the patient’s stimulus-dependent pain. However, in a randomized study evaluating 1000 µg of intrathecal adenosine given before and after hysterectomy, the treatment produced no significant impact on postoperative analgesic requirements or visual analog scale (VAS) pain scores compared to placebo. In a randomized, double-blind study conducted in 25 healthy parturients, Rane and colleagues found no clinically or statistically significant benefit when a one-time dose of adenosine 500 µg was added to intrathecal sufentanil for labor pain. In an assessment using a different formulation of adenosine currently marketed in the United States, Eisenach and coworkers found that intrathecal adenosine reduced hyperalgesia and allodynia associated with intradermal capsaicin injection, but it had no effect on acute noxious chemical or thermal stimulation. A follow-up study by the same group of investigators showed that intrathecal adenosine reduced areas of allodynia by 25% in volunteers given subdermal capsaicin. These findings are consistent with those of Rane and colleagues and indicate that adenosine may be more effective for neuropathic pain than it is for acute pain. The only side effects noted in the initial safety studies were headache and back pain.

There are no published studies investigating the long-term infusion of intrathecal adenosine in patients with chronic pain. To date, all human studies assessing neuraxial adenosine have been in either the perioperative setting or experimental pain models. Although adenosine shows promise as a treatment for chronic pain, it is premature to comment on its safety or efficacy. At present, adenosine is considered investigational or only for use in palliative care of terminal patients without further options and full consent of the patient.

**SOMATOSTATIN AGONISTS**

There is extensive literature on the use of neuraxial somatostatin for pain relief. To date, at least six somatostatin receptors have been identified, which are dispersed throughout the periaqueductal gray matter, ventral horn, primary afferent neurons, and substantia gelatinosa. The antinociceptive effects of somatostatin result from presynaptic inhibition. Stimulation of the somatostatin receptors results in hyperpolarization of the cell via a G-protein-coupled inwardly rectifying potassium current. This serves to block coupled calcium channels, reduce transmitter release, and decrease the synthesis of cyclic adenosine monophosphate (cAMP).

Epidural somatostatin has been demonstrated in several studies to provide postoperative pain relief for patients undergoing major surgical procedures. In an open-label study assessing the effect of 250 µg of epidural somatostatin on postoperative pain after abdominal surgery, complete pain relief (no other analgesics required) was obtained in
all eight patients. In two patients, an epidural somatostatin infusion also provided adequate intraoperative analgesia. There were no reported side effects in this pilot study.

There are also reports of intrathecal and epidural somatostatin being used in cancer pain. In a study performed by Mollenholt and associates examining the efficacy of continuous intrathecal and epidural infusions of somatostatin in eight patients with intractable cancer pain unresponsive to opioids, the authors described demyelination of spinal nerve roots and dorsal columns in two of their eight patients at autopsy. None demonstrated any clinical signs of neurologic deficits during their treatment. As the patients were receiving other treatments for cancer, including chemotherapy and radiation treatment, the pathologic changes could not definitively be attributed to somatostatin. All patients in this investigation required rapid dose escalation over a relatively short time period, perhaps indicating the development of tolerance. Analgesia was rated as either “good” or “excellent” in six of the eight patients. One patient experienced nausea, headache, and vertigo during the last 5 days of somatostatin treatment, and another became agitated and tremulous during the first night of therapy.

Research efforts have now turned to octreotide, a synthetic analog of somatostatin with a longer half-life. In preclinical studies involving rats with chronic constriction injury of the sciatic nerve, octreotide has been shown to reduce the behavioral effects of thermal hyperalgesia. In a dog model, IT octreotide infusions of 40 µg per hour were not found to be neurotoxic. Human use, although limited, has also not revealed any neurotoxicity. Deer and colleagues conducted a randomized, double-blind study comparing the safety and adverse effects with normal saline. Twenty patients received intrathecal doses of octreotide as high as 405 to 650 µg per day and showed no neurotoxicity or adverse effects. Intraoperative octreotide was found to provide long-term pain relief in two patients, one of whom was suffering from refractory central pain secondary to multiple sclerosis. In this patient, a double-blind “N of 1” trial with saline resulted in a sharp increase in pain during the 2-week placebo period, necessitating an increase in supplemental opioids. The patient continued on the intrathecal somatostatin therapy for 5 years with no adverse side effects. The increase in somatostatin required during this period was modest, from 20 µg/hr to 29 µg/hr.

Not all studies examining spinal somatostatin or octreotide for pain relief have found the drug to be of benefit. In a randomized controlled trial assessing epidural diamorphine and somatostatin in 24 patients undergoing cholecystectomy, only patients who received intraoperative diamorphine required less postoperative analgesics. The neuropeptide use of somatostatin was associated with minimal side effects. However, neuropeptide somatostatin and its analogs have been reported to produce substantial neurotoxicity in animals, and there have been no recent clinical trials assessing neuropeptide somatostatin as an analgesic. Octreotide is considered experimental or only for use in palliative care of terminal patients without further options and full consent of the patient.

**DOPAMINE AGONISTS**

The mechanism by which neuraxial droperidol, a butyrophenone, exerts its antinociceptive effects is not fully understood, but appears to involve D1 and D2 receptors in descending dopaminergic tracts in the dorsal horn of the spinal cord. When administered parenterally, neuroleptic drugs have been demonstrated to have analgesic, as well as sedative and anti-emetic, effects in humans. The use of epidural droperidol has been shown to enhance analgesia in several studies. In several clinical trials including two randomized controlled trials, droperidol was shown to potentiate epidural analgesia with opioids. Naji and colleagues reported significantly enhanced analgesia with lower morphine usage in patients undergoing hip replacement surgery. Wilder-Smith and collaborators followed up with a double-blind, placebo-controlled study demonstrating that a combination of epidural droperidol and intravenous sufentanil significantly reduced both the duration of analgesia and adverse effects compared with intravenous (IV) sufentanil alone. Several studies have reported that epidurally administered droperidol with opioids provides better analgesia with less nausea than epidural opioids alone. Furthermore, two prospective, randomized studies have demonstrated that epidural droperidol enhances analgesia when combined with tramadol, a combination analgesic that possesses weak µ-opioid, noradrenergic, and serotonergic effects. Gurses and colleagues demonstrated that a one-time bolus of epidural droperidol in combination with epidural tramadol increased the quality and duration of analgesia over tramadol alone in the immediate postoperative period in 90 patients undergoing abdominal surgery. Finally, Bach and associates conducted a retrospective study assessing the effect of adding epidural droperidol to epidural opioids in 20 patients with chronic pain, 17 of whom suffered from a malignancy. The authors found that adding droperidol to epidural morphine resulted in significantly reduced opioid requirements and improved pain relief (80% of patients reported decreased pain), with seven patients reporting reversible side effects.

The potential benefits of combining epidural droperidol with opioids include a reduction in opioid-related side effects, including nausea, vomiting, pruritus, urinary retention, and hypotension. Side effects of epidural droperidol include sedation, respiratory depression, and Parkinsonian sequelae.

There are no studies to date on the long-term intrathecal use of neuroleptics. The literature that does exist on neuraxial neuroleptics primarily deals with either the intrathecal effects of droperidol in animals or epidural droperidol in the perioperative setting.

**PRECLINICAL AGENTS**

Xen2174 is a structural analog of Mr1A, a chi-conopeptide recently isolated from the venom of the marine cone snail, Conus marmoreus. Its mechanism, similar to tricyclic antidepressants, is effected by inhibiting the norepinephrine transporter. However, chi-conopeptides are highly selective for the norepinephrine transporter and are less likely to cause the side effects associated with tricyclic antidepressants. Nielsen and colleagues compared intrathecal bolus doses of Xen2174 with tricyclic antidepressants and clonidine. They found that IT Xen2174 reduced allodynia in rats with either a chronic constriction injury of the sciatic nerve or an L5/L6 spinal nerve injury. It is hypothesized that the anti-allodynic, antihyperalgesic, and...
The use of neur axial analgesics to modulate pain has generated intense interest. Despite this interest and need for alternatives in pain care of patients in dire need, there is a saddening lack of effective analgesic agents that are already FDA approved. Compared to the oral and intravenous routes of administration, the intrathecal and epidural administration of analgesics is associated with a reduced incidence of most, but not all, side effects. To date, most of the literature regarding spinal analgesics has been conducted in surgical and cancer patients, in whom the development of cumulative side effects, tolerance, and system malfunction is less of a concern than it is for chronic, nonmalignant pain patients. In these patients, treatment with neur axial analgesics is more controversial, and long-term safety and efficacy studies are surprisingly scarce. One area that demonstrates particular promise is combining various neur axial analgesics to enhance efficacy and reduce side effects and tolerance. In addition to the agents mentioned in this chapter, other substances that show promise for future study include nitric oxide inhibitors, dynorphins, calcitonin, neurotensin, antidepressants, β-blockers, and cannabinoids. Clearly, more research is needed to determine the best candidates for neur axial therapy and which drug combinations have the best efficacy and side effect profiles.

KEY POINTS—cont’d

- The FDA has labeling for intrathecal bupivacaine and lidocaine when used in combination with dextrose.
- Intrathecal granulomas have been reported to form at the tip of the intrathecal catheter when infusing morphine, hydromorphone, and baclofen.
- Intrathecal fentanyl has not been associated with granuloma development; however, with its lipophilic properties it remains in the intrathecal space a very short time and requires catheter placement at the spinal level associated with the patient’s pain.
- Intrathecal medication pumps with opioid and nonopioid adjuvants can be extremely helpful in patients with cancer-related pain who are unable to be controlled or have significant side effects with standard parenteral therapies.
- Intrathecal ziconotide has efficacy in some neuropathic pain conditions but is often associated with severe side effects.
- Intrathecal therapy is much less effective in the treatment of non-cancer-related pain.
- The future of intrathecal therapy lies in the development of targeted, non-neurotoxic medications.

This chapter reviews the clinical pharmacology, pharmacokinetics, therapeutic mechanisms, and side effects of corticosteroids and botulinum toxins. Radiocontrast agents are reviewed in greater detail elsewhere in this text. All of these drugs have the potential to produce physiologic toxicity and therefore should be administered appropriately and in the smallest dose that will reliably produce the desired effect; an increase in total dose or volume should not be used to compensate for inadequate injection technique. In addition, this chapter reviews the main characteristics of the available injectable bone cements, their use, and their handling as an effective treatment in vertebral compression fractures. Novel techniques involving gene therapy in the treatment of chronic, unrelenting pain syndromes are also explored.

CORTICOSTEROIDS

Corticosteroids (CSs) are key mediators in the maintenance of normal physiology and in the complex adaptive mechanisms that protect an organism in the setting of internal or external stressors. CSs maintain the function and integrity of many important physiologic and biochemical processes, including the regulation of protein, carbohydrate, and lipid metabolism. Naturally occurring corticosteroids are classified into three functional groups: mineralocorticoids, glucocorticoids, and adrenal androgens.

Mineralocorticoids maintain normal fluid and electrolyte balance. Glucocorticoids (GCs) act primarily to enhance the production of high-energy fuel, glucose, and reduce other metabolic activity. Injections of glucocorticoids for the relief of vertebrogenic, arthritic, and radiculopathic pain are widely accepted.

GENERAL EFFECTS OF THE ENDOGENOUS CORTICOSTEROIDS

PHYSIOLOGIC EFFECTS OF CORTICOSTEROIDS

GCs stimulate hepatic gluconeogenesis, increase hepatic glycogen content, and inhibit insulin-mediated peripheral blood glucose uptake. They modulate protein metabolism by decreasing peripheral protein synthesis (by inhibiting amino acid incorporation) and stimulating protein catabolism while stimulating protein and enzyme synthesis in the liver. CSs regulate lipid metabolism largely by potentiating catecholamine-enhanced activation of cellular lipase, resulting in lipolysis.

GC actions on protein and lipid tissues vary in different parts of the body. Whereas cortisol can deplete the protein matrix of the vertebral column (trabecular bone), there may be minimal effect on long bones (compact bone). For adipose tissue, the subcutaneous lipid cell mass of the arms and legs decreases while that of the abdomen and interscapular area increases.

Cortisol maintains vascular responsiveness to circulating vasoconstrictors and, in high doses, may restore circulatory function in shock (hemorrhage, endotoxin, anaphylaxis, and trauma). Hemodynamically, GCs modulate α-adrenergic receptor synthesis and cell density, prevent α-adrenergic receptor desensitization and uncoupling, and inhibit nitric oxide synthase.

Cortisol maintains the microcirculation in the setting of acute inflammation by reducing capillary endothelial permeability and preventing edema formation. GCs modulate the immune response at many levels. They cause leukocytosis by enhancing the release of mature leukocytes from the bone marrow as well as inhibiting their egress from the circulation.

STEROID SYNTHESIS

All CSs are produced in the cortex of the adrenal gland, which is composed of three distinct zones. The outer zone, the zona glomerulosa, produces mineralocorticoids, specifically aldosterone, which is synthesized in response to stimulation by the renin-angiotensin-aldosterone system or hyperkalemia. The middle zone, the zona fasciculata, comprising more than 70% of the cortex, is the site of glucocorticoid production. Cortisol is the primary glucocorticoid and represents about 80% of GC production. The inner zone, the zona reticularis, produces GCs and in some species small amounts of androgens.

Adrenocortical cells contain large stores of lipid used for steroidogenesis. Adrenocorticotropic hormone (ACTH) induces physiologic, molecular, and morphologic changes in the adrenal cortex. In addition to releasing GCs, the adrenal gland undergoes upregulation of steroidogenic cytochrome P-450 mRNAs, as well as hypervascularization and cellular hypertrophy and hyperplasia. Circulating plasma lipoproteins provide most of the cholesterol for steroid synthesis. Cholesterol uptake by the adrenal cortex is mediated by the low-density-lipoprotein (LDL) receptor, whose quantities increase with ACTH stimulation. The first and rate-limiting step in steroid
STEROID BIOSYNTHESIS

Steroid biosynthesis is the conversion of cholesterol to pregnenolone under the control of ACTH and by the cytochrome P-450 enzymes in the mitochondria and smooth endoplasmic reticulum. Corticosterone is the immediate precursor to cortisol, and it is the principal glucocorticoid in certain animal species.

Adrenal steroids share a common carbon skeleton, the cyclopentanoperhydrophenanthrene ring, composed of three cyclohexane rings and one cyclopentane ring (Fig. 44.1). Variation among naturally occurring steroid compounds is related to the manner in which hydrogen, hydroxyl, and oxygen radicals and carbon atoms are attached to the basic steroid nucleus. Cortisol and other anti-inflammatory steroids contain a two-carbon chain attached to position 17, and are termed C21 steroids. Even the commonly administered steroid cortisone must be converted in vivo to hydrocortisone (cortisol) by the liver before it is biologically active.

FIGURE 44.1 Cyclopentanoperhydrophenanthrene ring.

NEGATIVE FEEDBACK ORGANISMS

Corticosteroids inhibit pituitary ACTH and hypothalamic CRH release. Cortisol and the synthetic glucocorticoids exert negative feedback inhibition on ACTH and CRH release. The feedback exerted by cortisol decreases ACTH and CRH secretion, which decreases synthesis of the pituitary and hypothalamic glucocorticoid regulatory factors. Cortisol and corticosteroids are also negative feedback inhibitors of ACTH and CRH receptors in the pituitary and hypothalamus.

CIRCADIAN PATTERN OF SECRETION

It is estimated that human cortisol production is approximately 5 to 10 mg/m² per day. This amount is the equivalent of about 20 to 30 mg/day of hydrocortisone or 5 to 7 mg/day of oral prednisone. The range of the circadian pattern of cortisol production varies more than threefold. Peak levels of ACTH and cortisol secretion occur between 4 and 8 a.m. There is minimal production of cortisol during the evening, and the lowest levels are observed between 8 p.m. and 12 a.m. In abnormal sleep-wake cycles, this diurnal pattern will adjust, so that peak cortisol levels occur just prior to awakening.

CNS CONTROL OF SECRETION

Baroreceptor and chemoreceptor afferent inputs to the medulla are transmitted via the pons to the hypothalamus. Nociceptive afferent signals activate both the medulla and thalamus, which independently activate the hypothalamus via the paleocortex limbic system. Emotional triggers also activate the hypothalamus through the paleocortex limbic system. The arrival of afferent input into the hypothalamic paraventricular nucleus stimulates the synthesis of CRH, which is secreted into the hypophyseal portal system to the anterior pituitary, causing ACTH release. In addition to afferent signals, other substances can stimulate the hypothalamus to secrete CRH and cause ACTH release. These include the proinflammatory cytokines IL-1β, IL-6, and tumor necrosis factor α (TNF-α). Other substances that influence CRH and ACTH secretion include vasopressin, angiotensin II, norepinephrine (NE), prostaglandin F2α (PGF2α), and thromboxane A2 (TXA2). Cortisol synthesis can increase 5- to 10-fold during severe stress, to a maximal level of approximately 100 mg/m² per day.

PHARMACOKINETICS AND PHARMACODYNAMICS OF THE STEROIDS

Cortisol circulates in the blood in three forms: free cortisol (5%), protein-bound cortisol, and cortisol metabolites. It is this unbound (free) portion that is the physiologically active hormone. Approximately 90% of cortisol is bound to cortisol-binding globulin (CBG), also known as transcortin, and albumin. CBG has a high affinity for cortisol but is present in small amounts. The second serum-binding protein, albumin, binds cortisol with less affinity but is abundantly present. During stress, there is a characteristic increase in total cortisol blood levels, including an increase in the unbound percentage. The level of CBG is increased in high-estrogen states, in pregnancy, and during administration of contraceptives. Most synthetic glucocorticoids have less affinity for CBG (approximately 70% binding), and this may account for their propensity to produce cushingoid symptoms at low doses. Cortisol primarily is metabolized in the liver, with subsequent renal excretion of the metabolites.
CORTICOSTEROID LEVELS IN STRESS RESPONSE AND IN VARIOUS CLINICAL SITUATIONS

Endogenous Corticosteroids
Cortisol levels increase within minutes of stress, whether physical (trauma, surgery, exercise), psychological (anxiety, depression), or physiologic (hypoglycemia, infection). Pain, fever, and hypovolemia all cause a sustained increase in ACTH and cortisol secretion. Surgery is associated with elevations in ACTH and cortisol levels, which usually persist for 24 to 48 hours. The magnitude of the stress response is directly proportional to the extent of surgical trauma. Less extensive procedures such as surgery on the joints, breasts, or neck produce a 36% increase in cortisol levels, whereas laparotomy is associated with an 84% increase in the serum cortisol level for 2 days postoperatively. Adult adrenal glands produce about 50 mg of cortisol/24 hours during minor surgery and 75 to 150 mg/24 hours during major surgery.

Elevated levels of circulating cytokines, which appear within minutes of trauma, stimulate the HPA axis to increase production of cortisol. Increased tissue corticosteroid levels are important protective and life-sustaining response in these settings. Corticosteroids improve survival in stress by reducing the duration of shock, decreasing the severity of inflammation, improving vessel contractility and hemodynamics, and preventing inflammatory cell recruitment, proliferation, and release of proinflammatory mediators. Corticosteroids also improve outcome by modulating α-receptor responsiveness to catecholamines. GCs both increase the number of α receptors and prevent uncoupling of the α receptor from adenylate cyclase.

Exogenous Corticosteroids
The introduction of cortisone, a purified glucocorticoid preparation, revolutionized the treatment of a number of medical diseases and provided physiologic replacement in patients with adrenal insufficiency. Shortly thereafter, a number of case reports and studies appeared describing the catastrophic effects of inadequate corticosteroid supplementation in glucocorticoid-treated patients with medical or surgical stresses. Glucocorticoid therapy is the most common cause of secondary adrenal insufficiency. Initially, glucocorticoid administration suppresses CRH and ACTH stimulation. Over time, tertiary iatrogenic adrenal insufficiency develops as the adrenal gland atrophies. Adrenal atrophy may persist for months, following even short courses of corticosteroid therapy.

The dose and duration of corticosteroid administration are only fair predictors of the extent of adrenal suppression, because ACTH and cortisol production vary greatly among individuals. The time to recovery from HPA suppression is highly variable, ranging from 2 to 5 days to 9 to 12 months. The hypothalamus is the first to be suppressed by steroid dosing but the first to recover (normalizing ACTH in several months), whereas the adrenal glands are the last to be suppressed and the slowest to recover, a process that may take 6 to 12 months. Data regarding corticosteroid-induced adrenal suppression are varied. Suppression of the HPA axis should be anticipated in any patient who has been receiving more than 30 mg/day of hydrocortisone (or 7.5 mg of prednisolone or 0.75 mg of dexamethasone) for more than 3 weeks. Given the large variation in cortisol production in healthy patients, it is difficult to predict the need for GC supplementation during stress. Also, the adrenal response to acute medical illness is variable. An intact HPA axis is paramount to survival during periods of major stress and critical illness. Adrenal insufficiency with decreased GC levels is associated with a significantly increased mortality in these settings. Adrenal suppression should be suspected in patients receiving corticosteroids, and these patients should receive replacement GCs when facing major surgery or critical illness.

Expert recommendations have suggested lower doses and shorter duration of glucocorticoid administration (Table 44.1). Patients undergoing minor procedures such as routine dental work, skin biopsy, inguinal repair, or minor orthopaedic surgery only require their normal daily dose of replacement, and not a supplemental dose. Some clinicians have advocated using hydrocortisone continuous infusions to limit the rapid clearance and peaks and nadirs of bolus therapy. Others have suggested using long-acting glucocorticoid agents, such as methylprednisolone or dexamethasone.

CORTICOSTEROIDS USED IN CLINICAL PRACTICE
Cortisol has a half-life of 70 to 90 minutes, whereas all synthetic analogues of cortisol have longer half-lives, based on slower rates of metabolism. The half-life does not reflect duration of action, which is best represented by the duration of ACTH suppression. Short-acting synthetic GCs have durations of action of 8 to 12 hours; these include the active agent hydrocortisone and the inactive cortisone (converted by the liver to the biologically active cortisol). The intermediate-acting GCs prednisone, prednisolone, methylprednisolone, and triamcinolone have durations of action of 24 to 36 hours. Prednisone is an inactive agent, which is metabolized to the active agent prednisolone by the liver. The longest acting GCs, dexamethasone and betamethasone, have durations of action longer than 48 hours (Table 44.2).

Short-acting GCs are advantageous when a rapid clinical effect is desired such as in allergic reactions. Long-acting agents are of interest for their prolonged anti-inflammatory effects and are well suited for disorders requiring inhibition of ACTH secretion. Because all GCs have some mineralocorticoid effect, their administration can have profound consequences for patients with impaired cardiovascular function. The shorter-acting GCs have the highest mineralocorticoid potency, and the long-acting agents have the weakest.

THERAPEUTIC EFFECTS OF CORTICOSTEROIDS
Corticosteroids are predominantly used in interventional pain management because of their proven anti-inflammatory effects with subsequent temporary relief of symptoms. They are the most potent and effective agents in controlling inflammation through numerous mechanisms, including effects on cytokines, inflammatory mediators, inflammatory cells, nitric oxide synthase, and adhesion molecules.

Effects on Cytokines
Cytokines are important mediators of inflammation, and the pattern of their expression largely determines the magnitude and persistence of the inflammatory response.
Steroids have potent inhibitory effects on cytokine transcription and synthesis, especially the ones relevant in chronic inflammation (IL-1, IL-3, IL-4, IL-5, IL-6, IL-8, TNF-α, and granulocyte-macrophage colony-stimulating factor). Steroids interfere with cytokine synthesis by blocking their synthesis. They inhibit the synthesis of the IL-2 receptor and oppose the induction of IL-2 and T-lymphocyte activation and proliferation.

**Effects on Inflammatory Mediators**

Data are based on extrapolation from the literature, expert opinion, and clinical experience. Patients receiving 5 mg/day or less of prednisone should receive their normal daily replacement but do not require supplementation. Patients who receive more than 5 mg/day of prednisone should receive the above therapy in addition to their maintenance therapy.

production of arachidonic acid metabolites. Arachidonic acid metabolism via the cyclooxygenase pathway produces prostaglandins and thromboxanes, and through the lipoxygenase pathway it produces leukotrienes. Steroids increase the synthesis of lipoprotein (annexin) 1, a phospholipase A2 inhibitor, and thus decrease the production of inflammatory mediators such as leukotrienes, prostaglandins, and platelet-activating factor. These adhesion molecules facilitate the trafficking of inflammatory cells to sites of inflammation. The expression of the adhesion molecules E-selectin, P-selectin, and intracellular adhesion molecule-1 on the surface of endothelial cells is induced by the cytokines IL-1β and TNFα. These adhesion molecules enable the endothelium to recruit leukocytes actively and nonselectively, including neutrophils, eosinophils, mononuclear cells, and basophils from the circulation. GCs are effective and potent inhibitors of TNFα and IL-1 release from macrophages, monocytes, and other infiltrating cells. There is a second class of cytokines that selectively activate the endothelium—IL-4 and IL-13, two cytokines associated with allergic diseases. Their release causes the endothelial expression of vascular cell adhesion molecule-1 only. Consequently, only circulating basophils, eosinophils, monocytes, and lymphocytes, but not neutrophils, can bind to the endothelial surface.

### Effects on Inflammatory Cells

GCs interfere with macrophage activity by impairing phagocytosis, intracellular digestion of antigens, and macrophage release of IL-1 and TNFα. By inhibiting the expression of chemokines, GCs prevent the activation and recruitment of inflammatory cells, including eosinophils, basophils, and lymphocytes. Steroids also markedly decrease the survival of certain inflammatory cells, such as eosinophils. Eosinophil activity is dependent on the presence of cytokines IL-3, IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), and interferon-γ. The presence of these cytokines promotes prolonged eosinophil survival, increased adhesion molecule expression, potentiated eosinophil degranulation, and movement of eosinophils across an endothelial barrier. Steroid administration blocks these cytokine effects, leading to programmed cell death, or apoptosis. GCs cause an expansion in the number of circulating neutrophils secondary to decreased adherence to vascular endothelium (demargination) and stimulation of bone marrow production. GCs interfere with T-cell mediated immunity. They inhibit the production of T lymphocytes by downregulating T-cell growth factors IL-1β and IL-2, and they inhibit the release of various T-lymphocyte cytokines.

### Effects on Adhesion Molecules

Adhesion molecules facilitate the trafficking of inflammatory cells to sites of inflammation. The expression of the adhesion molecules E-selectin, P-selectin, and intracellular adhesion molecule-1 on the surface of endothelial cells is induced by the cytokines IL-1β and TNFα. These adhesion molecules enable the endothelium to recruit leukocytes actively and nonselectively, including neutrophils, eosinophils, mononuclear cells, and basophils from the circulation. GCs are effective and potent inhibitors of TNFα and IL-1 release from macrophages, monocytes, and other infiltrating cells. There is a second class of cytokines that selectively activate the endothelium—IL-4 and IL-13, two cytokines associated with allergic diseases. Their release causes the endothelial expression of vascular cell adhesion molecule-1 only. Consequently, only circulating basophils, eosinophils, monocytes, and lymphocytes, but not neutrophils, can bind to the endothelial surface.

Other Anti-inflammatory Effects

Steroids inhibit plasma exudation from postcapillary venules at inflammatory sites. This effect is delayed, suggesting that gene transcription and protein synthesis are involved. It appears that the antipermeability effect is linked to the synthesis of vasocortin. In addition to nuclear anti-inflammatory effects, GCs also have direct effects on cells and cell membranes. Cortisol stabilizes lysosomal membranes, thus inhibiting lysosomal enzyme release. GCs prevent the sequestration of water intracellularly and the swelling and destruction of cells. GCs inhibit leukocyte accumulation and complement-induced polymorphonuclear neutrophil (PMN) aggregation and decrease PMN chemotaxis, T-cell and B-cell proliferation, and the differentiation and function of macrophages.

Other Mechanisms of Pain Relief

Following peripheral nerve injury, a number of morphologic and biochemical changes occur at the injury site including the formation of neuromas, which leads to increased electrical excitability. Ectopic discharge from the injury site leads to a persistent afferent barrage, which maintains neuralgic pain and paresthesias. GCs have been demonstrated to suppress spontaneous ectopic neural discharge originating in experimental neuromas and prevent the later development of ectopic impulse discharge in freshly cut nerves. The topical application of methylprednisolone was noted to block transmission of C-fibers but not the A-β fibers.

SIDE EFFECTS OF CORTICOSTEROIDS

Short courses of GC therapy (less than 2 to 3 weeks) are usually safe. Side effects from short-term therapy are rare but may include fluid retention, hyperglycemia, elevated blood pressure, mood changes, menstrual irregularities, gastritis, Cushing’s syndrome, increased appetite, weight gain, increased infections, delayed wound healing, and aceniform eruptions. Long-term GC therapy with near-physiologic GC doses is relatively safe. With long-term supraphysiologic doses of steroids, more serious side effects may occur.

Cushing’s Syndrome

Cushing’s is characterized by sudden weight gain, hypertension, glucose intolerance, oligomenorrhea, decreased libido, and spontaneous ecchymoses. There is centripetal weight gain, involving thickening of the facial fat that rounds the facial contour (moon faces), enlargement of the dorsocervical fat pad (buffalo hump), and truncal obesity. The development of multiple striae wider than 1 cm on the abdomen or proximal extremities is almost unique to Cushing’s syndrome. Mild hirsutism, acne, personality changes, depression, insomnia, and edema also occur. Despite the external signs of excess GC production, patients receiving GCs develop adrenal atrophy and are at risk for adrenal crisis in the setting of stress. Laboratory tests reveal low blood ACTH and cortisol and low urinary cortisol levels.

Skeletal Effects

Osteoporosis, aseptic necrosis, and growth retardation are all potential complications of long-term GC therapy. Osteoporosis occurs in as many as 50% of patients treated with long-term supraphysiologic doses of prednisone. Trabecular bone, found in the axial skeleton (vertebrae and ribs), is more susceptible to demineralization due to high metabolic turnover rate (eight times more) when compared with that of cortical bone. Corticosteroid-induced osteoporosis (CIOP) has a multifactorial cause—impaired intestinal absorption of calcium coupled with its increased renal excretion, increased osteoclast activity with resultant bone resorption, inhibition of osteoblast activity with decreased bone synthesis, and secondary hyperparathyroidism. The incidence of fractures in patients receiving GCs has been reported to be between 10% and 20%. Patients at greatest risk for corticosteroid-induced osteoporosis are postmenopausal women, children, immobilized patients, and patients with rheumatoid arthritis. Agents such as activated vitamin D products, hormone replacement therapy, fluoride, calcitonin, and bisphosphonates have been shown to maintain or improve bone mineral density in corticosteroid-induced osteoporosis.

Aseptic necrosis is a severe musculoskeletal complication of GC therapy. It occurs with greater incidence in alcoholics, patients with systemic lupus erythematosus, patients with fatty degeneration of the liver, patients with altered lipid metabolism, and renal transplantation patients. The mechanism is related to deposits of fat in terminal arterioles of certain sites of bone. The femoral head is the site most commonly affected, although the humeral head or knee may also be involved. Bone pain is almost always the first symptom and precedes radiologic signs of osteonecrosis by up to 6 months. Recovery may take months to 1 year; treatment includes a reduction in the GC dose and physical therapy with a rehabilitation exercise program.

Ophthalmologic Effects

Cataracts and glaucoma may occur with chronic GC therapy. Steroid-induced cataracts occur in the posterior subcapsular region of the lens and may be asymptomatic until well formed. Children are at greatest risk for this complication. Glaucous is caused by swelling of collagen strands at the angle of the anterior chamber of the eye, with resistance to the outflow of aqueous humor. The process is usually reversible after GC therapy is discontinued.

Gastrointestinal Effects

Nausea and vomiting are not uncommon with oral steroid therapy. Peptic ulcer disease is slightly increased with GC therapy and is more likely to be gastric than duodenal. GCs cause a decrease in mucus production and mucosal cell renewal. Concomitant use of aspirin and nonsteroidal anti-inflammatory drugs increase this risk and should be avoided, along with tobacco and alcohol, which also are ulcerogenic.
Metabolic Effects
Hyperglycemia results from GC effects of increased hepatic glucose synthesis and increased gluconeogenesis. GCs also antagonize peripheral insulin effects and can occasionally produce insulin resistance. Exacerbation of glucose intolerance is common, but the development of new cases of diabetes mellitus is not, and ketoadidious is rare. Weight gain is a common side effect of GC therapy and may be the result of increased appetite or fluid retention. Facial edema and fat are estimated to occur in 10% to 25% of patients on steroid therapy for 2 months.

Hyperlipidemia is another metabolic consequence of GC therapy and is likely secondary to relative insulin resistance. Increased plasma triglyceride levels are more common than increased cholesterol levels. Patients with previous lipid level elevations are at higher risk for this side effect. Electrolyte abnormalities such as hypokalemic alkalosis may also occur, usually with GCs possessing strong mineralocorticoid properties.

Cardiovascular Effects
Hypertension, edema, and atherosclerosis may occur with GC therapy. Elevations in blood pressure occur because of increased sodium retention and vasoconstriction. GCs cause vasoconstriction by potentiating the effect of norepinephrine and opposing the effect of endogenous vasodilators such as histamine. This side effect occurs more frequently in patients with preexisting hypertension, older adults, GCs with high mineralocorticoid potency, and high-dose or prolonged (longer than 2 weeks) glucocorticoid treatment courses. Edema occurs from fluid retention secondary to sodium retention. With initial GC dosing, there is a paradoxical diuresis caused by an early blockade of antidiuretic hormone release.

Hematologic Effects
Blood cell effects, immunosuppression, and impaired fibroplasia occur with steroid therapy. Immunosuppression is produced by GCs at many levels. GCs increase the release of granulocytes from bone marrow, thus increasing the number of circulating leukocytes. Lymphopenia occurs, with predominant depression of T-cell production and decreased eosinophil counts with enhanced eosinophil destruction. Tissue inflammation is reduced by inhibition of cytokine production and by impaired chemotaxis of macrophages, neutrophils, basophils, and eosinophils. There is inhibition of the metabolism of arachidonic acid into prostaglandin and leukotriene mediators, as well as a direct inhibition of COX-2. Steroid therapy increases susceptibility to many bacterial, fungal, viral, and parasitic infections. Wound healing is delayed by GC inhibition of fibroblasts, collagen production, and suppression of wound reepithelialization.

Nervous System Effects
Mood changes, nervousness, euphoria, insomnia, and headache are common side effects of GC therapy and are dose related. Psychosis is an uncommon side effect and is seen more commonly in patients with previous psychiatric disorders.

Cutaneous Effects
Skin changes typical of the hyperadrenal state may occur; these include purpura, telangiectasia, atrophy, striae, pseudo-scars, and facial plethora. The skin becomes thin and fragile. Hair growth changes include transient scalp hair loss and hirsutism on other parts of the body. Hyperpigmentation or hypopigmentation may occur, as well as acneiform eruptions. Steroid acne commonly presents on the back and chest as fine, uniform papulopustules.

Pregnancy and Lactation
There appears to be no teratogenic contraindication to corticosteroid therapy in pregnancy. However, intrauterine growth retardation has been reported, and steroid use late in pregnancy may cause adrenal suppression in the fetus. Corticosteroids are secreted in small amounts into breast milk, thus exposing the infant to the risk of adrenal suppression.

INJECTION STEROIDS IN INTERVENTIONAL PAIN MANAGEMENT
The most commonly used synthetic CSs for interventional pain procedures are derivatives of prednisolone (analog of cortisol) either by methylation (methylprednisolone) or fluorination (triamcinolone, betamethasone, and dexamethasone). As most corticosteroid solutions contain water-insoluble CS esters, they appear as microcrystalline suspensions in commercial preparations. Dexamethasone preparations are free of ester CSs and appear clear and nonparticulate. In the commonly used particulate CS preparations, the biologically active moiety is released by the action of cellular local esterases (hydrolysis) and therefore has the potential of lasting longer at the level of placement (joint, nerve root, intra-articular facets, etc.). On the other hand, the water-soluble CS solutions are taken up quickly by the cells and have a quicker onset of effect, but with a possible reduced duration of action. Many in vitro studies have demonstrated that for the ester CSs, in addition to variations in particle size, there are also differences in propensity of different CS crystals to aggregate into larger particles. Concentration of crystals also varies to compensate for different potencies and to allow equivalent doses between different CSs (Table 44.3).

The duration of action of injectable CSs depends on their biologic and pharmacologic half-lives as well as the duration of clinical benefits. Although the length of pain relief in response to a CS injection may be the most practical assessment, it is also a subjective variable on which literature data vary widely. Despite the assumption that heavy particulate formulations are expected to have a longer-lasting effect because they depend on the patient’s own hydrolytic enzymes (esterases) to release the active moiety, CS knee injection in rheumatoid arthritis provided pain relief for 14 to 66 days after triamcinolone and 8 to 56 days after methylprednisolone. Other studies comparing an ester CS with dexamethasone for major joint injections have shown no statistically significant difference between their onset, duration, or efficacy. When used in neuraxial techniques such as interlaminar or transforaminal epidural injections, the steroid injection has shown both short (less than 6 weeks) and long (more than 6 weeks) pain relief. Studies of steroid doses have found no difference in outcome between low-dose (40 mg) and high-dose (80 mg) methylprednisolone. Some authors have suggested that the depot formulation of steroids (Depo-Medrol) provided better pain control at 4 weeks than the aqueous preparation of betamethasone. In addition,
evidence from the literature supports minimizing the steroid used either by adding clonidine or by increasing the volume of injectate, as evidence suggests that a larger volume may provide the added benefit of adhesiolysis.66

COMPLICATIONS OF STEROID INJECTIONS

Although some patients experience no changes in fasting blood glucose or lipid levels after a single epidural injection of dexamethasone,57 other patients may experience a host of side effects. The depot steroid preparations used for epidural injections may produce ACTH suppression and cushingoid symptoms that can last up to a few weeks.58 Cushing’s syndrome has occurred following a single epidural injection of 60 mg of methylprednisolone34 or triamcinolone,59 and it has been reported in several patients following repeated epidural steroid injections when 200 mg of methylprednisolone was exceeded.60 Steroid myopathy involving the proximal muscles of the lower extremity has been reported following a single epidural triamcinolone injection. The progressive weakness developed over 2 to 4 weeks and did not resolve for 12 to 16 weeks.59 Lumbar epidural injection of triamcinolone, 80 mg, caused profound HPA axis suppression for 3 weeks, although steroid was undetectable in the plasma during this time. This suggests that GCs act directly on central GC receptors, presumably via CSF absorption.61 Comparable studies of patients who have received intra-articular steroid injections have shown detectable levels in the circulation and HPA axis suppression for up to 4 weeks.62

Epidural injection of triamcinolone, 80 mg, caused a marked reduction in insulin sensitivity in patients with normal glucose tolerance and caused fasting hyperglycemia in patients with a preexisting degree of insulin resistance.53 In this study, insulin sensitivity and fasting glucose levels were normal 1 week after injection. Because patients with diabetes commonly experience increased insulin requirements for several days following injection, it is suggested that they be given specific advice on the management of their condition following epidural GC injection. Sterile meningitis and arachnoiditis have been reported following intrathecal injection of methylprednisolone but may have been related to the polyethylene preservative.64 Rare anaphylactoid reactions have occurred following intravenous, intramuscular, and soft tissue injections of the succinate salts of methylprednisolone and hydrocortisone.65-67 Most of these patients were chronically atopic, and in two cases the patients had aspirin sensitivity.65,68 Signs and symptoms of anaphylaxis reported with the use of various hydrocortisone preparations include bronchospasm, shock, urticaria, and angioedema.66 Any type of anaphylactic reaction warrants prompt and aggressive life support therapy, including resuscitation of airway, breathing, and circulation, with oxygen support and cardiac life support when indicated.

CENTRAL NERVOUS SYSTEM EVENTS AFTER TRANSFORAMINAL EPIDURAL STEROID INJECTIONS

The overall safety of fluoroscopically guided epidural steroid injections has been confirmed in a retrospective study.69 However, there have been several reported cases of central nervous system injuries after transforaminal epidural steroid injections (Table 44.4).70-78 These injuries occurred after injection not only of the steroid but also of the local anesthetics and contrast. In addition, they have also been reported not only after fluoroscopy but also after computed tomography. These injuries involve the spinal cord in the form of paraplegia or the brain as embolic cerebrovascular accidents. The mechanisms of the spinal cord injuries have been ascribed to injury or spasm of the blood vessels supplying branches to the spinal cord (segmental artery, deep cervical, or ascending cervical arteries),

GC, glucocorticoids.
proximal intraneural spread of the injectate, or embolization of the particulate steroid through these vessels. Injury to these vessels is possible. Huntoon has shown in cadaver studies that the entry of the ascending cervical and deep cervical vessels in the posterior portion of the cervical intervertebral foramen is within a few millimeters of the path of the needle placed for transforaminal epidural steroid injections, and these findings were confirmed by Hoeft and colleagues. Spasm of the blood vessels occurs after trauma by the needle or after injection of the dye. Another mechanism is embolization of the particulate steroid through these blood vessels, resulting in segmental infarct of the spinal cord or embolization through the vertebral or an end cerebral artery, resulting in cerebral or cerebellar infarct.

Tiso and colleagues, Benzon and associates, and Derby and colleagues examined the sizes of the particles in the steroid preparations. They found that methylprednisolone has a significantly higher percentage of large particles (Fig. 44.2) and that the particles are large enough to occlude the vessels. One type of available betamethasone (Celestone Soluspan) had the smallest particle sizes, followed by triamcinolone. A compounded form of betamethasone, which can be ordered from compounding companies, does not appear to offer an advantage over triamcinolone, because the sizes of their particles appear to be the same. Whereas Tiso and coworkers noted small particles in dexamethasone and betamethasone sodium phosphate, the short-acting component in the commercial type of betamethasone, Benzon and colleagues noted that the two steroids are pure liquid, with no identifiable particles. It should be noted that the commercially available betamethasone preparation (Celestone Soluspan) contains 3 mg/mL of betamethasone sodium phosphate and 3 mg/mL of betamethasone acetate.

occurred in September 2012; the contaminated steroid was manufactured by the New England Compounding Company in Framingham, Massachusetts. The infections were initially noted in Tennessee, where the initial 66 cases presented with either meningitis, cauda equine syndrome or focal infection, or posterior cerebral artery distribution such as basilar stroke with or without meningitis. The risk of infection was noted to increase with the older vials, higher doses, multiple procedures, and translaminar approaches. Voriconazole was used to treat most of the patients, whereas the other patients were treated with liposomal amphotericin B. At least 4300 patients have been infected, and more are expected because approximately 14,000 patients had injections from the contaminated lots. Some of the spinal infections progressed into abscesses.

Compounding companies fall into a gray area between federal and state oversight. These companies are not registered with the U.S. Food and Drug Administration (FDA) as drug manufacturers, and adverse events do not have to be reported to the FDA. The authority of the FDA is limited to investigating problems once the problem is obvious. The lack of clear oversight on the safe and sterile practices of compounding companies led to calls for stronger oversight by the FDA on compounding companies.

For economic reasons or because of the lack of availability (e.g., high concentration bupivacaine), drugs will continue to be compounded. Between 1% and 5% of all prescriptions are compounded. These include drugs used in pain management such as oral ketamine and intrathecal drugs. Standards for compounding of drugs are written under United States Pharmacopeia, chapter 797 (USP 797), and include the particulate matter in the room air where the drug is compounded and the colony forming units per cubic meter of air per plate. There are approximately 7500 compounding companies in the United States; only 2% participate in the industry’s voluntary accreditation program. The pain medicine physician can ensure sterility of the compounded drug that he or she is using by getting the drug from a company accredited by the Pharmacy Compounding Accreditation Board (www.pcab.org).

In a laboratory study, the injection of the particulate steroid methylprednisolone into the carotid artery resulted in cerebral hemorrhage in 8 of 11 rats. This is compared to the lack of such injury when dexamethasone or saline was injected. Interestingly, the nonparticulate carrier of methylprednisolone caused the same injury in half of the rats. Another study of methylprednisolone injection into the vertebral artery of pigs resulted in brainstem edema, hypoxic and ischemic brain damage, ventilatory support, and inability to regain consciousness. In comparison, there was full recovery with dexamethasone and prednisolone.

Dexamethasone is a nonparticulate steroid, is long-acting, and has minimal or no mineralocorticoid activity. It has increased GC activity, theoretically resulting in a greater elevation of the blood glucose level. A dose ranging study compared transforaminal epidural dexamethasone, 4 mg versus 12 mg. The authors noted a reduction in radicular pain by 42%, 34%, and 27% at 4, 8, and 12 weeks, respectively, whereas the Oswestry Disability ratings improved from “moderate” at baseline to “minimal” at 12 weeks. There was no difference between the two doses. Studies comparing dexamethasone with a particulate steroid are few. One clinical study on dexamethasone showed it to be slightly less efficacious than triamcinolone. Another study compared 10 mg dexamethasone with 40 mg triamcinolone for cervical transforaminal epidural steroid injection and showed no difference in efficacy. However, the study was not randomized; dexamethasone was used between 2006 and 2007, whereas triamcinolone was employed between 2007 and 2008. Also, the follow-up was short (1 month). Triamcinolone was slightly more effective (80% versus 69%) but did not reach statistical significance. It therefore appears that dexamethasone is slightly less effective than triamcinolone for transforaminal injections. However, clinical studies of better quality
are needed. The theoretical disadvantages of dexamethasone are its easy washout from the epidural space and the reports of convulsions after intrathecal injection in animals.58,44

The better efficacy of the transforaminal approach over the interlaminar approach has not been completely established; one study showed the two approaches to be similar in efficacy in terms of pain relief and functional capacity.95 If cervical transforaminal epidural steroid injection is to be given, dexamethasone should be used; particulate steroid should not be injected in the cervical levels. For lumbar transforaminal injections, dexamethasone should preferably be tried first. If the relief is short, then a steroid with smaller particles (i.e., commercial betamethasone or triamcinolone) is then tried. The CNS events have not been reported after interlaminar injections, so any of the available steroids can be used. Digital subtraction angiography should be employed for cervical and upper lumbar transforaminal injections to detect intravascular injections.

The question of neurotoxicity and possible allergic reactions to steroids arises from the vehicle and preservatives of the commercially available steroids (Table 44.5).

Dexamethasone contains methylparaben and sodium bisulfite, compounds that have been implicated in allergic reactions to local anesthetics.84 Polyethylene glycol, the vehicle used in methylprednisolone and triamcinolone, can decrease the compound action potential of the A, B, and C fibers.86 However, these changes are reversible, and concentrations above 20% are required for this effect (methylprednisolone and triamcinolone contain only 3% polyethylene glycol [PEG]). In addition, the concentration of PEG in the vial can be significantly decreased by inverting the vial for 1 to 2 hours and aspirating and using the steroid component.97 Interestingly, the intrathecal injection of the vehicle in dogs showed minimal histologic changes, whereas methylprednisolone resulted in a dose-dependent intrathecal inflammatory reaction.88

†Triamcinolone acetonide does not contain polyethylene glycol (PEG), whereas triamcinolone diacetate does; both contain benzyl alcohol. Triamcinolone diacetate has been recently discontinued in the United States.

BOTULINUM TOXIN THERAPY

HISTORY

Botulinum toxins are produced by the gram-negative anaerobic bacterium Clostridium botulinum. They produce flaccid paralysis by preventing the presynaptic release of acetylcholine (ACh) at the neuromuscular junction. There are eight botulinum toxin (BTX) subtypes: A, B, C₁, C₂, D, E, F, and G.99 Types A, B, E, and F have been described to cause botulism, a syndrome of generalized muscle weakness following the ingestion of botulinum-contaminated food. The FDA approved the use of onabotulinum toxin A for the treatment of strabismus, blepharospasm, and hemifacial spasm. In 2000, the FDA approved botulinum toxin B for treating cervical dystonia, and 10 years later the agency approved the use of onabotulinum toxin (Botox or Botox Cosmetic) for chronic migraine treatment.

PHARMACOLOGY OF BOTULINUM TOXIN

TOXIN STRUCTURE AND QUANTIFICATION

Botulinum toxin is synthesized as a single-chain polypeptide, consisting of a heavy chain (H chain; molecular weight [MW], 100,000) and a light (L) chain (MW, 50,000). The H chain is responsible for binding to presynaptic cholinergic nerve terminals at the neuromuscular junction, whereas the L chain is the neurotoxic component. The H and L chains are bound together by disulfide bonds, and the toxin is activated by proteolytic enzymes in a cleaving process. BTX is quantified in mouse units (MU); 1 MU is the dose required to kill 50% of a batch of 18- to 20-g female Swiss-Webster mice (LD₅₀). It is estimated that the human lethal dose of botulinum toxin A (BTX-A) is about 2800 to 3500 units for a 70-kg adult. The lethal dose of BTX-B in humans is estimated at 144,000 units. The type A subtypes appear to be the most potent and have the longest duration of action.

PREPARATION AND DOSING

Two botulinum neurotoxins, types A and B, are used in clinical practice. There are three commercially available type A preparations: Botox, Dysport, and Xeomin. Each vial of Botox (Allergan, Inc., Irvine, California) contains 100 units of onabotulinum toxin A as a sterile, vacuum-dried form without preservative (the toxin is redissolved prior to drying in a solution containing saline and albumin and sterile filtered through a 0.2 μm filter) that can be reconstituted with sterile nonsaline solution prior to injection. Dysport (abobotulinum toxin A) (Ipsen, Ltd., Berkshire,
United Kingdom) is marketed in the form of 500-MU vials. Data from patients treated for cervical dystonia suggest that 1 MU of Botox equals 3 to 5 MU of Dysport. Xeomin (Merz Pharmaceutical, Greensboro, NC) is marketed as 100 units of incobotulinum toxin A powder, reconstituted upon use in normal saline. Myobloc (Solstice Neurosciences, Inc.) is marketed as a sterile liquid formulation of a purified botulinum toxin B (rimabotulinum toxin B). Each 3.5 ml glass vial of Myobloc contains 5000 units of B toxin per milliliter in 0.05% human serum albumin, 0.01 M sodium succinate, and 0.1 M sodium chloride at approximate pH 5.6.

BTX-A in the Botox formulation, the commercially available product in the United States, is inactivated by heat, shaking, excessive dilution, and surface tension from bubbles during reconstitution. Boiling dissolves the disulfide bonds between the heavy and light chains of BTX-A, thus rendering the toxin inactive, because neither chain can exert neurotoxicity independently. BTX-A must be reconstituted with normal saline without a preservative. Dilution of a 100-MU vial may be performed with 1, 2, 5, or 10 mL of 0.9% sodium chloride. This will yield a concentration of 10, 5, 2, or 1 MU/0.1 mL, respectively. The higher concentrations are appropriate for larger muscles—for example, hip flexors or piriformis muscles. Lower concentrations are used for facial injections, such as for the glabella, temporalis, and frontalis muscles. Tuberculin syringes are used to dilute and draw up the toxin, and new 30-gauge needles are used to give the injections so as to reduce discomfort, local trauma, and bleeding. BTX-A should be used within 4 hours of preparation and stored at 2°C to 8°C during this time. It has been shown that there is no loss of activity 6 hours after reconstitution at room temperature; however, a 44% loss of activity is observed at 12 hours. Refreezing the toxin after reconstitution causes a 70% reduction in bioactivity at 1 to 2 weeks.

MECHANISMS OF ACTION

Botulinum toxins act by blocking the presynaptic release of ACh from cholinergic terminals of motor and autonomic nerves. BTX neurotoxicity occurs in three stages: binding, internalization, and proteolysis. Following activation by proteolytic cleavage, the BTX heavy chain binds irreversibly to the presynaptic terminals of cholinergic neurons. The C-terminal region of the heavy chain binds in a serotype-specific manner to receptors on the motor end plates and at autonomic cholinergic ganglia.

In addition to the pain relief associated with its paralytic effect, BTX-A has been studied in relation to its effect on noncholinergic neurons to reduce peripheral sensitization. By acting as an inhibitor for the release of glutamate, BTX-A subsequently decreases the amount of substance P, the neuropeptide essentially involved in pain perception, vasodilation, and neurogenic inflammation. This mechanism is modulated by the synaptosomal-associated protein 25 (SNAP-25). In addition to substance P, other mediators have been involved in response to the BTX-A. Those neuropeptides, calcitonin gene-related peptide and neurokinin A, play a major role in neurogenic inflammation and are released from dense-core vesicles at sites away from the synaptic active zone, as part of the nonadrenergic, noncholinergic (NANC) transmitter system.

The effects of BTX-A on inhibiting central sensitization stem from studies suggesting the transport of BTX-A by axons to the CNS after intramuscular injections. Because many neurotransmitters released in vesicles by exocytosis mechanisms are dependent on soluble Nethylmaleimide sensitive factor attachment protein receptor (SNARE) proteins, the target of botulinum toxins, it appears that BTX-A may be implicated in nervous pathways whose transmitters extend beyond acetylcholine-dependent mechanisms. Therefore, BTX-A may play an important role in central nervous system “neuroplasticity” that involves pain transmission and modulation.

CLINICAL EFFECTS

Botulinum neurotoxins irreversibly inhibit the release of Ach from cholinergic terminals of motor neurons, preganglionic sympathetic fibers, and pre- and postganglionic parasympathetic fibers. The BTX molecule cannot cross the blood-brain barrier and therefore does not have any direct CNS effects. At the neuromuscular junction, BTXs cause a chemical denervation, thereby inhibiting skeletal muscle contraction. Experiments on mouse phrenic nerve have revealed that binding of BTX to nerve terminals takes about 32 to 64 minutes. In humans, clinical effects typically appear after 2 to 3 days, but peak effects are observed at 2 to 6 weeks. The primary muscle relaxant effect is on a motor neuron function, but it may also affect the y motor neurons in the muscle spindles, resulting in lower resting muscle tone. In both animal and human muscle biopsy studies, muscle atrophy occurs within 2 weeks of injections. Atrophy continues for about 4 weeks and then stabilizes. Muscle mass has been estimated to return to about 70% to 80% of original size after 3 months.

BTX may also have other mechanisms of analgesia in addition to those related to the relief of muscle spasm. Specifically, there is evidence to suggest that BTX-A may block the release of glutamate, substance P, calcitonin g-related peptide, and neurokinin A. The subcutaneous injection of BTX-A into the paws of rats exposed to the formalin experimental pain model, although causing no motor effects, results in reduced pain behaviors, decreased release of glutamate, and inhibition of c-fos expression in the dorsal spinal cord.

RECOVERY

BTX-induced chemical denervation is permanent, so skeletal muscle remains paralyzed until new axons and synapses have formed to reestablish the neuromuscular junction. Functional recovery takes place by neurogenesis in the form of axonal sprouting, reinervation and enlargement of some end plates, and the formation of new smaller end plates. The number of muscle fibers innervated per axon also increases. Sprouting begins within 10 days of BTX exposure. Functional denervation is apparent for 6 weeks up to 6 months following injection, but it typically lasts for 3 to 4 months. Recovery is complete after allowing sufficient time for reinervation, and neuromuscular function returns essentially to normal, even after multiple cycles of injection and recovery.

THERAPEUTIC USES IN PAIN MANAGEMENT

CERVICAL DYSTONIA

Cervical dystonia is characterized by involuntary head and neck movements, in the form of either sustained muscle
contraction or intermittent jerking motions. Both types may coexist and cause significant disability. Neck pain with or without headaches is a complaint in 70% of patients. Treatment with oral medications may yield inconsistent and unsatisfactory results. Surgical treatments, including thalamotomy, myectomy, neurotomy, and selective peripheral denervation of neck muscles, may produce limited benefits. It is estimated that treatment with BTX-A is effective in over 80% of cases, with an average duration of benefit of 3 to 4 months. A survey of 19 studies in which BTX-A was used to treat cervical dystonia revealed a mean weighted percentage of 76% (range, 50% to 100%) of patients reporting pain relief, from 16 studies that reported pain results. Injections into the superficial neck muscles, such as the sternocleidomastoid, splenius capitis, levator scapulae, and trapezius, may be done without electromyographic guidance. The dose of BTX-A per muscle ranged from 50 to 100 MU. It has been suggested to divide the dose into 25-MU quanta and inject these in an even distribution throughout the length of the muscle. A study of patients with cervical dystonia treated with BTX-A has revealed that pain relief occurs long before any reduction in muscle spasm can be detected.

MIGRAINE HEADACHE

Since 2010, onabotulinum toxin A (Botox, Allergan, Inc., Irvine, California) has been FDA approved for the treatment of patients with chronic migraine headaches. The diagnosis of chronic migraine can be made for individuals who experience 15 or more headache days each month, at least 8 of which would be consistent with migraine, for at least 4 hours per day for at least 4 months. Multiple studies led to the Phase REsearch Evaluating Migraine Prophylaxis Therapy (PREEMPT) trials, which ultimately led to the FDA approval of onabotulinum toxin A for chronic migraine.

In a multicenter, open-label study on the efficacy of Botox (BTX-A) for the acute and prophylactic management of migraine, BTX-A was injected into the glabellar, temporal, frontal, or suboccipital muscles of the head and neck. In 77 true migraine patients treated prophylactically with a mean dose of 31 units (range, 5 to 110 units), 51% reported complete response with a mean duration of relief of 4.1 months, and 38% reported a partial response with a mean duration of relief of 2.7 months. In the acute treatment group, 70% of 10 true migraine patients treated with a mean dose of 31 units reported complete response at 1 to 2 hours after treatment. A double-blind, vehicle-controlled study was done on 123 migraineurs in which the patients were randomized to receive the vehicle or BTX-A 25- or 75-unit injections at one visit into symmetric points in the frontalis, temporalis, and glabellar muscles. BTX-A, 25 units, was significantly superior to vehicle in reducing migraine frequency and severity, the use of acute migraine medication, and migraine-associated vomiting. The beneficial effects of BTX-A were observed at 2 and 3 months. The 75-unit dose of BTX-A had a higher incidence of side effects, including blepharoptosis, diplopia, and injection site weakness. BTX-B (Myobloc) has been evaluated for treating transformed migraine headaches. Forty-seven patients received injections of 5000 units of BTX-B into three or more muscles. Of these, 64% reported improvement in headache intensity and severity, and all patients experienced a decrease in migraine frequency over 4 weeks.

Two large randomized, controlled, multicenter clinical trials, PREEMPT I and II, reported their results in 2010. Each study enrolled approximately 700 patients with a comparable number in toxin treatment and placebo administration groups in a 24-week blinded arm followed by a 32-week open arm. In the treatment group, patients received 155 U of onabotulinum toxin A divided in 31 injections sited across 7 head and neck muscles using a fixed-site fixed-dose (FSFD) paradigm (Table 44.6). Each injection was performed with 5 U in 0.1 ml, obtained by reconstituting the toxin powder in 2 ml of normal saline.

The primary outcomes and a number of secondary outcomes were evaluated at 24 weeks for both studies. PREEMPT II met its primary and secondary outcomes at all time points, whereas PREEMPT I met only its secondary outcomes and not the primary ones. However, the number of headache days (the reached primary outcome for PREEMPT I) was considered the better outcome measure than the headache episodes (not the reached primary outcome for PREEMPT II) for the study of chronic migraine (headache with a frequency of 15 or more headache days per month for more than 3 months). Therefore based on those studies, Botox or Botox Cosmetic (manufactured by Allergan) was approved in October 2010 to be used for the treatment of chronic migraine.

Overall, the use of onabotulinum toxin A for chronic migraine significantly improves headache symptoms and demonstrates improved patient functioning, vitality, psychological distress, and overall quality of life.

TENSION HEADACHE

Tension-type headache (TH) is characterized as a dull, aching, pressure-like or squeezing feeling; the International Headache Society (IHS) has characterized the pain as pressing or tightening. A population study of 1000 adult patients revealed a lifetime prevalence of TH of 78%, with 87% of chronic headache sufferers demonstrating pericranial muscle tenderness and pain threshold abnormalities. Onabotulinum toxin A has shown some efficacy in the treatment

Total dose range: 155 units to 195 units.
of TH. In one retrospective study, 21 patients with chronic TH were injected with onabotulinum toxin A, 100 units, divided evenly over five injection sites representing the most tender muscle points in the scalp and upper neck.\textsuperscript{118} There was a 50\% reduction in headache frequency in 18 of the 21 patients and a 50\% reduction in tenderness to palpation in 20 patients. In another study, the efficacy of onabotulinum toxin A was assessed in a randomized, double-blind, placebo-controlled trial in 37 patients.\textsuperscript{119} Patients received onabotulinum toxin A, 100 units, or placebo, divided among six injection sites—two in the temporal muscles and four in the cervical muscles. The actively treated group experienced decreased headache severity and more headache-free days over 3 months following injection.\textsuperscript{119}

WHIPLASH INJURY

Whiplash-associated disorders (WADs) include a number of clinical features, including neck pain, nonspecific headache, and temporomandibular joint pain. Clinical findings in WADs include myofascial tenderness, trigger points in the affected musculature, increased pain with function, and cervical muscle spasm.\textsuperscript{120} Onabotulinum toxin A has been studied in small trials of WADs and has been found to relieve pain and increase range of motion. A randomized, double-blind, placebo-controlled study has examined the effects of onabotulinum toxin A in patients with motor vehicle accident (MVA)-associated WADs of longer than 6 months’ duration. Half of the patients received onabotulinum toxin A, 100 units, into five trigger points, and the other 50\% received normal saline injections. The muscles treated bilaterally included the splenius capitis, rectus capitis, semispinalis capitis, and trapezius. At 4 weeks postinjection, the onabotulinum toxin A treatment group demonstrated improvement in range of motion (ROM) and subjective pain. Another randomized, placebo-controlled study evaluated the potential benefits of relaxing selected neck muscles with onabotulinum toxin A.\textsuperscript{121} Twenty-eight patients with chronic grade 2 WADs received injections of onabotulinum toxin A, 100 units, or saline placebo. Each patient received five injections into the five most tender cervical muscular points. At 2 weeks, the onabotulinum toxin A group showed a trend of improvement in ROM and pain reduction. At 4 weeks postinjection, this group was significantly improved from preinjection levels.

Botulinum toxin B has also been studied in WADs. An open-label study evaluated botulinum toxin-B for the treatment of 31 patients with chronic headaches following injury. Botulinum toxin B, 5000 units, was injected in divided doses into the suboccipital muscles (rectus capitis posterior major and minor, oblique capitis inferior and superior). Of these, 71\% experienced a decrease in headache pain and frequency.\textsuperscript{122}

HEMIFACIAL SPASM

Hemifacial spasm is usually caused by irritation or compression of the root of the facial nerve by an anomalous blood vessel. This is a slowly progressive syndrome characterized by intermittent tonic or clonic contractions of the muscles supplied by the facial nerve. Treatment with anticonvulsants such as carbamazepine may provide relief initially but becomes less effective with long-term use. Surgical microvascular decompression of the facial nerve may be highly successful in relieving this condition, but serious potential complications, such as facial paralysis, hearing loss, and stroke, deter many patients from this procedure. Onabotulinum toxin A injections into the facial muscles have now become the treatment of choice for hemifacial spasm.\textsuperscript{123,124} It is recommended that for the first treatment only the orbicularis oculi be injected, with a starting dose of 12.5 units of onabotulinum toxin A.\textsuperscript{104} Other commonly injected muscles include the frontalis (5 to 10 MU), risorius (2.5 to 5 MU), depressor anguli oris (5 MU), platysma (2.5 MU per strand of muscle), and zygomatic major (2.5 MU). The dose for botulinum toxin B is 125 to 250 units per muscle site (total dose, 750 to 5000 units).

LOW BACK PAIN

The efficacy of botulinum toxins for the relief of chronic low back pain was investigated in a randomized, double-blind study of 31 patients who had nonradiating back pain for at least 6 months.\textsuperscript{125} Fifteen patients received 200 units of onabotulinum toxin A, 40 units per site at five lumbar paravertebral levels on the side of maximum discomfort, and 16 patients received normal saline. At 3 weeks, 86\% of patients in the onabotulinum toxin A group reported some degree of pain relief, with 73\% in the onabotulinum toxin A group reporting more than 50\% relief. At 8 weeks, 60\% in the botulinum toxin group versus 12.5\% in the saline group reported pain relief exceeding 50\%. Onabotulinum toxin A was not associated with any increase in low back pain or worsening in functioning.

MYOFASCIAL PAIN

Botulinum toxin injections may be used for cases refractory to a series of trigger point injections with local anesthetics and steroids. Onabotulinum toxin A was evaluated for the treatment of chronic myofascial pain in a randomized, double-blind, placebo-controlled study of six patients with myofascial pain involving cervical paraspinal and shoulder girdle muscles.\textsuperscript{126} Patients were injected with 50 units of onabotulinum toxin A or normal saline on two occasions. Four of the 6 patients experienced more than a 30\% reduction in pain and muscle spasm following botulinum toxin injections. The onset of the response occurred within the first week, and the mean duration of response was 5 to 6 weeks.

Studies have shown the lack of efficacy of botulinum toxin injections for myofascial pain syndrome. In a randomized, double-blind crossover study, onabotulinum toxin A (25 units per trigger point) was found to provide the same degree and duration of pain relief compared with 0.5\% bupivacaine.\textsuperscript{127} Another study has shown no difference in results between onabotulinum toxin A, at 5 units per trigger point, and saline.\textsuperscript{128} Finally, a study that compared different doses of onabotulinum toxin A (5, 10, 25, or 50 units per trigger point) with saline showed no differences in the pain scores, pain threshold as measured by pressure algometry, and number of rescue medications.\textsuperscript{129} It appears, therefore, that onabotulinum toxin A does not offer any advantage over bupivacaine or saline, regardless of the dose.

PIRIFORMIS SYNDROME

Initial treatment of piriformis syndrome is conservative and includes physical therapy combined with anti-inflammatory drugs, analgesics, and muscle relaxants to
reduce inflammation, spasm, and pain.\textsuperscript{130} When conservative therapy fails, patients may benefit from local anesthetics, steroid injections, or both into the piriformis muscle; caudal epidural steroid injections;\textsuperscript{131} botulinum toxin injections; or surgery. A randomized, double-blind study of 72 cases of piriformis syndrome has examined the effect of onabotulinum toxin A, 200 units, compared with lidocaine and triamcinolone or placebo. Onabotulinum toxin A therapy resulted in a 50\% pain reduction in 65\% of patients as compared with a 32\% response in the triamcinolone and lidocaine group and 6\% in the placebo group.\textsuperscript{132}

**ANTIBODY FORMATION AND ADVERSE REACTIONS**

Repeated injections of onabotulinum toxin A have been associated with antibody formation, which renders subsequent onabotulinum toxin A injections ineffective. A study of 32 patients with spasmodic torticollis treated with repeated onabotulinum toxin A injections has revealed that 4 patients (12.5\%) produced antibodies after 2 to 9 months of treatment.\textsuperscript{133} The larger doses used likely explain this relatively high incidence. The data from numerous studies have suggested that the incidence of antibody formation with onabotulinum toxin A for the treatment of cervical dystonia is probably less than 5\%.\textsuperscript{101} Because onabotulinum toxin A and botulinum toxin B are structurally different, it has been thought that neutralizing antibodies to onabotulinum toxin A would not cross-react with botulinum toxin B. It appears that higher toxin doses and frequent injections are the leading factors in the development of neutralizing antibodies.\textsuperscript{134} The reported complications of botulinum toxin injection include brachial plexopathy, polyradiculoneuritis, and local psoriasiform dermatitis. Muscle weakness occurs if more than 50 units of onabotulinum toxin A are injected into a muscle.\textsuperscript{129}

**SUMMARY OF CLINICAL EVIDENCE FOR USE OF BOTULINUM TOXIN IN HUMAN SUBJECTS**

Jabbari and Machado,\textsuperscript{115} in an evidence-based review, used American Academy of Neurology (AAN) methodology as stated by the guidelines of the society’s Therapeutics and Assessment Subcommittee to rate the scientific evidence for the use of BTXs in clinical practice. They found four levels of clinical evidence (Table 44.7). Although evidence supports using this treatment in several specific conditions such as cervical dystonia and chronic migraine, clinical studies for other chronic pain conditions have produced contradictory results.\textsuperscript{135,136}

**OTHER AGENTS USED IN INTERVENTIONAL PAIN MANAGEMENT**

**INJECTABLE BONE CEMENT**

Vertebroplasty and kyphoplasty are minimally invasive interventions routinely used to treat vertebral body compression fractures of multiple etiologies (osteooporosis, malignancy, metastasis). By injecting bone cement into the fractured vertebral body, the procedure aims to stabilize the fracture and, it is hoped, prevent further collapse. It is reported to be highly effective, with an immediate and lasting pain relief seen in 80\% to 90\% of cases.\textsuperscript{137,138} The most common injectable bone cement used in clinical practice is polymethylmethacrylate (PMMA). Its main effect is to reinforce the fragile or broken vertebral bodies, thus leading to extensive bone stiffening. However, its handling differs between vertebroplasty and balloon kyphoplasty.\textsuperscript{139} More fluid PMMA with a longer liquid phase working time and a very short set time is necessary in vertebroplasty procedures where the cement is injected directly into the bone.

through the introducer with relatively higher pressure. Kyphoplasty involves the introduction of an inflatable bone tamp into the compressed vertebrae with creation of a cavity, which is subsequently filled with partially cured PMMA with a short liquid phase and a longer “doughy” phase working time.

PMMA is a bio-inert material considered an ideal substrate for use in vertebral augmentation procedures, specifically because of its ease of handling, strength, and cost-effectiveness. It has a number of disadvantages, including its lack of biologic potential to remodel or integrate into the surrounding bone; it has an excessive inherent stiffness, a high polymerization temperature, and potential monomer toxicity. Several studies have demonstrated temperatures as high as 70°C in the center of the vertebrae during setting. Accidental release of the component monomer can be associated with cytotoxic effects such as tissue irritation, inflammation, or systemic effects on lungs, kidneys, and liver resulting from circulatory uptake. Although PMMA’s main indication is for vertebral fracture stabilization, with increased strength, it may excessively increase the stiffness of the augmented vertebrae, sometimes up to 174% when compared to the intact osteoporotic bone. This overly rigid reinforcement of the broken vertebrae may enhance the risk of an additional fracture in adjacent levels.

PMMA consists of several components: a polymer powder and a monomer liquid whose admixture renders an exothermic reaction with in vitro temperatures as high as 113°C and in vivo temperatures of 40° to 56°. N,N-dimethyl-p-tolu-idine acts as an accelerator while the traces of hydroquinone stabilize the monomer, preventing premature polymerization. The major characteristics of PMMA that affect its use in vertebral augmentation are polymerization time and opacification. The polymerization time, or curing rate, varies among the different products, and the preparation material may be suited for injection in as little as 5 minutes to close to 20 minutes. The polymerization time of any PMMA can be prolonged by refrigerating its components prior to their use or by wrapping syringes filled with the acrylic in a sterile glove filled with ice. For acrylics with a longer curing time, the powdered polymer component needs to dissolve completely in the liquid monomer before injecting. Some manufacturers recommend the addition of a “rest period” of approximately 1 minute after mixing and before injection.

The amount of barium sulphate within the products, the quality of the imaging chain, the size of the patient, and the location of the targeted vertebral body influence visualization of the bone cement. The common materials present in the currently used commercial preparations for vertebral augmentation are listed in Table 44.8.

The most feared complication of PMMA is leakage of the filler material in the adjacent structures with devastating nerve root impingement and cord compression. In addition, during liquid phase PMMA injection, fatal complications have been reported due to pulmonary cement embolism via venous sinuses. This risk seems to be slightly decreased with the use of partially cured cement that is injected under low pressure in kyphoplasty.

The cement monomer is arrhythmogenic and cardiotoxic at the volumes used in total hip arthroplasties, with an estimated risk of 1 in 3000 to 5000 surgeries. Assuming the same risk for vertebral augmentation procedures at a mean of 6 cc of cement injected per vertebral body, it might be prudent to limit the kyphoplasty/vertebroplasty levels treated to 2 (12 cc of PMMA total) per surgical intervention. In addition, a potentially higher incidence of cement leak and embolization may occur in vertebroplasty, where liquid PMMA with a higher concentration of “free” toxic monomer (available to enter the systemic circulation) is forcibly injected within the vertebra body.  

**BIOLOGIC AGENTS IN CHRONIC PAIN THERAPY**

Advances in the understanding of chronic pain mechanisms allowed the emerging of new treatment strategies involving the delivery of short-lived potent bioactive molecules with therapeutic properties to sensory nerves, spinal cord, and meninges for the treatment of refractory pain. Building on a number of preclinical studies, researchers focused on the use of nonviral or viral vector-based gene transfer for the treatment of chronic pain. When comparing those two systems, the viral agents seemed to be more efficient in delivering exogenous genes to target cells and inducing long-term gene expression than their nonviral counterparts and are currently viewed as the preferred target delivery system in chronic pain. Table 44.9 summarizes preclinical data on various animal pain models that use viral system loaded genes targeting specific structures implicated in chronic pain states.

The use of viral vectors loaded with genes targeting specific structures for the treatment of chronic pain involves genetically engineering the viral genome to create a nucleic acid sequence that encodes a promoter to drive both the gene expression and the analgesic transgene. This delivering system exploits the properties of the virus to enter a normal cell and alter its transduction. Targeted vector delivery also evades the side effects of systemic administration. The ideal viral system needs to be safe and well tolerated, should not elicit any immune response, and should also be replication incompetent, and thus unable to produce an infection. In addition, it should be able to infect multiple cell types and express large and small transgenes. Its mode of delivery should be varied depending on the targeted cell: either directly via neuro-axial administration (injected in the sensory nerves, intrathecal, meninges) or indirectly via distal, subcutaneous injection of a virus with engineered increased tropism for dorsal root ganglia.

The first human trial of gene therapy for chronic pain started enrolling patients with chronic cancer pain in 2008 and it is currently in phase II. The product, named NP2, is a replication-defective herpes simplex virus (HSV)-based vector expressing human preproenkephalin (PENK). Injected subcutaneously in a dermatomal distribution of focal pain in individuals with moderate to severe cancer pain requiring more than 200 mg morphine equivalents daily, it proved to decrease pain scores in escalating doses. Another vector expressing glutamic acid decarboxylase, potentially beneficial in neuropathic pain, is currently being studied by the same research group.

Gene therapy is an exciting new development in treating chronic refractory pain. Perfecting the genetically engineered viral vectors as well as correctly identifying delivery modes is possible due to our increased understanding of pain generation, transmission, and maintenance. Other therapies, such as the regulation of neurotropic factors and cell transplantation, currently still in preclinical trials may emerge as effective pain treatments for chronic unrelenting pain.

DRG, dorsal root ganglia; BDNF, brain-derived neurotropic factor; its overexpression reduces allodynia and hyperalgesia in chronic constriction injury model; GDNF, glial cell line-derived neurotrophic factor; in neuropathic pain it is decreased; increased, its expression may be effective in treatment of neuropathic pain; GAD, glutamic acid decarboxylase; its expression can decrease mechanical allodynia and thermal hyperalgesia in spinal cord injury model; HSV, herpes simplex virus.

**KEY POINTS**

- There are theoretical advantages for the use of the transforaminal technique, but the reports of central nervous system injuries make its continued use in the cervical area inadvisable. These events have been described with all the steroids, local anesthetics, and contrast. The use of computed tomography does not prevent the occurrence of these injuries.
- Recommended precautions for preventing CNS events include aspiration before injection, the use of blunt needles, flexible extension tubing, and digital subtraction imaging.
- Steroids with larger particles, such as methylprednisolone, should not be used in transforaminal epidural steroid injections. The commercial form of betamethasone, with its small particles, may be the ideal particulate steroid for transforaminal injections.
- Soluble steroids such as dexamethasone have no particles, are long acting, and have minimal mineralocorticoid properties. However, they have increased glucocorticoid activity, similar to betamethasone, and are easily washed out from the epidural space. Definitive prospective, randomized, controlled studies on the efficacy of these steroids are lacking.
- CNS injuries have not been described with the interlaminar epidural technique. Any of the steroids can be used with this technique.
- The outbreak of fungal (Exserohilum rostratum) meningitis in September 2012 was associated with contaminated methylprednisolone from a compounding company. The pain medicine physician can ensure sterility of the compounded drug that he or she is using by obtaining the drug from a company accredited by the Pharmacy Compounding Accreditation Board.
- Botulinum toxins are effective drugs when used for their FDA-approved indications. Studies have shown inconsistent efficacy for patients with myofascial pain syndromes.
- New indications for the botulinum toxin are emerging. When used for chronic migraine, onabotulinum toxin A significantly improved headache symptoms and demonstrated improved patient functioning, vitality, psychological distress, and overall quality of life.

**KEY POINTS—cont’d**
KEY POINTS—cont’d

- Injectable bone cements are widely used in vertebral augmentation procedures. In vertebroplasty, the currently preferred product, polymethylmethacrylate, can be injected into the vertebral body under high pressure and in liquid form. An alternate technique, kyphoplasty, involves injecting the vertebral body with semisoft, partially cured acrylic paste under low pressure, possibly allowing for better control for the dispersed substance. Several other agents are under investigation as injectable bone cements.

- Gene therapy is an emerging technique to treat chronic unremitting pain. Genetically engineered herpes simplex virus type 1 (HSV 1) vector has been used to treat cancer pain in a phase I study with favorable results. Other methods of vector delivery are under investigation for the treatment of neuropathic pain.

Psychological Interventions

Dennis C. Turk

A number of psychological interventions have been developed for patients with chronic pain, with a large body of research supporting their efficacy. Before reviewing the approaches with the greatest empirical support, it is important to consider the plight of a person with chronic pain, the role of psychological factors, and the mechanisms involved in the experience of chronic pain because these factors serve as the basis for the development of treatment modalities. The various psychological models and conceptualizations of chronic pain will then be outlined and the most commonly used treatment interventions described.

Note that the term *patient* will be used to designate individuals when they are in the health care provider’s office, clinic, or hospital and the term *person* to designate those with chronic pain when they are outside the confines of health care facilities. This is an important distinction because chronic pain is by definition not curable and can persist over extended periods, for years and even decades. Persons with a chronic pain syndrome must learn how to adapt and self-manage their pain, associated symptoms, and lives. Chronic pain might be viewed as analogous to diabetes; in the physician’s office a person with diabetes is a diabetic patient but, at all other times, is someone who has to learn how to live with diabetes. This involves carrying out all the necessary activities—routinely testing glucose levels (if insulin dependent), taking medication orally or injecting with insulin, maintaining an appropriate diet, modulating exercise patterns, and monitoring skin for infections. All these activities occur outside the formal health care system. Similar behavior is required of those with various types of chronic pain. In the absence of cure, self-management becomes critical.

Although patients with acute pain can often obtain relief from primary health care providers, people with persistent pain become enmeshed in the medical system as they shuttle from physician to laboratory test to imaging procedure to medical specialist in a frustrating quest to have their pain diagnosed and successfully treated, if not eliminated completely. Thus, at the same time that returning to work and earning an income become less possible, medical bills for unsuccessful treatments accumulate. This experience of “medical limbo”—the presence of a painful condition that in the absence of acceptable pathology might have psychiatric causation, suggests malingering, or perhaps might even be an undiagnosed but potentially progressive disease—is itself a source of significant and persistent stress that can initiate emotional distress or aggravate a premorbid psychiatric condition.

People with chronic pain reside in a complex and costly world that is also populated by their significant others, health care providers, employers, and third-party payers. Family members feel increasingly hopeless and distressed as medical costs, disability, and emotional suffering mount while income and available treatment options decline. Health care providers grow increasingly frustrated and feel defeated and ineffective as available treatment options are exhausted while the pain condition remains a mystery and may worsen. Employers, who are already resentful of growing workers’ compensation benefits, pay higher costs while productivity suffers because the employee frequently calls in sick or cannot perform at the usual level (“presenteeism”). Third-party payers watch as health care expenditures soar with repeated diagnostic tests and treatments, often with inconclusive results. Over time, the legitimacy of the individual’s report of pain may be questioned because often a medical reason fails to substantiate the cause of the symptoms.

People with chronic pain may begin to feel that their health care providers, employers, and even family members are blaming them when their condition does not respond to treatment as expected. Some may suggest that the individual is complaining excessively to receive attention, avoid undesirable activities, or be relieved from onerous obligations (e.g., gainful employment, household responsibilities). Others may suggest that the pain reported is not real, people reporting unremitting pain are feigning or exaggerating their symptoms, and it is all in their heads, “psychogenic.” Third-party payers may even suggest that the individual is intentionally exaggerating the pain to obtain financial gain, whereas others may attribute the reported symptoms to the desire to obtain mood-altering medications. In this way, people reporting pain may come to be regarded as wimps, crocks, or fakes.
As a result of these attitudes and the absence of cure or even substantial relief, those with chronic pain may withdraw from society, lose their jobs, alienate family and friends, and become more and more isolated, despondent, depressed, and in general demoralized. Their bodies, the health care system, and their significant others have let them down. They may even believe that they have failed themselves as they relinquish their usual activities and responsibilities because of symptoms that are intractable but frequently almost invisible when not validated by objective pathologic findings. This emotional distress, however, can be exacerbated by other factors, including fear, inadequate or maladaptive support systems, inadequate personal and material coping resources, treatment-induced (iatrogenic) complications, overuse of potent drugs, inability to work, financial difficulties, prolonged litigation, disruption of usual activities, and sleep disturbance.

Fear of pain or movement and injury or reinjury is an important contributor to the disability associated with several chronic pain disorders, including back pain and fibromyalgia syndrome. People with chronic pain often anticipate that certain activities will increase their pain or induce further injury. These fears may contribute to avoidance of activity and subsequently greater physical deconditioning, emotional distress, and ultimately, greater disability. Their failure to engage in activities prevents them from obtaining any corrective feedback about the association between activity and pain and injury.

In addition to fear of movement, people with persistent pain may be anxious about the meaning of their symptoms for the future—will their pain increase, will their physical capacity diminish, will they have progressive disability and ultimately end up in a wheelchair or become bedridden? In addition to these anxieties, people in pain may fear that others will not believe that they are suffering or will tell them that they are beyond help and will just have to “learn to live with it.” Such fears can contribute to additional emotional distress and increased physiologic arousal, which may directly exacerbate and maintain the pain. Living with persistent pain conditions requires considerable emotional resilience. It tends to deplete people’s emotional reserves and taxes not only the individual but also the capability of family, friends, coworkers, and employers to provide support.

Chronic pain is estimated to be present in up to 30% of the adult U.S. population. If we assume that most people do not live alone but in a social context with significant others, more than the majority of the population may be affected directly or indirectly. Pain is expensive; health care and indirect costs associated with disability compensation, lost tax revenues, retraining, less than optimal performance on the job, and legal fees exceed $550 billion each year. To put it bluntly, pain hurts—it hurts the person with the symptoms, it hurts significant others, and it hurts society.

Despite advances in knowledge of the neurophysiology of pain and the development of new pharmacologic agents with analgesic properties, sophisticated surgical interventions, and advanced technologies (e.g., spinal cord stimulation, implantable drug delivery systems), cure of pain has eluded the best efforts of health care providers. Regardless of the treatment, the amount of pain reduction averages only about 35%; less than 50% of persons treated with these interventions obtain even this result, and the extent of improvement in emotional, physical, and social functioning is often below this level.

As noted, chronic pain is by definition incurable. People with chronic pain continually confront noxious sensations and other aversive symptoms that affect every aspect of their lives—social, emotional, interpersonal, and economic, as well as physical. Thus, those with chronic pain are faced with managing their symptoms on their own. Faced with this task, the common response is, “How?”

It is well to recall Bonica’s comment in the preface to the first edition (1954) of his seminal work The Management of Pain (and repeated in the third edition almost 50 years later):

*The crucial role of psychological and environmental factors in causing pain in a significant number of patients only recently received attention. As a consequence, there has emerged a sketch plan of pain apparatus with its receptors, conducting fibers, and its standard function which [sic] is to be applicable to all circumstances. But…in so doing, medicine has overlooked the fact that the activity of this apparatus is subject to a constantly changing influence of the mind.*

Based on the overview provided, two conclusions should be obvious: (1) psychological factors play a significant role in the experience, maintenance, and exacerbation, if not the cause, of pain, and (2) because there are no cures for chronic pain and some level of pain will persist in most people with chronic pain regardless of treatment, psychological approaches may be useful complements to more traditional medical and surgical approaches.

---

**PSYCHOLOGICAL FORMULATIONS OF CHRONIC PAIN**

A number of different psychological perspectives on chronic pain have evolved over time. It is important to consider these initially because psychological treatments are based on different, and at times competing, psychological principles.

**PSYCHOGENIC VIEW**

As is frequently the case in medicine, when physical explanations seem inadequate or when the results of treatment are inconsistent, reports of pain are attributed to a psychological cause (i.e., psychogenic). Although psychogenic views of pain have been discussed since the formulation of psychodynamic theory, a psychodynamic perspective on chronic pain was first described systematically in the 1960s, when people with pain were viewed as having compulsive and masochistic tendencies, inhibited aggressive needs, and feelings of guilt—“pain-prone personalities.” It was commonly believed that people with pain had childhood histories fraught with emotional abuse, family dysfunction (e.g., parental quarrels, divorce), illness or death of a parent, early responsibilities, and high motivation toward achievement. Some studies reported associations between chronic pain and childhood trauma, although the findings are not consistent.

Based on the psychogenic perspective, assessment of those with chronic pain is directed toward identifying the psychopathologic tendencies that instigate and maintain...
pain. Although evidence to support this model is scarce, the American Psychiatric Association has created a psychiatric diagnosis, somatoform pain disorder. Diagnosis of a pain disorder requires that the person’s report of pain be inconsistent with the anatomic distribution of the nervous system or, if it mimics a known disease entity, cannot be adequately accounted for by organic pathology after extensive diagnostic evaluation. Even in the presence of a medical condition that may cause pain, psychological factors may be implicated, and thus the person may receive a psychiatric diagnosis of “pain disorder associated with both psychologic factors and a general medical condition.”

It is assumed that reports of pain will cease once the psychogenic mechanisms have been resolved. Treatment is geared toward helping patients gain insight into the underlying maladaptive psychological contributors.

Empirical evidence supporting the psychogenic view is scarce. A number of people with chronic pain do not exhibit significant psychopathology. Furthermore, insight-oriented psychotherapy has not been shown to be effective in reducing symptoms in most patients with chronic pain. Studies have suggested that the emotional distress observed in patients with chronic pain more typically occurs in response to the persistence of pain and is not a causal agent and may resolve once the pain is treated adequately. The psychogenic model has thus come under scrutiny and may be flawed in its view of chronic pain.

**BEHAVIORAL FORMULATIONS**

According to the classical or respondent conditioning model, if a painful stimulus is repeatedly paired with a neutral stimulus, the neutral stimulus will by itself come to elicit a pain response. For example, a person who experienced pain after performing a treadmill exercise may become conditioned to experience a negative emotional response to the presence of the treadmill and to any stimulus associated with it (e.g., physical therapist, gym). The negative emotional reaction might instigate tensing of muscle in anticipation, thereby exacerbating the pain and further reinforcing the association between the stimulus and pain. Based on this conditioned correlation, people with chronic pain may avoid activities previously associated with onset or exacerbation of the pain.

In 1976, Fordyce extended operant conditioning to chronic pain. This view proposes that acute pain behavior (e.g., avoidance of activity for fear of pain) may come under the control of external contingencies of reinforcement (i.e., responses increase or decrease as a function of their reinforcing consequences) and thus develop into a persistent pain problem. Fordyce underscored that because there is no objective means of measuring pain, the only way that we can know of other people’s pain is by their behavior, expressed verbally or nonverbally. Overt pain behavior includes verbal reports, paralinguistic vocalizations (e.g., sighs, moans), motor activity, facial expressions, body postures and gesturing (limping, rubbing a painful body part, grimacing), functional limitations (e.g., reclining for extensive periods, inactivity), and behavior designed to reduce pain (e.g., taking medication, use of the health care system).

The central features of pain behavior are that behavior is (1) a source of communication and (2) observable. Observable behavior is capable of eliciting a response, and the consequences of the behavior will influence subsequent behavior. Through a learning process, behaviors that receive positive consequences will more likely be maintained, whereas types of behavior that fail to achieve positive consequences or that receive negative consequences will be less likely to occur (i.e., extinguished). Pain behavior may be positively reinforced directly, such as by attention from a spouse or health care provider, monetary compensation, or avoidance of undesirable activity. It may also be maintained by escape from noxious stimulation through the use of drugs or rest or by avoidance of undesirable activities such as work. In addition, “well behavior” (e.g., activity, working) may not be positively reinforcing and the more rewarding pain behavior may therefore be maintained.

The operant conditioning model does not concern itself with the initial cause of pain. Rather, it considers pain an internal subjective experience that can be directly assessed and may be maintained even after an initial physical basis of the pain has resolved. The pain behavior originally elicited by organic factors as a result of injury or disease may come to occur, totally or in part, in response to reinforcing environmental events.

It is important, however, not to make the mistake of viewing pain behavior as synonymous with malingering. Malingering involves consciously and purposely faking a symptom such as pain for some gain, usually financial. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent.

The social learning model emphasizes that behavior can be learned not only by actual reinforcement of behavior but also by observation of what happens to others. This is a particularly powerful way of learning when the others being observed are judged to be similar to the observer. For example, a middle-aged man might learn what to expect by observing how other middle-aged men with similar medical problems are treated, as opposed to observing young women with a very different pain disorder. Thus, the development and maintenance of pain behavior may occur by observational learning and modeling processes. Specifically, people can acquire responses that were not previously in their behavioral repertoire by the observation of others performing these activities. Expectations and actual behavioral responses to noxious stimulation are based, at least partially, on people’s prior learning histories.

Children develop attitudes about health and health care and about the perception and interpretation of symptoms and physiologic processes from their relatives and others whom they confront in their social environment. They learn how others respond to injury and disease and thus may ignore or over-resist to symptoms that they experience based on the behavior modeled in childhood. For example, children of chronic pain patients have been shown to exhibit more pain-related responses during stressful times or exhibit more illness behavior (e.g., complaining, days absent, visit to the school nurse) than children of healthy parents based on what they have observed and learned at home.

Expectations and actual behavioral responses to noceptive stimulation are based partially on prior social learning history. Models can influence the expression, localization,
and methods of coping with pain. Even physiologic responses may be conditioned during observation of others in pain.20

A central construct of the social learning perspective is self-efficacy.21 This is a personal expectation that is particularly important for patients with chronic pain. A self-efficacy expectation is defined as a personal conviction that a course of action (e.g., performing the required behavior) can successfully be executed to produce a desired outcome in a given situation.22 Given sufficient motivation to engage in a behavior, it is a person’s self-efficacy beliefs that determine the choice of activities that the person will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences. In this way, self-efficacy plays an important role in therapeutic change.22

Efficacy judgments are based on four sources of information regarding one’s capabilities, listed in descending order of effect16: (1) one’s own past performance at the task or similar tasks; (2) the performance accomplishments of others who are perceived to be similar to oneself; (3) verbal persuasion by others that one is capable; and (4) perception of one’s own state of physiologic arousal, which in turn is partly determined by previous estimation of efficacy. Performance mastery can then be achieved by encouraging people to undertake subtasks that are initially attainable but become increasingly difficult and to subsequently approach the desired level of performance. It is important to remember that coping behavior is influenced by a person’s beliefs that the demands of a situation do not exceed her or his coping resources.

How people interpret, respond to, and cope with illness is determined by cultural norms and perceptions of self-efficacy. These two sets of factors contribute to the marked variability in response to objectively similar degrees of physical pathology noted by health care providers.

**GATE CONTROL MODEL**

Though not a psychological formulation itself, the gate control model23 was the first to popularize the importance of central psychological factors in perception of pain. Perhaps the most important contribution of the gate control theory is the way in which it changed thinking about pain perception. Melzack and Casey24 differentiated three systems related to the processing of nociceptive stimulation, all thought to contribute to the subjective experience of pain—sensory-discriminative, motivational-affective, and cognitive-evaluative. Thus, the gate control theory specifically includes psychological factors as an integral aspect of the pain experience. It emphasizes central nervous system mechanisms and provides a physiologic basis for the role of psychological factors in chronic pain.

The gate control model contradicts the notion that pain is either somatic or psychogenic. Instead, it postulates that both factors have potentiating and moderating effects. According to this model, both the central and peripheral nervous systems interact to contribute to the experience of pain. It is not only these physical factors that guide the brain’s interpretation of painful stimuli that are at the center of this model; psychological factors (e.g., thoughts, beliefs, emotions) are also actively involved.

Before formulation of the gate control theory by Melzack and Wall,25 psychological processes were largely dismissed as reactions to pain. Although the physiologic details of the gate control model have been challenged,25 it has had a substantial impact on basic research and can be credited as a source of inspiration for diverse clinical applications to control or manage pain, including neurophysiologically based procedures (e.g., neural stimulation techniques involving peripheral nerves and collateral processes in the dorsal columns of the spinal cord), pharmacologic advances, behavioral treatments, and interventions that target modification of the attentional and perceptual processes involved in the pain experience.

**COGNITIVE-BEHAVIORAL PERSPECTIVE**

The cognitive-behavioral (CB) model, perhaps the most commonly accepted model for the psychological treatment of individuals with chronic pain,26,27 incorporates many of the psychological variables previously described—anticipation, avoidance, and contingencies of reinforcement—but suggests that cognitive factors rather than conditioning factors are of central importance. The model proposes that conditioned reactions are largely self-activated on the basis of learned expectations rather than being automatically evoked. The model suggests that behavior and emotions are influenced by interpretations of events, and emphasis is placed on how people’s beliefs and attitudes interact with physical, affective, and behavioral factors. In other words, it is the individual’s information processing that results in anticipatory anxiety and avoidance. The critical factor, therefore, is that people learn to anticipate and predict events and to express appropriate reactions.28

In the CB model, people with pain are viewed as having negative expectations about their own ability to control certain motor skills without pain. Moreover, people with chronic pain tend to believe that they have limited control over their pain. Such negative maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and over-reaction to nociceptive stimulation. These appraisals and expectations are postulated to have an effect on behavior by leading to reduced effort and activity, which may contribute to increased psychological distress (helplessness) and subsequent physical limitations. If one accepts that pain is a complex subjective phenomenon that is uniquely experienced by each person, knowledge about idiosyncratic beliefs, appraisals, and coping ability becomes critical for optimal treatment planning and for evaluating treatment outcome accurately.

Several important factors may facilitate or disrupt people’s sense of control: their beliefs and appraisals, their expectations about pain, their ability to cope, their social supports, their disorder, the medicolegal and health care systems, and their employers. These factors also influence patients’ investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectations for treatment, and acceptance of treatment rationale.

Cognitive interpretations also affect how people experiencing pain present their symptoms to others, including health care providers. Overt communication of pain,
suffering, and distress will enlist responses that may reinforce the pain behavior and impressions about the seriousness, severity, and uncontrollability of the pain. That is, complaints of pain may induce physicians to prescribe more potent medications, order additional diagnostic tests, and in some cases, perform surgery. Significant others may express sympathy, excuse the person with chronic pain from responsibilities, and encourage passivity, thereby fostering further physical deconditioning.

People with persistent pain often have negative expectations about their own ability and responsibility to exert any control over their pain and frequently view themselves as helpless. Such negative maladaptive appraisals about their condition, situation, and personal efficacy in controlling their pain and problems associated with the pain reinforce their experience of demoralization, inactivity, and over-reaction to nociceptive stimulation. These cognitive appraisals are posited to have an effect on behavior by leading to reduced effort, less perseverance in the face of difficulty, lowered activity level, and increased psychological distress. It should be obvious that the CB perspective integrates the operant conditioning emphasis on external reinforcement with the respondent view of conditioned avoidance within the framework of information processing.

The CB perspective on pain management focuses on providing patients techniques to gain a sense of control over the effects of pain on their lives, as well as on actually modifying the affective, behavioral, cognitive, and sensory facets of the experience. Behavioral experiences help show persons with pain that they are capable of more than they assumed, thereby increasing their sense of personal competence. Cognitive techniques (e.g., self-monitoring to identify the relationships among thoughts, mood, and behavior; distraction using imagery; and problem solving, described below) help place affective, behavioral, cognitive, and sensory responses under the person’s control.

The assumption is that long-term maintenance of behavioral changes will occur only if the person with pain has learned to attribute success to his or her own efforts. It has been suggested that such treatments can result in changes in beliefs about pain, coping style, and reported pain severity, as well as in direct behavioral changes. Treatment that results in increases in perceived control over pain and decreased catastrophizing also results in decreases in pain severity and functional disability. When successful rehabilitation occurs, there is a major shift from beliefs about helplessness and passivity to resourcefulness and ability to function regardless of pain, as well as a shift from an illness conviction to a rehabilitation conviction.

A number of studies have supported the contribution of cognitive factors to pain and disability.22,29 These studies have consistently demonstrated that individuals’ attitudes, beliefs, and expectations about their plight, themselves, personal coping strategies, and the health care system affect reports of pain, activity, disability, and response to treatment. For example, people respond to medical conditions in part based on their subjective ideas about their illness and symptoms. When pain is interpreted as signifying ongoing tissue damage or a progressive disease, it is likely to produce considerably more suffering and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve.

Once beliefs and expectations are formed, they become stable, rigid, and relatively impervious to modification. Individuals with chronic pain tend to avoid experiences (e.g., physical activity) that could invalidate their beliefs (disconfirmations) and guide their behavior in accordance with these beliefs, even in situations in which these beliefs are no longer valid. It is thus essential for people with chronic pain to develop adaptive beliefs about the relationships among impairment, pain, suffering, and disability and to de-emphasize the role of experienced pain in their regulation of functioning.

Distorted thinking can also contribute to the maintenance and exacerbation of pain. A particularly potent and pernicious thinking style that has been observed in people with chronic pain is catastrophizing—holding negative thoughts about one’s situation and interpreting even minor problems as major catastrophes.30 Research has indicated that people who spontaneously use more catastrophicizing thoughts report more pain than do those who do not catastrophize.30

Coping strategies, or a person’s specific ways of adjusting to or minimizing pain and distress, act to alter both the perception of pain intensity and the ability to manage or tolerate pain and continue daily activities. Overt behavioral coping strategies include rest, medication, and the use of relaxation. Covert coping strategies include various means of distractive oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving.

Active coping strategies, such as efforts to function despite pain or distracting oneself from pain, tend to be associated with adaptive functioning, and passive coping strategies, such as depending on others for help with pain control, avoiding activities because of fear of pain or injury, self-medication, and alcohol, tend to be related to greater pain and depression.29 Regardless of the type of coping strategy, if people with chronic pain are instructed in the use of adaptive coping strategies, their rating of the intensity of the pain decreases and their tolerance of the pain increases.29 Thus, the perspective on how people function and the emphasis on facilitating self-management are more important than any specific cognitive or behavioral techniques used to bring about changes in thinking and behavior.

BIOPSYCHOSOCIAL MODEL

Although the gate control theory introduced the role of psychological factors in the maintenance of pain symptoms, it focused primarily on the basic anatomy and neurophysiology of pain. The biopsychosocial model, which expands the CB model of pain, views illness as a dynamic and reciprocal interaction between biologic, psychological, and sociocultural variables that shape the experience and the response to pain.22,29 What is unique about this model is that it takes into consideration the influence of higher-order cognition, including perception and appraisal. It accepts that people are active processors of information and that behavior, emotions, and even physiology are influenced by interpretation of events rather than solely by physiologic factors.29,29 People with chronic pain may therefore have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, those with pain behavior elicit responses from significant others that can reinforce adaptive and maladaptive modes of thinking, feeling, and behaving.
The biopsychosocial model presumes some form of physical pathology or at least physical changes in muscles, joints, or nerves that generate nociceptive input to the brain. At the periphery, nociceptive fibers transmit sensations that may or may not be interpreted as pain. Such sensation is not pain until subjected to higher-order psychological and mental processing that involves perception, appraisal, and behavior. Perception entails the interpretation of nociceptive input and identifies the type of pain (e.g., sharp, burning, punishing). Appraisal involves the meaning attributed to the pain and influences subsequent behavior. A person may choose to ignore the pain and continue working, walking, socializing, and engaging in previous levels of activity or may choose to leave work, refrain from activities, and assume the sick role. In turn, this interpersonal role is shaped by responses from significant others that may promote the healthy response or the sick role. The biopsychosocial model has been instrumental in the development of CB treatment approaches for chronic pain, including assessment and intervention (described later in this chapter).28,29

FAMILY SYSTEMS PERSPECTIVE

In family systems—and this could be expanded to significant others, not only to traditional concepts of nuclear families—the individual and his or her behavior are placed within a social unit. The family is viewed as an interactional unit, and family members (significant others) have a profound impact on each other’s emotions, thoughts, and behavior. Thus, the functioning of family members interdependent, and family relationships are important for not only psychological but also physical health.31,32

Increasing evidence supports the concept that family members contribute to behavioral risk factors such as smoking, lack of exercise, and poor diet, which can influence the development of numerous chronic illnesses, as well as compliance or noncompliance with treatment regimens.33 Additionally, families influence the development of chronic pain via operant theory. As noted, expressions of acute pain (e.g., reporting pain, grimacing, avoidance of activity, use of pain medication), because they are overt and observable, may be reinforced through expressions of concern from family members. Furthermore, in support of this idea, a number of investigators34-36 have found that spouses attentiveness to expressions of pain is positively correlated with higher levels of reported pain, pain behavior frequency, and disability.

The experience of chronic stress within the family has also been hypothesized to contribute to the development of chronic illness.37 Specifically, chronic stress may play an important role in the sympathetic nervous system and endocrine dysregulation often found in chronic pain patients. As noted, pain does not take place in isolation but in a social context. Pain does not occur solely in people’s bodies, nor does it occur solely in their brains, but rather it occurs in their lives. The emphasis on the role of significant others is important. It reminds us that treating a chronic pain patient successfully requires that we not only assess and treat the patient but also target significant others, who can be supportive but can also be impediments to rehabilitation when they are overly punitive or solicitous.35,37

INTERFACES OF PSYCHOLOGY, PHYSIOLOGY, AND NEUROCHEMISTRY

Pain is a biopsychosocial phenomenon, with the implication being that psychological, social, and biologic factors contribute to the experience. Moreover, these factors interact: psychological and social factors are reflected in bodily processes and have physiologic consequences, and psychological and social variables are influenced by an individual’s unique biology. Advances in research and technology are permitting increased understanding of the intricate associations between biology and behavior.28,29

Psychoneuroendocrinology is a specialized field of research that studies the interactions between behavior and the brain, nervous system, and endocrine system. The primary emphasis of this area is on the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis is believed to be the primary part of the neuroendocrine system that responds to stress.38-40 The long-term effects of altered secretion of glucocorticoids have adverse effects on various health outcomes, and dysregulation of the HPA axis has been associated with many chronic pain conditions. There have been discrepant findings in research regarding enhanced versus attenuated HPA axis activity.38 Although the dysregulation cannot be accounted for entirely by psychosocial distress and somatization,40 release of hormones by the HPA axis in the face of psychosocial stress has been established, and dysregulation of the HPA axis does appear to contribute significantly to the maintenance and severity of chronic pain conditions.39,41,42

Psychophysiology is the science of understanding the link between psychology and physiology. Psychophysiology examines how psychological activities (e.g., stressful events or emotions) produce a physiologic response. Thus, in individuals with chronic pain, psychophysiology examines how exposure to a stressful situation or strong emotions produces a result expressed as the pain experience.28 Commonly used measures of psychophysiology include measures of brain activity event-related potentials, functional magnetic resonance imaging (fMRI), skin temperature, skin conductance (also known as the galvanic skin response), cardiac measures (heart rate, heart rhythm, heart rate variability), and muscle responses (electromyogram, muscle tension, and myofascial trigger points).28,43,44

Autonomic dysregulation is the main component of psychophysiology that has been investigated.34,45 Although autonomic dysregulation has not been confirmed as a causative factor in chronic pain, dysregulation with evidence of sympathetic tone has been demonstrated to be a significant mediator in the long-term maintenance and subjective severity of the pain experience in many chronic pain conditions.45,46 The results of studies examining psychoimmunity and psychophysiology, along with more recent studies using brain imaging, are not only beginning to confirm the interrelationships between physiologic and psychological factors in chronic pain but are also demonstrating the mechanisms involved in such interactions (see Chapter 12).
ASSESSMENT AND EVALUATION

To understand and appropriately treat a person whose primary symptom is pain, one must begin with a comprehensive history and physical examination. Physical examination procedures and sophisticated laboratory and imaging techniques are readily available for use in detecting organic pathology. Physical and laboratory abnormalities, however, correlate only modestly with subjective reports of pain, and it is often not possible to make any precise pathologic diagnosis or even to identify an adequate anatomic origin of the pain. Thus, adequate pain assessment also requires the use of clinical interviews, observation, and assessment tools to help evaluate the myriad psychosocial and behavioral factors that influence the subjective report.48

There is no “pain thermometer” that can provide an objective quantification of the amount or severity of pain experienced; it can be assessed only indirectly based on a patient’s description, verbally and behaviorally. Patients are usually asked to describe the characteristics (e.g., stabbing, burning), location, and severity of their pain. However, even this can make pain assessment difficult because, as outlined, pain is a complex, subjective phenomenon composed of a range of factors and is uniquely experienced by each person. Wide variability in pain severity, quality, and impact may be noted in reports of people with pain as they attempt to describe what appear to be objectively identical phenomena. Their pain descriptions are also colored by cultural and sociologic influences, as well as by previous experiences.

INTERVIEW

A list of topics that can be covered in an assessment interview is presented in Box 45.1.48 A functional assessment of the pain can also be made by asking the person about the current level of pain or pain over the past week or month, or a diary or journal can be maintained to indicate pain intensity, with ratings recorded several times daily for several days or weeks. Merely inquiring about the characteristics of the pain, though necessary, is not sufficient. Diaries or journals can provide more information than just the varying pain intensity. A clinician can use information about the pain obtained during the interview and from a patient’s writings to identify patterns in behavior, including potential antecedents and consequences of exacerbation of the pain, and treatment decisions can be facilitated by the availability of such data.

The beliefs of people with pain about the cause and trajectory of their symptoms and the availability of beneficial treatments will have important influences on coping with the pain and adhering to therapeutic interventions. Thus, when conducting an interview with a person chronically in pain, focus should be on the specific thoughts, types of behavior, emotions, and physiologic responses that precede, accompany, and follow the pain episodes or exacerbations, including environmental and temporal conditions and the consequences associated with the patient’s responses (e.g., cognitive, emotional, and behavioral, including frequency, specificity, and generality). It is important to note any patterns of maladaptive thoughts because they may contribute to a sense of hopelessness, dysphoria, and unwillingness (e.g., fears) about engaging in specific activities.

It is also important to determine expectations and goals of treatment for patients and their significant others. For example, an expectation that pain will be eliminated completely may be unrealistic and should be addressed to prevent discouragement if it does not occur. Additionally, formulating treatment goals (e.g., reduction in symptoms; reduced emotional distress; improved physical, social, and vocational functioning; reduction of inappropriate use of the health care system) is helpful in returning individuals to optimal functioning given their age, sex, education, and presence of physical impairments.

BEHAVIORAL OBSERVATION

A number of different observational procedures have been developed to quantify pain behavior.49 Behavioral checklists can identify the frequency and type of pain behavior exhibited by a person with pain. Such checklists can be self-reports or reports by others—for example, behavioral observation scales can be used by significant others, and health care providers can use observational methods to quantify various types of pain behavior systematically (e.g., observing the person in the waiting room, while being interviewed, during a structured series of physical tasks, in the presence of a significant other). Noting the type and frequency of pain behavior can provide detailed information about when someone performs pain behavior, around whom the behavior is elicited, and the responses of others to the pain behavior. It is not surprising to find that people with chronic pain tend to carry out more pain behavior around others who give them positive reinforcement of the pain behavior (e.g., providing soothing statements, physical intimacy, assistance in performing tasks). Obtaining details about factors that increase and decrease behavior (e.g., patterns) can be useful when developing treatment goals.

SELF-REPORT QUESTIONNAIRES

A number of assessment instruments designed to evaluate people’s attitudes, beliefs, and expectations about themselves,
their symptoms, and the health care system have been developed (some common assessment instruments have been described by Turk and Melzack\(^{30}\)). There are many advantages to the use of standardized instruments—they are easy to administer, require minimal time, assess a wide range of behavior, and obtain information about behavior that may be private (sexual relations) or unobservable (thoughts, emotional arousal), and most importantly, they can be submitted to analyses that permit determination of their reliability and validity. These instruments should not be viewed as alternatives to interviews; rather, they may suggest issues to be addressed in more depth during an interview or to be investigated with other measures. Additionally, they allow comparison among groups of people with pain and provide valuable information about the functional status of individuals in relation to others with the same condition. Questionnaires have been developed to assess reports of engaging in a range of functional activities, such as the ability to walk up stairs, sit for specific periods, lift specific weights, and perform activities of daily living, as well as the severity of the pain experienced when performing these activities.\(^{49,50}\)

Measures of psychosocial functioning have been developed for use specifically in people with pain to assess psychological distress, impact of pain on their lives, feeling of control, coping behavior, and attitudes about disease, pain, and health care providers and the person’s plight.\(^{49,50}\) However, these responses to pain may be distorted as a function of the disease or as a result of medications taken. For example, common measures of depression ask people about their appetites, sleep patterns, and fatigue. Because disease status and medication can affect the responses to such questions, scores may be elevated and thus distort the validity of the responses. Therefore, it is always best to corroborate information gathered from these instruments with other sources, such as personal interview, report by significant others, and chart review.

**REFERRAL FOR PSYCHOLOGICAL INTERVENTION**

The health care provider should be alert for red flags that may serve as an impetus for more thorough evaluation by a psychologist who specializes in the treatment of pain. Box 45.2 lists questions worth considering for persons who report persistent or recurring pain. Positive responses to these questions should not be viewed as sufficient to make a referral for more extensive evaluation, but when more than six or seven of them are positive, referral should be considered. These questions need not be regarded as an interview or questionnaire but should be routinely included when interacting with chronic pain patients during the course of the history and physical examination if appropriate. By the end of the evaluation, the health care provider should have elicited enough information to make a decision whether a psychological evaluation is warranted.

**THERAPEUTIC INTERVENTIONS**

A number of different clinical approaches to the treatment of chronic pain have been developed based on the models and variables described, including insight-oriented approaches, behavioral approaches, cognitive-behavioral therapy (CBT), family systems perspective, and biobehavioral interfaces. In addition, several specific techniques based on these models have been used successfully (e.g., motivational interviewing, biofeedback, relaxation, guided imagery, hypnosis, meditation) on their own or as part of more comprehensive

---

**Box 45.2 Screening Questions**

1. Has the patient’s pain persisted for 3 months or longer despite appropriate interventions and in the absence of progressive disease? [Yes]
2. Does the patient repeatedly and excessively use the health care system, persist in seeking invasive investigations or treatments after being informed that these are inappropriate, or use opioid or sedative-hypnotic medications or alcohol in a pattern of concern to the patient’s physician (e.g., escalating use)? [Yes]
3. Does the patient come in requesting specific opioid medication (e.g., hydromorphone [Dilaudid], oxycodone [OxyContin])? [Yes]
4. Does the patient have unrealistic expectations of the health care provider or the treatment offered (“total elimination of pain and related symptoms”)? [Yes]
5. Does the patient have a history of substance abuse or is he or she currently abusing mind-altering substances? [Yes]
   - Patients can be asked, “Have you ever found yourself taking more medication than was prescribed or have you used alcohol because your pain was so bad?” or “Is anyone in your family concerned about the amount of medication you take?” [Yes]
6. Does the patient display a large number of types of pain behavior that appear to be exaggerated (e.g., grimacing, rigid or guarded posture)? [Yes]
7. Does the patient have litigation pending? [Yes]
8. Is the patient seeking or receiving disability compensation? [Yes]
9. Does the patient have any other family members who have had or currently suffer from chronic pain conditions? [Yes]
10. Does the patient demonstrate excessive depression or anxiety? [Yes]
    - Straightforward questions such as “Have you been feeling down?” or “What effect does your pain have on your mood?” can clarify whether this area is in need of more detailed evaluation.
11. Can the patient identify one significant or several stressful life events before symptom onset or exacerbation? [Yes]
12. If married or living with a partner, does the patient indicate a high degree of interpersonal conflict? [Yes]
13. Has the patient given up many activities (e.g., recreation, social, familial, in addition to occupational and work activities) because of pain? [Yes]
14. Does the patient have any plans for renewed or increased activities if the pain is reduced? [No]
15. Was the patient employed before the onset of pain? [No]
    - If yes, does he or she wish to return to that job or any job? [No]
16. Does the patient believe that he or she will ever be able to resume normal life and normal functioning? [No]

*If there is a combination of more than six “yes” answers to questions 1 to 13 and “no” answers to questions 14 to 16 or if there are general concerns in any one area, consider referral for psychological assessment.*
treatment regimens. Each of these will be described briefly. Perhaps the most commonly used approach, however, is CBT, which incorporates and integrates many techniques from other approaches. Thus, more attention will be given to this general approach to patients and treatment.

INSIGHT-ORIENTED THERAPIES

Therapy based on the psychodynamic view and insight-oriented approaches are primarily focused on early relationship experiences, which are reconstructed within the context of the therapeutic relationship. The therapeutic relationship is meant to “correct” the person’s previous maladaptive experience by reintegrating emotions into symbolic and available mental processes to achieve improved emotional regulation. It is important for the person with pain and the therapist to have a supportive and trusting relationship. Although insight-oriented psychotherapy may be useful in selected individuals, this approach has rarely been shown to be effective in reducing symptoms in most persons with chronic pain. No well-designed, randomized controlled trials have been published that demonstrate the efficacy of insight-oriented psychotherapy for those with chronic pain problems.

BEHAVIORAL APPROACHES

RESPONDENT CONDITIONING

If a nociceptive stimulus is repeatedly paired with a neutral stimulus in close temporal proximity, the neutral stimulus will come to elicit a pain response. This is referred to as classical, respondent, or pavlovian conditioning. In chronic pain, many activities that were neutral or even pleasurable may come to elicit or exacerbate pain and are thus experienced as aversive and actively avoided. Over time, a growing number of stimuli (e.g., activities and exercises) may be expected to elicit or exacerbate pain and will be avoided, a process termed stimulus generalization. The anticipatory fear of pain and restriction of activity—and not just the actual nociception—may contribute to disability. Anticipatory fear can also elicit a physiologic reaction that may aggravate the pain. Thus, conditioning may directly increase nociceptive stimulation and pain.

As long as avoidance of activity succeeds in preventing initiation or exacerbation of the pain, the conviction of pain sufferers that they must remain inactive is difficult to modify. Treatment of pain via the classical conditioning model involves repeated exposure to feared or avoided activities that result in less pain than the patient may have predicted (i.e., corrective feedback). In this way patients’ anticipatory fear of the activity is reduced or extinguished. Such transformations add support to the importance of quota-based physical exercise programs, with participants progressively increasing their activity levels despite fear of injury and discomfort associated with the use of deconditioned muscles.

OPERANT APPROACH

Operant approaches focus on extinction of pain behavior by withdrawal of positive attention from pain behavior and increasing well behavior by positive reinforcement. As noted, the operant learning paradigm does not seek to uncover the cause of the pain but focuses primarily on maintenance of the pain behavior and deficiency of well behavior. Target pain behavior is identified, as are its controlling antecedents and consequent reinforcers or punishments, such as overly solicitous, distracting, or ignoring behavior by a spouse.

Removal of the contingent relationship between overt pain behavior and its positive or negative consequences, along with positive and negative reinforcement, is used to increase and maintain the desired behavior and decrease pain-compatible behavior (e.g., with operant behavioral treatment) because patients are expected to be active in setting treatment goals and following through with recommendations. The efficacy of operant treatment has been demonstrated in several studies of persons with chronic pain disorders, including low back pain and fibromyalgia syndrome.

COGNITIVE-BEHAVIORAL THERAPY

As noted, it is important to make a distinction between the CB perspective and cognitive and behavioral techniques. The CB perspective is based on the idea that people believe that they cannot function because of their pain and that they are helpless to improve their situation. Treatment goals thus focus on helping patients with pain realize that they can manage problems and on providing the skills to respond in more adaptive ways that can be maintained after the treatment has ended. These techniques include those described earlier and more specific interventions, as noted here.

The CBT approach combines cognitive and behavioral techniques, including assertiveness, stress management, relaxation training, goal setting, guided imagery, and pacing of activities. Biofeedback, meditation, and hypnosis can all be incorporated within the framework of CBT. Therapists assist patients with concerns about the future, returning to work, and physical limitations; they help people build their communication skills, gain a sense of control over their pain, and cope with fear of pain and reinjury and with frustration resulting from the responses of others (e.g., physicians, insurance companies, employers, family, significant others) to the patient’s pain reports or behavior. Individuals are educated in developing positive coping strategies.
and are encouraged to increase their activities in a graded fashion. It is expected that they will gain mastery over their pain, which will then result in improved mood and foster self-confidence.22,29,55

Four key components of CBT have been described22,29—the education, skills acquisition, skills consolidation, and generalization and maintenance. The education component consists of helping the patient challenge negative perceptions regarding his or her ability to manage pain through a process termed cognitive restructuring by making the person aware of the role of thoughts and emotions in potentiating and maintaining stress and physical symptoms. Steps in cognitive restructuring include identifying maladaptive thoughts during problematic situations (e.g., during pain exacerbations, stressful events), introduction and practice of coping thoughts, shifting from self-defeating to coping thoughts, introduction and practice of positive or reinforcing thoughts, and finally home practice and follow-up. Using these steps, the therapist encourages patients to test the adaptiveness (not the so-called rationality) of thoughts, beliefs, expectations, and predictions. The crucial element in successful treatment is bringing about a shift from well-established, habitual, and automatic but ineffective responses to systematic problem solving and planning, control of affect, behavioral persistence, and disengagement, when appropriate.22,29

The goal of skills acquisition and consolidation is to help patients learn skills for new pain management behavior and cognition, including training in relaxation, problem solving, distraction, activity pacing, and communication. Using role-playing techniques and homework assignments, patients can practice emerging skill sets and evaluate their usefulness for the management of their pain.

Finally, generalization and maintenance are aimed at solidifying skills and preventing relapse. Problems that arise throughout treatment are viewed as opportunities to assist patients in learning how to handle any setbacks and lapses that may occur following treatment. During this phase they can learn how to anticipate future problems and high-risk situations so that they can think about and practice the behavioral responses that may be necessary for successful coping. The goal of this phase is to enable patients to develop a problem-solving perspective in which they believe that they have the skills and competency to respond appropriately to problems as they arise. In this manner, attempts are made to help the patient learn to anticipate future difficulties, develop plans for adaptive responding, and adjust behavior accordingly.

Recently, some variations in CBT have been proposed. Acceptance-based approaches use a series of exercises to teach patients to be more mindful and less judgmental about their experience and to focus on achieving valued goals.56,57 However, the specific techniques used and mediating variables targeted by CBT interventions may turn out to be less important than the overall objective of helping patients change their view of themselves as being helpless, passive, and dependent to a view of themselves as active agents who are resourceful and capable of self-managing their symptoms and their lives.29

The efficacy of CBT has been demonstrated in a large number of studies of chronic pain disorders and has been reviewed extensively.26,58,60 Evidence suggests that individual and group CBT can help restore function and mood, as well as reduce pain and disability-related behavior.26,54 Despite the fact that CBT is undoubtedly the intervention used most often for those with chronic pain, it has limitations. For example, although CBT has been found to be helpful for a number of individuals, there are some for whom CBT is not beneficial. Researchers are just beginning to explore different aspects of CBT to answer the question, “what works for whom?”61-63

Some specific techniques can be incorporated into CBT when treating chronic pain patients. The specific details involved in these techniques may be less important than the primary objective. Each technique described is designed to help patients feel a sense of control; a common feature is their ability to combat the feelings of helplessness and demoralization experienced by many of those with chronic pain.22

**MOTIVATIONAL INTERVIEWING**

Most people with chronic pain adhere to a biomedical model; for example, the nature of their symptoms is closely aligned with physical pathology. As the pain persists, some people may become aware of the role of factors such as emotional stress in their experience of pain. They may begin to consider that they can learn and use self-management techniques to help them adapt to life with a chronic pain condition. Others with chronic pain, however, have difficulty with this expanded perspective. The stage of acceptance of self-management is important because those who are not ready for the use of psychological techniques will tend to avoid and dismiss such methods. Thus, the clinician needs to be aware of an individual’s readiness to accept and undertake the steps necessary to achieve self-management. The assessment process described earlier should help the health care provider determine the patient’s readiness for the use of nonphysical approaches.

Motivational interviewing as a treatment intervention was initially developed for those with substance abuse disorders,55 although it has been used increasingly for chronic pain patients.64 Specific stages of change have been postulated, and interventional techniques are tailored to each stage.

In the precontemplation stage, patients with chronic pain have not yet begun to consider changing from a purely somatic view of pain and have adopted a passive role as they wait for the health care provider to identify and provide appropriate treatment. The clinician attempts to assist the person by fostering acknowledgment of risks and problems resulting from inactivity, such as increased pain and physical deconditioning.65

Once patients with chronic pain take responsibility for their prior inactivity, they enter the next of the proposed stages, the contemplation stage. Here, the clinical goal is to encourage the patient to conclude that the risks associated with inactivity outweigh the perceived benefits. When they are ready to become more active (the preparation stage), the clinician helps outline appropriate structured physical activities in which the patient is willing to participate. Finally, in the action stage, the clinician helps the patient increase activity levels. This is followed by maintenance geared toward the individual’s ongoing motivation and commitment.66
It is important for physicians to be tolerant as patients move through these stages. Clinicians can encourage transition to different stages by providing motivational statements, listening with empathy, asking open-ended questions, providing feedback and affirmation, and handling resistance.\(^55,65\) Because motivational interviewing has been applied to chronic pain only rather recently,\(^65\) the efficacy of this intervention in different chronic pain populations is not yet well documented. Motivational interviewing is a general framework for preparing persons for treatment and for adherence to the CB perspective and can be readily used with CBT.

**BIOFEEDBACK**

Developed in the 1960s, biofeedback is a self-regulation technique that has been used successfully to treat a number of chronic pain states, such as headache, back pain, chronic myofascial pain, and irritable bowel syndrome.\(^66,67\) The objective of biofeedback is to teach people to exert control over their physiologic processes. During biofeedback, the patient is connected by electrodes to equipment linked to a computer that records physiologic responses. These processes may include skin conductance, respiration, heart rate, heart rate variability, skin temperature, brain wave activity, and muscle tension. The recording equipment amplifies and converts the readings into visual or auditory signals on a monitor that the patient can observe. In this way, the information recorded is “fed back” to the person, which potentially helps the individual learn to change physiologic responses by manipulating the auditory or visual signals.

Important forms of biofeedback therapy include electromyographic biofeedback, in which patients (e.g., those with tension headaches) are provided with information fed back to them from the physiologic recordings and taught to manipulate the tension in their frontalis muscle. Patients with migraine are provided with thermal feedback. They are instructed to warm the temperature of their hands by using visual or auditory cues.\(^29\) Alternatively, patients may be given biofeedback associated with heart rate variability, which has been shown to be associated with pain perception.\(^68,69\)

Real-time fMRI has been used as a sophisticated source of biofeedback to help train participants to control activation in the rostral anterior cingulate cortex (rACC) and has shown promising results. This brain region is reputedly involved in pain perception and regulation. When the participants deliberately induced changes in the rACC, there was a corresponding change in their perception of the pain.\(^70\)

With practice, most people can learn to control voluntarily important physiologic functions that may be associated directly with pain and stress.\(^71\) Biofeedback generates a state of general relaxation. Typically, patients being treated with biofeedback will be instructed to practice using the methods that have been successful in altering physiologic parameters in the clinic.

The actual mechanisms involved in the success of biofeedback are still unknown. However, the assumption of biofeedback treatment is that the level of pain is maintained or exacerbated by dysregulation of the autonomic nervous system, which is believed to be associated with the production of nociceptive stimulation (e.g., muscle tension in a person with low back pain). In addition to the physiologic changes accompanying biofeedback, patients are provided with a sense of control over their bodies. Given the high levels of helplessness observed in those with chronic pain problems, the perception of control may be as important as the actual physiologic changes observed. A general sense of relaxation is also an important feature of biofeedback. Again, it is not clear whether the alterations in specific physiologic parameters putatively associated with pain are the most important component of biofeedback or whether it is the broader relaxation and self-control created.

There are many relaxation techniques that have been used in combination with biofeedback and on their own. However, reports are mixed about whether biofeedback is any more effective than relaxation. The pain condition being treated may differ in regard to the greatest contribution of a possible component (relaxation, sense of control, general relaxation). Moreover, the components may not be mutually exclusive and may even be synergistic.

**MEDITATION**

Meditation is a 2500-year-old practice that has become a popular mental exercise. It is defined as the “intentional self-regulation of attention,” a systematic inner focus on particular aspects of inner and outer experience.\(^72,73\) Unlike many approaches in behavioral medicine, such as biofeedback, meditation was developed in a religious or spiritual context. It is regarded as the ultimate goal of spiritual growth in that it can end suffering, enable personal transformation, and provide a transcendental experience.\(^74\) However, as a health care intervention, it has been taught effectively, regardless of the individual’s cultural or religious background.\(^75,76\)

Many forms of meditation are practiced worldwide. Here, two general approaches are described that have been researched extensively: transcendental meditation and Zen or mindfulness meditation.\(^77\) Transcendental meditation is concentrative in that it involves focus on one of the senses, like a zoom lens focusing on a specific object. For example, the individual repeats a silent word or phrase (mantra) with the goal of transcending the ordinary stream of mental discourse.\(^74,76\) Mindfulness meditation is the opposite of transcendental meditation in that its goal is awareness of the whole perceptual field, like a wide-angle lens. Thus, it incorporates focused attention and whole-field awareness in the present moment. For example, the individual simply observes without judgment, thoughts, emotions, sensations, and perceptions as they arise moment by moment.\(^75,79\) Bonadonna\(^80\) has proposed that those with chronic illness have an altered ability to concentrate; therefore, transcendental meditation may be less useful than mindfulness meditation.

Mindfulness meditation reframes the experience of discomfort such that physical pain, malaise, or suffering becomes the object of meditation. The attention and awareness of discomfort or suffering are another part of human experience; rather than being avoided, which is the most common reaction, it is to be investigated, experienced, and explored.\(^80\) This form of meditation was incorporated into behavioral medicine in the 1980s\(^79\) and has been used successfully as an adjunctive intervention for health conditions such as fibromyalgia, psoriasis, and cancer pain. Studies have found that mindfulness-based interventions decrease pain symptoms, increase healing speed, improve mood,
reduce stress, contain health care costs, and decrease visits to primary care facilities.\textsuperscript{73,74,81} 

Meditation has captured the attention of medicine, behavioral medicine, psychology, and neurocognitive science, partly because experienced meditators demonstrate calmer responses to daily stress and perform better at tasks that require focused attention. Many believe that meditation can confer health benefits.\textsuperscript{82,83} Lazar and associates\textsuperscript{82} found that long-term meditation by Western practitioners who were not monks results in increased cortical thickness in areas related to somatosensory, auditory, visual, and interoceptive processing. They found thickening in the right Brodmann areas 9 and 10, which have been shown to be involved in the integration of cognition and emotion. A hypothesis based on this structural change is that by becoming increasingly aware of sensory stimuli during practice, the practitioner is gradually able to use self-awareness to navigate potentially stressful encounters more successfully. This may be useful for those experiencing chronic pain because of the reciprocal relationship between stress and pain symptoms.

Additionally, Lutz and coworkers\textsuperscript{83} observed that Buddhist practitioners at baseline and while in a state of unconditional loving kindness and compassion while meditating have higher self-induced gamma-wave synchrony than do controls. Gamma-wave activity is the synchrony of areas of the brain communicating with each other. This also suggests how meditation may be beneficial for people with chronic pain because of dysregulation within the HPA axis and autonomic nervous system. Furthermore, meditators have demonstrated changes in electroencephalographic activity; specifically, they have higher alpha brain wave activity. This has been found to have beneficial health effects and to promote a general sense of well-being.\textsuperscript{84,86}

**GUIDED IMAGERY**

Guided imagery can be useful for helping people with pain relax, achieve a sense of control, and distract themselves from pain and the accompanying symptoms. This modality involves the generation of mental images by oneself or the practitioner. Thus, it overlaps with the available relaxation techniques and hypnosis. Although guided imagery has been advocated as a stand-alone intervention to reduce presurgical anxiety and postsurgical pain and accelerate healing,\textsuperscript{87} it is most often used in conjunction with other treatment interventions, such as CBT or relaxation.\textsuperscript{22,28}

With guided imagery using visualization or imagination, patients are asked to evoke specific images that they find pleasant and engaging. In this way, a detailed representation tailored to the individual can then be created. When the person with chronic pain is feeling pain or is experiencing an exacerbation of pain, he or she can use imagery to help redirect attention away from the pain and achieve a psychophysiologic state of relaxation.

Images can be sensory or affective; however, the most successful images tend to be those that involve all the senses (vision, sound, touch, smell, and taste). People with chronic pain are thus encouraged to use images that evoke these senses. Some patients, however, may have difficulty generating a particularly vivid visual image and may find it helpful to listen to a taped description or look at a poster on which they can focus their attention as a way of assisting their imagination.

**HYPNOSIS**

Hypnosis has been defined as a “natural state of aroused attentive focal concentration coupled with a relative suspension of peripheral awareness.” There are three central components of a hypnotic trance: (1) absorption, or intense involvement in the central object of concentration; (2) dissociation, in which experiences that would commonly be felt consciously occur outside of conscious awareness (i.e., the converse of meditation); and (3) suggestibility, in which persons are more likely to accept outside input without cognitive censorship or criticism.\textsuperscript{88}

Hypnosis has been used as a treatment intervention for pain control since at least the 1850s. It has been shown to be beneficial in relieving pain in people with headache, burn injury, arthritis, cancer, and chronic back pain.\textsuperscript{89-91} As with imagery, relaxation, and biofeedback, hypnosis is infrequently used alone for chronic pain; although it has been used as a psychological model with some success in cancer patients,\textsuperscript{92} it is often used concurrently with other treatment interventions. Hypnotic suggestions have been used to instill positive attitudes in people, facilitate compliance with treatment, foster distraction from negative thoughts or stimuli, alleviate anxiety related to medical procedures, reduce reliance on medication, and promote relaxation and rehearsal of adaptive behavior.\textsuperscript{91,93}

A meta-analysis\textsuperscript{91} has suggested an overall benefit of the addition of hypnosis to nonhypnotic pain management strategies, although this may be affected by the level of hypnotic suggestibility. Furthermore, there are discrepancies in the literature with regard to the methods used to induce hypnosis, thus making it difficult to evaluate the efficacy of this intervention accurately.\textsuperscript{92} Finally, based on systematic reviews, Patterson and Jensen\textsuperscript{89,90} suggested that hypnosis has more usefulness for the treatment of acute pain than chronic pain. Thus, the degree to which hypnosis is helpful beyond the effectiveness of other interventions and for which populations it is useful remain to be elucidated.

I have only briefly described the range of psychological approaches and techniques that have been used in chronic pain patients. Some illustrative studies have been highlighted and reference made to systematic reviews and meta-analyses; the reader may wish to consult these sources to learn more about these approaches. These methods can readily be integrated into more comprehensive rehabilitation programs. They can be useful complements to physical therapy, medication management, and vocational rehabilitation by helping patients become active participants in their own care when pain flares up, as well as being a routine part of a self-management program. Using these techniques, the patient may feel more hopeful rather than helpless and dependent.

**INTERDISCIPLINARY PAIN REHABILITATION PROGRAMS**

Psychological approaches and techniques have found strong support in the literature when used on their own. However, interdisciplinary pain rehabilitation programs (IPRPs) are also efficacious because the CB perspective and cognitive and behavioral techniques are often important components of these programs\textsuperscript{26,58-60} and have been recommended...
A person experiencing chronic pain is continually in quest of relief that often remains elusive, which leads to feelings of helplessness, hopelessness, demoralization, and outright depression. Emotional distress may be attributed to various factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disability, financial difficulties, litigation, disruption of usual activities, inadequate social support, and sleep disturbances. Thus, chronic pain represents a demoralizing situation; the individual with pain not only faces the stress created by the pain but also experiences a cascade of ongoing stressors that compromise all aspects of life. Living with chronic pain requires considerable emotional resilience, tends to deplete emotional reserve, and taxes not only the pain sufferer but also the capability of family members and significant others to provide support.

A large body of evidence demonstrates that psychological factors can interfere with or hinder a person’s ability to cope with the pain experience. As a result, psychological intervention in the assessment and treatment of chronic pain is becoming standard practice. Psychological treatment can focus on the emotional distress that accompanies chronic pain and provide education and training in the use of cognitive and behavioral techniques, which may reduce perceptions of pain and related disability. Psychologists and psychological principles have played a major role in understanding and treating people with pain, and psychologists have an important function in IPRPs as clinicians and researchers.

None of the treatments described are successful in eliminating pain completely; the same statement can be made in reference to the most commonly used pharmacologic, medical, and surgical interventions. Consequently, most people have to adapt to the presence of chronic pain and learn self-management in the face of persistent pain and accompanying symptoms. The psychological interventions described in this chapter provide a general overview of various treatment strategies. By far, however, treatment with CBT alone or within the context of an IPRP holds the greatest empirical evidence for success. There is a substantial and overwhelming body of research supporting the effectiveness of various psychological approaches. It therefore seems prudent to consider the use of psychological treatment in conjunction with traditional medical interventions.

Currently, few data are available that consistently identify the characteristics of those who would most likely benefit from the pain treatment methods described in this chapter, although some studies have suggested that individualized treatment is associated with more relief of symptoms than standard treatment is. Further studies are needed to determine which treatments—and how they should be delivered—are most effective for patients with certain characteristics and result in the fewest iatrogenic complications and adverse events.

Positive results will permit more clinically effective and cost-effective ways to treat the difficult population of patients with chronic pain.

**KEY POINTS**

- Pain is a complex, subjective experience with psychosocial and behavioral as well as biologic contributors.
- The biologic treatments currently available are inadequate, and significant levels of pain persist despite the most advanced pharmaceutical, anesthetic, and surgical treatments.
- Persistent pain has an impact on all aspects of individuals’ lives.
- People with chronic pain are demoralized because their bodies and the health care system have let them down.
- The presence of chronic pain affects not only patients but also their significant others, health care providers, employers, and third-party payers.
- There is wide individual variation in the experience of chronic pain, styles of coping and adaptation, and response to treatment.

**CONCLUSION**

A large body of evidence demonstrates that psychological factors can interfere with or hinder a person’s ability to cope with the pain experience. As a result, psychological intervention in the assessment and treatment of chronic pain is becoming standard practice. Psychological treatment can focus on the emotional distress that accompanies chronic pain and provide education and training in the use of cognitive and behavioral techniques, which may reduce perceptions of pain and related disability. Psychologists and psychological principles have played a major role in understanding and treating people with pain, and psychologists have an important function in IPRPs as clinicians and researchers.

None of the treatments described are successful in eliminating pain completely; the same statement can be made in reference to the most commonly used pharmacologic, medical, and surgical interventions. Consequently, most people have to adapt to the presence of chronic pain and learn self-management in the face of persistent pain and accompanying symptoms. The psychological interventions described in this chapter provide a general overview of various treatment strategies. By far, however, treatment with CBT alone or within the context of an IPRP holds the greatest empirical evidence for success. There is a substantial and overwhelming body of research supporting the effectiveness of various psychological approaches. It therefore seems prudent to consider the use of psychological treatment in conjunction with traditional medical interventions.

Currently, few data are available that consistently identify the characteristics of those who would most likely benefit from the pain treatment methods described in this chapter, although some studies have suggested that individualized treatment is associated with more relief of symptoms than standard treatment is. Further studies are needed to determine which treatments—and how they should be delivered—are most effective for patients with certain characteristics and result in the fewest iatrogenic complications and adverse events. Positive results will permit more clinically effective and cost-effective ways to treat the difficult population of patients with chronic pain.

**KEY POINTS**

- Pain is a complex, subjective experience with psychosocial and behavioral as well as biologic contributors.
- The biologic treatments currently available are inadequate, and significant levels of pain persist despite the most advanced pharmaceutical, anesthetic, and surgical treatments.
- Persistent pain has an impact on all aspects of individuals’ lives.
- People with chronic pain are demoralized because their bodies and the health care system have let them down.
- The presence of chronic pain affects not only patients but also their significant others, health care providers, employers, and third-party payers.
- There is wide individual variation in the experience of chronic pain, styles of coping and adaptation, and response to treatment.

**CONCLUSION**

A person experiencing chronic pain is continually in quest of relief that often remains elusive, which leads to feelings of helplessness, hopelessness, demoralization, and outright depression. Emotional distress may be attributed to various factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disability, financial difficulties, litigation, disruption of usual activities, inadequate social support, and sleep disturbances. Thus, chronic pain represents a demoralizing situation; the individual with pain not only faces the stress created by the pain but also experiences a cascade of ongoing stressors that compromise all aspects of life. Living with chronic pain requires considerable emotional resilience, tends to deplete emotional reserve, and taxes not only the pain sufferer but also the capability of family members and significant others to provide support.
**KEY POINTS—cont’d**

- Environmental factors (e.g., attention by significant others, including health care providers) can reinforce behavioral responses by patients.
- Patients’ beliefs, attitudes, and expectations influence the experience of pain, disability, and treatment response.
- A comprehensive approach to assessment of patients with chronic pain that addresses the medical, psychological, and environmental contributors is necessary to develop an optimal treatment plan.
- The cognitive-behavioral perspective makes several assumptions about patients: (1) they are active processors of information and not passive responders; (2) thoughts, mood, behavior, and physiology are interdependent and interactive; (3) patient behavior is influenced by both personal and environmental factors; (4) patients can learn more adaptive ways of thinking, feeling, and behaving in response to persistent pain; and (5) patients should be actively involved as agents in changing their thoughts, feelings, and behavior, and this may in turn have an impact on the physiologic factors associated with persistence and magnitude of the pain.
- Since there is no cure for chronic pain, patients need to learn to accept their own role in self-management of their pain and their lives.
- A number of behavioral (e.g., relaxation, biofeedback) and cognitive (e.g., problem solving, meditation) modalities that may be helpful to patients can be taught and learned as complements to traditional medical treatments.
- Interdisciplinary pain rehabilitation programs that integrate psychological and physical treatments have been demonstrated to provide benefits to patients with recalcitrant chronic pain.
- Research is needed to identify the best treatment combination for patients with different physical and psychosocial characteristics.

REFERENCES

This chapter focuses on the physical medicine techniques used to treat patients in pain. At the conclusion of reading this chapter the reader will have a thorough understanding of physical medicine techniques and how they fit into the multidisciplinary comprehensive treatment of patients with pain. Although the physical medicine approach can help decrease pain and increase function, if combined with medication, behavioral modification, cognitive modification, and sometimes interventions, the results can be much more dramatic.

In the third edition of this text, Linchitz and Sorell defined physical medicine and rehabilitation and the role of the physiatrist. They noted that “Physical medicine and rehabilitation have traditionally been the medical specialty that oversees and prescribes the application of physical modalities to treat disease and disorders, including the rehabilitation of patients with pain. The physiatrist, whose primary perspective is typically one of the functions, is an expert on the musculoskeletal and locomotor systems and is knowledgeable about how to use physical agents and how to coordinate the rehabilitation team. As part of the multidisciplinary medical team, the physiatrist participates in the evaluation and treatment of those individuals with pain.”

However, there are not enough physiatrists to treat all patients with pain. Therefore, all physicians need to understand the rationale, indications, contraindications, and prescription of physical medicine techniques and their appropriate use. Many of these techniques can be used for acute, subacute, and chronic pain. However, with progression to more chronic pain, techniques should be more active and less passive and more behavioral and cognitive in nature. Although many of these techniques will help decrease pain, the long-term goal should be to increase function despite the presence of the pain syndrome.

APPROACH TO TREATMENT

Patients with pain can be evaluated and treated by individual physicians and therapists. This type of approach is more often used and successful in patients with acute or subacute pain. However, as the pain becomes more chronic and includes psychosocial and vocational issues, a multidisciplinary or interdisciplinary approach is recommended.

Although the terms multidisciplinary and interdisciplinary are often used interchangeably, multidisciplinary more formally refers to collaboration among members of different disciplines (including various medical specialists and therapists), managed by a leader who directs a range of ancillary services. Interdisciplinary describes a deeper level of consensus-based collaboration in which the entire process (i.e., evaluation, goal setting, and delivery of treatment) is orchestrated by the team, facilitated by regular face-to-face meetings, and primarily delivered at a single facility. The interdisciplinary team is commonly led by a pain specialist and includes physical and occupational therapists; pain psychologists; relaxation training experts; vocational, rehabilitation, and therapeutic recreational specialists; social workers; and nurse educators. The role of these team members is discussed later in this chapter.

It should be noted that comprehensive reviews of the cost-effectiveness and efficacy of interdisciplinary programs have demonstrated significant improvements in return to work, increased function, reduced health care use, and closure of disability claims. These comprehensive programs have also shown clear benefits over conventional management with regard to decreasing pain behavior and improving mood. The interdisciplinary model provides ongoing communication among all members of the treatment team, which helps facilitate patients’ care while they progress to behavioral, cognitive, and active therapy.

ROLE OF THE THERAPY TEAM

Ideally, a pain program should be comprehensive and interdisciplinary. Typically, the team is led by a physician and consists of physical therapists, occupational therapists, and often recreational therapists, dieticians, and psychologists. Combined assessment by these professionals is used to devise a comprehensive approach to allow the patient to benefit maximally, reintegrate fully into life, and have as few restrictions as possible.

It is important that realistic goals be set before therapy begins. Such goals include but should not be limited to decreasing muscle tightness, increasing strength in areas of muscle weakness, increasing general aerobic conditioning, and improving ease in performance of activities of daily living. In general, one wants to first restore flexibility and then increase strength and develop endurance. Completely removing the pain may not be a realistic goal of therapy, but increased function should be. Box 46.1 lists the goals of therapy to be accomplished.
Sometimes, the distinction between physical and occupational therapists is lost. Physical therapists focus on the strength, flexibility, and coordination of large muscle groups. They assess and help in developing strength and flexibility of the legs, pelvic girdle, and trunk and address mobility by ambulation. They also train patients in back and body mechanics. Occupational therapists focus on fine and gross motor strength, flexibility and coordination of the hands, and activities of daily living. For pain patients, they are also good in teaching conservation techniques. They can help patients in their work by instructing them in ergonomics, work simplification, and energy conservation. Another important aspect that they address is proper posture, which can result in a significant reduction in pain if put into practice daily. The roles of physical and occupational therapists are presented in Box 46.2.

Recreational therapists assist in providing pleasurable outlets to help maintain physical conditioning. Instead of prescribing a boring set of home exercises, incorporating pleasurable activities that are also distracting often increases the patient’s interest and cooperation. The psychologist’s role is to identify factors that may be complicating the pain experience and help the patient deal with the process in a better way. There are many useful tools and tests to help the psychologist determine other confounding factors so that the patient’s functioning can be increased maximally. These include the Minnesota Multiphasic Personality Inventory, Beck Depression Inventory, Oswestry scale, Symptom Checklist 90, and McGill Pain Questionnaire. The psychologist, working alone or with the team, can encourage pain reduction by teaching the patient stress management, relaxation, and self-monitoring techniques. Stress reduction can be achieved through cognitive-behavioral therapy.

The physician’s role is mainly to lead the team in complete management of the patient. This includes making sure that there is no disease process that might be causing the pain and, if present, that there is no other treatment or intervention that should be pursued before initiating therapies. It also includes monitoring safe participation in physical rehabilitation while optimizing medication management. If it is thought that the patient could benefit from interventions, it is easier if this is done before initiating a comprehensive rehabilitation program.

Physical conditioning programs use a cognitive-behavioral approach plus intensive physical training that includes aerobic capacity, muscle strength and endurance, and coordination. These approaches can be work related, given and supervised by a physiotherapist or multidisciplinary team, and seem to be effective in reducing the number of sick days for some with chronic back pain when compared with usual care.

### Box 46.1 Goals of Therapy
- Restore biomechanical dysfunction.
- Improve strength.
- Improve posture.
- Improve gait symmetry.
- Improve general aerobic conditioning.
- Improve efficiency of activities of daily living.
- Decrease edema.
- Instruct patients to monitor pain response and to pace activity.
- Use back or joint conservation techniques.

### Box 46.2 Role of Physical Therapists and Occupational Therapists

**Physical Therapists**
- Loss of flexibility
- Strength and weakness of trunk and limb muscles
- Core strengthening
- General aerobic conditioning
- Balance and coordination
- Contractures
- Assisted mobility

**Occupational Therapists**
- Joint conservation techniques
- Work simplification techniques
- Back conservation
- Posture
- Energy conservation techniques
- Activities of daily living and self-care
- Edema control

### BASIC MANAGEMENT CONSIDERATIONS

#### CLINICAL EVALUATION

Patients with acute or chronic pain may be referred for physical medicine evaluation and treatment as a component of a multidisciplinary management approach or for certain specific treatments. Before initiating treatment, it is important to perform a history and physical examination (Chapter 13), review the medical records to identify factors contributing to the patient’s complaints, and assess the impact of pain on the patient’s functioning. Contraindications to physical medicine treatments and precautions for treatment should be identified. A careful and thorough history and physical examination also help establish trust between the clinician and patient and facilitate consensus with treatment recommendations.

#### HISTORY

A detailed history is obtained by interviewing the patient and reviewing questionnaires and medical records. It is important to obtain information about the time course, intensity, and location of the pain, as well as relieving and exacerbating factors. The functional state of the patient before onset of the problem and the current functional level should be determined to establish a baseline and guide expectations for improvement. The patient’s experiences and responses to previous diagnostic and therapeutic interventions should be noted because they may predict responses to future treatment. Medical conditions that can affect or be affected by physical medicine treatments should be identified. It is also important to obtain information on medications, coexisting psychological and psychiatric disorders, substance abuse or
addiction, and involvement in litigation because these factors can affect the patient’s response to treatment.

**PHYSICAL EXAMINATION**

A complete physical examination with a focus on the neurologic and musculoskeletal systems should be performed. Active and passive joint range of motion (ROM), muscle bulk, strength, and sensation should be assessed and documented. Findings in the involved area should be compared with those on the asymptomatic side when possible. Patterns of pain and sensory loss can provide clues to the site of nervous system pathology or dysfunction. Signs of vasomotor instability, such as changes in skin temperature and alterations in hair, nails, or perspiration, may indicate autonomic dysfunction. Pain may limit testing of ROM, strength, and sensation; if this is the case, it should be noted. Reflex testing can be particularly helpful because it is one of the more objective parts of the examination. Abnormal or asymmetrical reflex responses may indicate dysfunction or pathology of the nervous system. Evidence of previous surgery or injury should be noted.

A patient’s gait, posture, and movement can provide diagnostic clues to the source and severity of the pain. It is helpful to observe the patient and form a general impression before carrying out the formal physical examination. Inconsistencies between the patient’s complaints and behavior should be noted.

**FUNCTIONAL EVALUATION**

A functional evaluation should be performed on pain patients before, during, and after completion of any treatment or functional restoration program. Functional evaluation may range from direct observation of function by the clinician to formal functional capacity evaluation (FCE) performed by trained health care personnel.

Functional assessment can provide additional useful information because tests of pain perception, psychological distress, and self-perception of abilities and limitations do not accurately assess a person’s physical capacity for work. Physicians and patients often have great difficulty estimating functional limitation and physical ability. Functional capacity evaluations (FCEs) have existed in one form or another since the 1940s, although their use and application have changed over time. They are primarily used in industrial medicine and in legal and disability settings. Reasons for ordering an FCE include making disability determinations, setting goals and planning treatment for industrial rehabilitation, monitoring progress through industrial rehabilitation, determining a person’s readiness to return to work after injury, performing pre-employment evaluation, and determining case closure.

Most FCE protocols include some or most of the following components: an interview, record review, self-administered questionnaire, psychological test battery, musculoskeletal evaluation, functional testing, validation of sincerity of effort, and comparisons to specific job requirements. Functional testing may include material handling, specific tasks, holding static postures, and repetitive task performance. A job analysis should be done before administration of an FCE because measurement of work capacity is specific to the demands posed by a job.

There are scientific and practical limitations associated with FCEs with regard to standardization, validity, and reliability. They have not necessarily been shown to predict return to work. However, they may be helpful in charting changes in function, comparing functional disparities with job demands, identifying nonmedical factors influencing the ability to work, and serving as a tool to guide work restrictions for patients returning to work or for initial therapy prescriptions for patients beginning a rehabilitation program.

**PSYCHOLOGICAL EVALUATION**

A psychological evaluation should be considered when the pain is resulting in significant impairment in psychological, vocational, or social functioning. Such evaluations can determine the emotional, cognitive, behavioral, social, or vocational factors that could be affecting the patient’s perception of pain.

It is important that the psychological evaluation of a patient in chronic pain be conducted by a clinician who is sensitive to and knowledgeable about the psychological aspects of chronic pain. It should be appreciated that many chronic pain patients may be defensive about a psychological referral and are more likely to be evaluated if they are provided with an appropriate rationale and explanation for the referral. This topic is discussed further in Chapter 16.

**ELECTRODIAGNOSTIC TESTING**

Electrodiagnostic testing encompasses nerve conduction studies (NCSs) and electromyography (EMG), which provide information about the peripheral nerves and muscles, and evoked potentials, which are used mainly to assess the central nervous system. Chapter 14 presents a more detailed discussion of the role of electrodiagnostic testing.

Electrodiagnosis can play an important role in identifying an underlying problem in a patient with a pain disorder. It helps not only in diagnosis but also in determining the
chronicity and severity of the condition and can even assist in prognosis. Electrodagnostic testing has another advantage when dealing with a patient who has signs of radiculopathy. Because disk bulges seen with magnetic resonance imaging (MRI) may be found routinely at many levels, EMG can help determine whether one of these disk bulges is actually producing nerve damage. However, it has also been shown that the findings on EMG do not necessarily correlate with severity of the pain.

Most physicians will perform NCSs and EMG together in the same session. The NCSs usually involve testing of sensory and motor nerves and sometimes reflex studies. Common nerves studied in the lower extremity include the sural, tibial, and deep peroneal and, in the upper extremity, the median, ulnar, and radial nerves. The facial and trigeminal nerves are studied in the lower extremity and deep peroneal, and, in the upper extremity, the median, ulnar, and radial nerves. The facial and trigeminal nerves are tested less often.

When performing a motor NCS, the active electrode is placed over the muscle belly, the reference electrode is placed over the tendon insertion, and the nerve is stimulated at a fixed distance from the muscle. F-wave responses can also be recorded during motor studies; they can indicate the integrity of the entire motor nerve.

When performing a sensory NCS (usually done antidromically), the active and reference electrodes are placed over a distal nerve segment and the nerve is stimulated proximally (Fig. 46.2). The EMG study can be done with concentric or monopolar needles. There are two parts of EMG—evaluation of spontaneous activity and evaluation of motor unit action potentials (MUAPs). Typically, in neurogenic conditions the electromyographer will notice fibrillation potentials or positive sharp waves (PSWs) with spontaneous activity, which indicates instability of the muscle fiber membrane, enlarged MUAPs, and decreased MUAP recruitment.

**RADICULOPATHY**

The sensitivity of EMG in the diagnosis of radiculopathy is lower than that of MRI, but its specificity is significantly better. EMG helps identify not only which nerve is involved but also the severity and chronicity of the lesion. It is important to remember that in radiculopathy, sensory NCS findings are normal because compression of the nerve root usually occurs proximal to the dorsal root ganglion, which therefore spares it. In S1 radiculopathy, the H-reflex is often prolonged.

Diagnosis of radiculopathy relies primarily on the electromyogram. With subacute, single–nerve root involvement, one should find denervation (fibrillation potentials, PSWs, or both) in two or more muscles of that myotome, involvement of the paraspinal muscles at the same level, and no denervation in other myotomes. It usually takes about 3 to 4 weeks for denervation to appear in the extremity muscles, but there may be earlier signs, such as decreased recruitment of motor units in muscles innervated by the involved root or signs of denervation in the paraspinal muscles. A more detailed discussion is presented in Chapter 14, so Table 46.1 summarizes abnormalities in some common disorders found by only NCSs and EMG.

**REFLEX SYMPATHETIC DYSTROPHY**

Despite the involvement of sympathetic nerves, electrophysiologic studies do not reveal specific abnormalities unless there is an associated nerve injury. One study has suggested relative reductions in the amplitude of the sympathetic nerve fiber function in the affected area as compared with the affected extremity.

**TREATMENT GOALS**

The etiology of the pain syndrome should be determined from a medical and psychosocial point of view, and if possible, the location of the “pain generator” should be identified. Attempts to decrease pain generators are important and should be carried out first, followed by consideration of other treatment options.

The goals of treatment center on moderating pain, increasing function, decreasing psychosocial issues, and reducing health care use. These objectives can be achieved by modifying pain medication and pain behavior, decreasing reliance on medical care, increasing activity through exercise, and dealing with psychological and vocational issues.

The Fordyce model of behavioral modification is useful in the treatment of patients with chronic pain syndromes. The goal in these patients is not to cure the pain but to interrupt the pain behavior reinforcement cycle by rewarding healthy behavior and setting appropriate goals for the patient. Such goals include a reduction in the use of medications, modulation of the pain response, increased activity, and reduction in pain behavior.

**ROLE OF MEDICATIONS**

Pain commonly limits participation in a physical therapy or rehabilitation program. Adequate pain management is an important component of rehabilitation. Many patients may be free of pain at rest and have incident pain provoked by activity or movement. Analgesic medications that are not timed to the patient’s pain may lead to overdosing at rest and underdosing during pain or activity. Simple measures such as taking oral analgesic medications 30 to 60 minutes before the onset of therapy or other activity that incites pain.
can provide satisfactory pain relief and increase the success of therapy.

In the postoperative setting, patients may benefit from multimodal analgesic techniques, including the use of combinations of analgesic medications and regional-peripheral nerve blocks. Parenterally administered analgesic medications are more effective for treating severe, acute, or rapidly changing pain because of their rapid onset of action and ease of dose titration. Patient-controlled analgesia allows self-titration of analgesic medication to an individual’s pain and activity level.

Patients with different types of pain—neuropathic, musculoskeletal, inflammatory—will benefit from medications that address the different causes of pain. Some patients have comorbid conditions that can increase the experience of pain, such as soft tissue inflammation, muscle spasms, or depression. The concurrent use of medications to treat these coexisting symptoms may help reduce the degree of pain experienced.

**ROLE OF PHYSICAL MODALITIES**

Physical modalities are physical agents and techniques used to produce a therapeutic response. There is a long history of use of physical modalities to treat pain that dates back to ancient human prehistory and civilizations. Physical modalities and techniques commonly used to relieve pain include therapeutic heat and cold, hydrotherapy, ultrasound, electricity, and traction. Evidence-based guidelines regarding the use of physical modalities for acute and musculoskeletal pain have been published.

It is important to realize that physical modalities do not eliminate pain by themselves and generally should not be prescribed as stand-alone treatments. Rather, they are best used as adjunctive treatments to an active exercise program. Modalities that the patient can safely use at home, such as hot and ice packs and transcutaneous electrical nerve stimulation (TENS), are more useful for chronic pain management. Modalities that require health care personnel to administer are best reserved for those with acute pain syndromes or intermittent exacerbations of chronic pain.

Before prescribing or administering a physical modality, an accurate diagnosis needs to be established and the goals of treatment determined. It is important to be aware of contraindications to the use of a specific modality. Precautions that need to be taken should be specified in the prescription.

**PHYSICAL MODALITIES**

**THERAPEUTIC HEAT**

Heat is one of the oldest physical modalities used to relieve and reduce pain. In addition to relief of pain, heat elicits other physiologic responses in local tissues that may be therapeutic, including increased blood flow, increased connective tissue extensibility, decreased muscle spasm, decreased joint stiffness, and reduced edema. Heat may also have a modulating effect on pain at the spinal and supraspinal levels. There is evidence that heat wrap therapy provides a short-term reduction in acute or subacute low back pain.

Clinicians considering the use of therapeutic heat should first decide whether superficial or deep heat is required and then choose the appropriate heating modality. Superficial modalities include hot packs, heating pads, heat lamps,
paraffin and whirlpool baths, and fluidotherapy. Deep heating agents include ultrasound, short wave, and microwave.

Contraindications to therapeutic heat are listed in Box 46.3. The risk for burns from external heat sources is real, and physicians should always write precautions to monitor for burns when heat is prescribed.

Superficial heat is delivered primarily by conduction, convection, and conversion. Modalities that transfer heat by conduction include hot packs (hydrocollator packs), heating pads, and paraffin baths. These heating modalities generally penetrate to depths of less than 2 cm from the skin. Skin and subcutaneous tissue temperatures are increased by 5° C to 6° C after 6 minutes and maintained for up to 30 minutes after application.32

A heating duration of 15 to 30 minutes may be necessary to increase muscle temperature by 1° C at depths of up to 3 cm.33 A 1.2° C increase in knee intra-articular temperature has been demonstrated after superficial heat application.33

Hydrocollator packs are hot packs that contain a silicate gel product encased in canvas. These packs are heated and stored in thermostatically controlled water baths. Before application, the packs should be wrapped in several layers of towels and excess water allowed to drain off. To minimize the risk for burns, hot packs should be placed on the patient rather than under the patient because body weight and pressure impair circulation and dissipation of heat from the heated area.

Heat lamps provide superficial heating through convection. Heat is generated in tissue through induction of molecular vibration by infrared waves emitted by the lamps. The degree of heating is a function of lamp wattage, angle of application, and distance to the body part. Radiant heat from lamps may be preferred when heating a diffuse area is required or when direct contact of a heating pad with the skin is not desirable.

Paraffin baths are a superficial heat modality commonly used for the treatment of distal extremity pain and stiffness from rheumatoid arthritis, osteoarthritis, and other connective tissue diseases. The two primary methods of application are dip and wrap and dip and immerse.32 The former is more popular; it consists of dipping and removing the body part from the paraffin bath 8 to 10 times, followed by wrapping to assist in retention of heat. The paraffin–mineral oil mixture used should be heated in a bath with a thermostatically controlled heater.

Hydrotherapy is the use of water for medical purposes; it includes treatments as diverse as aquatic therapy and wound care. Patients with painful musculoskeletal conditions can often exercise more easily in water because of reduced weight bearing and additional support. Warm water also provides heat transferred by convection to immersed body areas. A whirlpool or agitation device can be used to maintain a constant water temperature around the treated areas and provide gentle mechanical stimulation to the immersed body parts.

Fluidotherapy uses glass beads, pulverized corncobs, or other finely pulverized substances with low heat affinity that are heated by hot air to form a warm medium with liquid-like properties. The body part or extremity to be treated is immersed in a cabinet containing this dry and warm medium for treatment.32 Fluidotherapy is particularly useful for treating limbs affected by complex regional pain syndrome because it provides gentle tactile desensitization through stimulation of thermoreceptors and mechanoreceptors. Unlike hot packs and paraffin baths, there is no loss of heat over time. Stretching and exercise can also be performed during application of the heat.

When deep heating is required, ultrasound, short wave, and microwave diathermy can be used. These modalities deliver heat to deep tissues via conversion of physical energy to heat.

Ultrasound uses high-frequency sound waves to deliver energy to the target tissue. The sound waves produce thermal and nonthermal therapeutic effects.34 Ultrasound waves pass through, are absorbed, or are reflected, depending on the type of tissue encountered. Higher temperatures are generated when the ultrasound energy is absorbed. Energy is absorbed more effectively at muscle-bone interfaces, which results in higher tissue temperatures in these areas. Ultrasound is also more effective in heating tendons and ligaments than in heating muscle, which absorbs ultrasound relatively poorly.

Ultrasound is used clinically to treat subacute and chronic inflammatory soft tissue disorders such as tendinitis and bursitis. There is evidence that therapeutic ultrasound may improve acute shoulder pain in patients with calcific tendinitis.28,29 It can also be used for deep heating to facilitate stretching of contractures and shortened soft tissue structures. Low-intensity pulsed ultrasound has been shown to facilitate tissue repair and healing.34,35 Contraindications to the use of ultrasound are listed in Box 46.4.

Short wave diathermy uses electromagnetic radio waves to deliver heat down to 3 to 5 cm below the skin without overheating the skin and subcutaneous tissue. Indications for short wave diathermy are similar to those for ultrasound. Contraindications include the presence of metal, implanted pacemakers, spinal cord stimulators, surgical implants, and copper-containing intrauterine devices, because of the risk for excessive heating.

---

**Box 46.3 Contraindications to Therapeutic Heat**

- Insensate skin
- Atrophic skin
- Inability to communicate or respond to pain
- Acute inflammation
- Malignancy
- Ischemia
- Growth plates
- Peripheral vascular disease
- Demyelinating disease

**Box 46.4 Contraindications to Ultrasound**

- Contraindications to therapeutic heat
- Laminectomy sites
- Over a pregnant uterus
- Over the heart or carotid sinus
- Over an implanted pacemaker
Microwave diathermy uses electromagnetic radio waves with frequencies of 915 and 2456 MHz. It is rarely used in current clinical practice. Protective eyewear must be worn during its application to minimize the risk for cataract formation. Because of its more rapid heating of tissues with high water content, it should not be used in patients with edema, blisters, or hyperhidrosis.

Short wave and microwave diathermy is not commonly used in clinical practice, partly because there are more contraindications (Box 46.5) than with other heat agents and partly because of the availability and ease of use of other therapeutic heating options.

THERAPEUTIC COLD

Therapeutic cold is another time-tested modality used for pain relief and reduction of edema and muscle spasm. Other effects of cold include reduction of metabolic activity, muscle tone, and spasticity. Evidence that local cooling postoperatively reduces pain is mixed, with reports of a significant reduction in pain scores and opioid use after certain types of orthopedic surgery, but such results of a significant reduction in pain scores and opioid use postoperatively reduces pain is mixed, with reports of a significant reduction in pain scores and opioid use after certain types of orthopedic surgery, but such results have not been demonstrated in other studies. There is no good-quality evidence that local cooling is effective in the treatment of low back pain. The rationale for using cold is similar to that for using therapeutic heat—as an adjunctive treatment to physical therapy and exercise.

Therapeutic cold can be delivered by means such as ice packs and slushes, iced whirlpools, ice rubs, chemical ice packs, and evaporative cooling sprays. The same general precautions for therapeutic heat should be used during therapeutic cold treatments to avoid thermal injury. Contraindications to therapeutic cold are listed in Box 46.6.

CONTRAST BATHS

Contrast baths are a combination of therapeutic heat and cold and are generally used for the treatment of complex regional pain syndrome and sympathetically mediated pain syndromes. One method is to immerse the limb or body part in a warm bath at a temperature of 38°C to 43°C for about 6 minutes, transfer the limb to a cold bath at 13°C to 18°C for about 4 minutes, then transfer the body part back to the warm bath. This cycle is then repeated several times.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

TENS involves the application of electrical stimulation across the skin to the peripheral nerves. Many acute and chronic pain syndromes have been treated with TENS because of its ease of use and relatively low side effects. There is evidence that high-intensity TENS can reduce postoperative analgesic requirements and improve pain relief after inguinal herniorrhaphy, laparoscopic tubal ligation, and thoracotomy, and it has been found to be of value in the treatment of primary dysmenorrhea. However, there is insufficient evidence to support the use of TENS for various musculoskeletal conditions such as acute shoulder pain, acute neck pain, and low back pain. Based on the gate theory of pain, TENS is thought to block or modulate pain transmission in C fibers through stimulation of large myelinated A fibers. Research has indicated that there are probably more complex mechanisms to explain its clinical effect.

Currently, many different types of TENS units are available, which allows a variety of settings and modes of application. The different TENS modes include conventional narrow pulse duration, high pulse rate, low frequency, burst, modulation, and hyperstimulation. Use of conventional TENS results in a comfortable electrical paresthesia, whereas low-frequency modes result in rhythmic muscle contractions. There are many different protocols for the placement of electrodes and TENS settings. The efficacy of TENS can be optimized by an individualized approach to parameter settings and electrode placement. When the unit and electrodes are used appropriately, side effects are minimal. Contraindications to the use of TENS are listed in Box 46.7.

IONTOPHORESIS

Iontophoresis is the use of direct electrical current to drive electrically charged molecules actively, such as those in medications, across the skin and into the underlying tissue. It functions more as a drug delivery system than as a therapeutic modality. The most popular agents transported are local anesthetics such as lidocaine, steroids, and nonsteroidal anti-inflammatory drugs. Iontophoresis is generally well tolerated, and few complications have been reported.
TRACTION

Traction is the application of forces in direct opposition to each other to produce a separation of two body parts or stretching of soft tissues. In the area of spine care, traction is commonly used to treat cervical and lumbar pain. Despite a seemingly endless variety of traction techniques and treatment protocols, most types of traction are applied by a therapist (manual traction), by machine (mechanical traction), or by weight (gravitational traction) in a sustained or intermittent manner.

Traction has been prescribed to treat various spinal disorders, including radiculopathy, disk herniation, disk degeneration, foraminal stenosis, and nonspecific low back pain (Fig. 46.3). Research in this area has been confounded by the multiple types of traction techniques and treatment protocols and by methodologic flaws. The benefits of traction for neck and back pain may be mediated through anatomic changes such as diminution of disk protrusion, reduction of disk pressure, widening of disk spaces and intervertebral foramina, reduction of pressure on exiting nerve roots, stretching or separation of joints and ligaments, and relaxation of muscle spasm.

Contraindications to the use of traction are listed in Box 46.8. Cervical traction should be avoided in patients with rheumatoid arthritis and significant vertebral or carotid artery disease. Lumbar traction should be done cautiously, if at all, in patients who are pregnant or have abdominal conditions that may be worsened by increased intra-abdominal pressure. Inversion lumbar traction can increase systolic and diastolic blood pressure and increase oxygen uptake; it should be avoided in patients with cardiac or pulmonary insufficiency. Despite controversy about its physical and physiologic effects and benefits, it continues to be part of the treatment armamentarium for spinal pain.

MANUAL TECHNIQUES

Manual medicine refers to hands-on therapy and includes gentle joint stretching or mobilization to improve joint mobility and muscle dysfunction in the spine or adjacent structures based on the concept that joint restriction contributes to pain. Integral to the skills of ancient surgeons and physicians from Greece to China, manipulation and mobilization are still practiced after thousands of years, not just by chiropractors and medically trained practitioners but as part of folk practice in many parts of the world. Hippocrates (460-355 BC) was the first in recorded history to describe and illustrate joint manipulation and traction techniques.

There is debate on the long-lasting effects of manual techniques, but few can argue that there is at least subjective short-term relief of neck and low back symptoms. Guidelines of the Agency for Health Care Policy and Research include manipulation as an effective strategy for the initial treatment of acute low back pain. Studies by Bronfort and Van Tulder and colleagues have suggested that manual therapy is effective for the treatment of acute and chronic musculoskeletal pain. A randomized controlled trial comparing spinal manipulative therapy with exercise therapy (16 treatments delivered over a 2-month period) found that spinal manipulation significantly decreased pain and increased functioning and return to work at 12 months when compared with exercise therapy. Geisser and associates have shown that patients with chronic low back pain benefit from manual therapy with specific adjuvant exercise.

Many theories have been proposed to explain how manual therapy actually reduces pain. Skyba and coworkers have shown that joint manipulation produces a nonopioid form of analgesia mediated by spinal serotonergic and noradrenergic receptors. DiGiovanna theorized that manual therapy increases circulation via local effects or sympathetic reflex and increases venous and lymphatic drainage, which leads to decreased local swelling and edema. Vernon and colleagues have shown that manual therapy causes a change in the pain threshold secondary to an increase in serum endorphin levels.

Modern manipulative therapy can range from slow oscillating glides to high-velocity, low-amplitude (HVLA) techniques. It has been shown that spinal manipulative therapy reduces pain over the short term (<6 weeks) and long term (>6 weeks) when compared with sham manipulation and improves function over the short term.
TYPES OF MANUAL THERAPY

Biomechanical Model (Osteopathic Approach)

This model can be used in several ways. Using muscle energy, manual medical treatment involves voluntary contraction of the patient’s muscle in a precisely controlled direction against a counterforce applied by the operator. Use of strain-counterstrain can help relieve spinal pain by passively placing the joint in its position of greatest comfort.

Manipulation

This is similar to the biomechanical model and is also used by osteopaths and chiropractors. Manipulation refers to a modality in which the practitioner passively, often forcefully, moves (or “thrusts”) a bone through its physiologic barrier in an attempt to improve ROM or alignment of a joint. The goal is to improve function and decrease pain. The thrust is an HVLA movement. Use of this HVLA technique is what differentiates manipulation from mobilization. The ROM of a joint during HVLA movement depends on where the restriction lies in the joint’s normal ROM.

When performed appropriately and by a trained person, manipulation can usually result in immediate relief of pain. This is thought to be due to a decrease in muscle spasm while increasing ROM and the level of serum endorphins. Contraindications to manipulation include osteoporosis, acute inflammation, infection, vertebral-basilar insufficiency, fracture, or any other cause of structural instability.

Norwegian Approach (Kaltenborn)

The range (hypomobility, hypermobility, or normal mobility) and quality of movement are evaluated by using translatory movement in addition to rotational movement. During treatment, translatory traction and gliding movements rather than rotational movements are preferred to avoid compressing a joint that is already strained by pathology.

Maitland (Australian) Approach

With this approach there is continual (ongoing) assessment and reassessment of the patient and consideration of the pathology and anatomy in relation to the signs and symptoms manifested by the patient. The accessory and physiologic joint movements are tested. Treatment strategies involve the use of mobilization, manipulation, adverse neural tissue mobilization, traction, and exercise based on this continual assessment.

McKenzie Approach

This is a popular approach to patients with back pain that uses pain centralization and decentralization methods to diagnose and treat spinal pathology. The key concept here is that during movements of the spine there is a change in position of the nucleus pulposus and that a flexed lifestyle generally leads to a more posterior position of the nucleus. The treatment involves having the patient use repeated movements to treat the spinal pathology.

Myofascial Release

This type of soft tissue treatment stretches the fascial structures of the body along its planes.

MASSAGE

Massage is a general term that refers to application of the hands to soft tissues (e.g., skin, muscles, ligaments, tendons) to produce a therapeutic effect. Even though preferred and appreciated by many, massage has little objective research to support its long-term benefit. Massage can...
be subcategorized as classic massage, sports massage, reflexology, shiatsu, and acupuncture. There are many forms of classic massage, including the following:

1. **Stroking or effleurage.** This is light movement, either superficial or deep, over the skin in a slow, rhythmic fashion.49

2. **Kneading and pétrissage.** Pétrissage is the application of firm but gentle pressure in a rhythmic fashion while gently grasping the underlying tissues and lifting and squeezing them. Movement is accomplished by gliding of the hands in a centripetal pattern. Kneading lifts, squeezes, and moves larger amounts of tissue than pétrissage does.65

3. **Friction massage.** This is carried out by applying pressure in a slow circular pattern with the fingers or ball of the thumb. It is used primarily to loosen scars or adhesions.

4. **Tapotement.** This technique involves applying light “chops” or “cups” in series as percussive methods.

Sports massage is massage therapy for athletes that focuses on the muscles. A literature review by Callaghan65 showed subjective reports of benefit, but little agreement on the efficacy of massage has been documented.

Reflexology is a massage system based on a series of points in the hands and feet that are believed to correspond to a reflex pattern in all areas of the body. Treatment consists of compression of the hands or feet by firm pressure applied by the thumbs of the practitioner.65

Shiatsu and acupressure are massage techniques that use pressure applied by the practitioner’s fingers over predetermined points. These are the same points and meridians used for acupuncture. Shiatsu, on the other hand, is derived from traditional Japanese massage, called anma, and has a more anatomic and physiologic basis.56

The indications for massage are muscle cramps, stress and tension, contracture of joints, strains and sprains, tendinitis or tenosynovitis, and edema and lymphedema. Contraindications to massage include local malignancy, local infection, calcification of soft tissues, inflammatory arthritis (gout, infective), bursitis, open wounds, bleeding disorders, and entrapment neuropathy.

The theoretical mechanical effects of massage include improved circulation, breakdown of soft tissue adhesions, and activation of the peripheral nervous system. Arterial flow, venous flow, and lymphatic flow are all theoretically improved with massage.67 Benefits on the peripheral circulation include improvement in local nutrition and removal of waste products.65 This helps decrease aches in muscles and facilitate healing. Activation of the peripheral nervous system is thought to be beneficial via the gate control theory of Melzack and Wall68,69 and inhibition of overactive proprioceptors.

### ROLE OF EXERCISE

In physiology, we learn that regular exercise may increase strength, muscle bulk, and stamina. Physiologically, exercise does not directly reduce pain, although reports have indicated that the performance of exercise modulates pain by a physiologic mechanism that has not yet been fully elucidated.70 Reports on the efficacy or benefit of therapies are mixed, but most physicians agree that being more active rather than less active is more beneficial for most pain patients. A recent Cochrane review has shown that performance of strengthening exercises, trunk stabilization, and advice to stay active had more beneficial results than placebo did.71

Exercise has systemic and local effects on the body. Systemically, it increases blood flow and cardiac output; locally, it helps increase flexibility of the muscles and mobilize joints. In addition, it also strengthens weak muscles, builds endurance and speed, and establishes balance and coordination.18 Therapeutic exercise should include not only flexibility and strengthening exercises but also exercises for redeveloping the normal patterns of movement of specific muscle groups.18

Physical inactivity, if helpful at all, is helpful only during the acute inflammatory phase of an injury, and activities should be resumed rapidly, unless an obvious risk for structural damage is present.72

With sprains and strains of joints and ligaments, the acronym RICE is used—rest, ice, compression, and elevation. Kellett73 has explained that the duration of rest and icing should be 48 to 72 hours, so progressive mobilization within the limits of pain is prescribed. Acute soft tissue injuries should be rested, supported, and iced, and nonpainful early mobilization is probably beneficial.

### EXERCISE FOR PATIENTS WITH LOW BACK PAIN

Regarding low back pain, the benefit of rest is debatable, with the current trend being toward shorter periods of rest or none at all. Thirty years ago it was believed that there does need to be a period of rest, ranging from days to longer than a month. Deyo and colleagues72 noted that there is no advantage to bed rest and that those who do not have complete bed rest have fewer missed days of work and better disability scores. Hagen and associates,74 in a literature search of musculoskeletal controlled trials, deduced that “bed rest compared to advice to stay active will, at best, have small effects, and at worst might have harmful effects on acute low back pain.”

In patients with back pain it has been shown that both stretching and strengthening exercises are important. Khalil and colleagues75 studied patients with myofascial low back pain and noted that stretching plus a multimodality rehabilitation program versus only a rehabilitation program improves measures of muscle function and significantly decreases pain in 2 weeks. Takemasa and associates76 have shown that strengthening exercises not only improve strength but also reduce pain. Several studies have shown that exercises, whether flexion based (Fig. 46.6) or extension

![Figure 46.6](image-url) Abdominal curls.
based (Fig. 46.7), improve back pain more than treatment with only modalities does.77,78

It is important to understand that in chronic pain patients, physical therapy alone will not completely eradicate the pain. Physical therapy and exercise, however, can decrease the musculoskeletal sequelae of chronic pain. Exercise can improve the patient’s tolerance of functional activity by increasing flexibility, strengthening weaker muscles, and improving aerobic endurance.

TYPES OF EXERCISES

There are three main types of therapeutic exercises—stretching, strengthening, and endurance activities. Strengthening exercises involve the application of weights or resistance to a muscle group during several repetitions at maximal effort to increase the force of the muscle. Stretching involves sustained static lengthening of a muscle to increase the flexibility of that specific muscle. Figure 46.8 demonstrates stretching exercises. Endurance exercises involve the application of repeated movements with low resistance to large locomotive muscle groups to increase cardiopulmonary stamina.

There are three types of strengthening exercises. Isometric exercises involve exertion of force against a fixed object or a muscle contraction that holds an object in one position. Isotonic exercises involve exertion of force against weight that moves it through a specific ROM (e.g., handheld weights). Isokinetic exercises entail exertion of force against an object that moves it at a fixed velocity. Table 46.2 lists the indications and precautions for these types of exercises.8 Table 46.3 summarizes some useful exercises and assistive devices for various painful medical and surgical diagnoses.9

PRECAUTIONS AND CONTRAINDICATIONS

Patients with unstable medical and surgical conditions, including unhealed fractures, unstable angina, and uncompensated

cardiac, pulmonary, hypertensive, and thrombotic disorders, should not participate in strengthening, endurance, or flexibility exercises.

Precautions for resistive exercises include cardiovascular factors, overwork, osteoporosis, and immediate muscle soreness associated with exercise. A specific complication of isometric exercise is the potential for a significant increase in blood pressure.79

BEHAVIORAL MODIFICATION APPROACH TO EXERCISE

We suggest that physical medicine techniques performed in conjunction or along with a behavioral modification approach should produce a better outcome, especially in patients with chronic pain. Figure 46.9 graphically depicts the use of exercise within a behavioral concept.9

Appropriate exercises specific for the painful area and general conditioning exercises such as bicycling, walking, or swimming are usually indicated. Fordyce80 has noted that appropriate exercise in a behavior modification program must be relevant to the patient’s pain and limitations, as well as being quantifiable, visible, and accessible. The patient’s baseline exercise level is determined by asking the patient to exercise to tolerance (until pain, weakness, or fatigue necessitates stopping) over a few days.9 Once the patient’s baseline has been established, the initial goal of exercise is set within the patient’s tolerance and then gradually increased, with new goals being set every few days.9 Rewards and reinforcement are given when established goals are accomplished without demonstration of pain behavior.31 In some patients, however, it is necessary to reduce excessive activity levels by teaching them to pace themselves more appropriately.9

This concept makes sense because among the treatment goals of pain management are a decrease in illness behavior (reduced drug use and visits to physicians) and an increase in well behavior (increased physical activities and mobility and return to gainful employment).82 This may be accomplished by blocking noxious sensory input, decreasing tension and depression, rearranging reinforcement contingencies, or assisting in the learning of new behavior.83 Biofeedback, cognitive-behavioral modification, operant approaches, hypnosis, operant pain hypnosis, and relaxation techniques can assist in the treatment of chronic pain behavior.56-87

CONCLUSION

In this chapter we discussed the physical medicine techniques used for treating pain. We presented the concept that although there are a number of approaches to the treatment of patients with pain, a multidisciplinary or interdisciplinary approach is recommended as the symptom becomes more chronic. Additionally, the treatment modalities used should be more successful if carried out within a behavioral modification approach.

Before treatment is undertaken, a comprehensive evaluation is necessary, including assessment of function and setting of treatment goals that need to be delineated and agreed on by all involved in the treatment program. Physical modalities, manual techniques, and exercise can modify pain symptoms but will probably not cure them, especially in patients with chronic pain. The appropriate use of medications, injections, and psychosocial intervention, in conjunction with physical medicine techniques, is often required to achieve the maximum outcome.

KEY POINTS

- All physicians need to understand the rationale, indications, contraindications, and prescription of physical medicine techniques and their appropriate use. Many of these techniques can be used for acute, subacute, and chronic pain. However, with progression to more chronic pain, techniques should be more active and less passive and more behavioral and cognitive in nature. Although many of these techniques will help decrease pain, the long-term goal should be to increase function despite the presence of the pain syndrome.
- Patients with pain can be evaluated and treated by individual physicians and therapists. This type of approach is more often used and successful in patients with acute or subacute pain. However, as the pain becomes more chronic, a multidisciplinary or interdisciplinary approach is recommended.
- The role of the therapy team in a pain program should be comprehensive and interdisciplinary. Typically, the team is led by a physician and consists of physical therapists, occupational therapists, and often recreational therapists, dieticians, and psychologists.7 Combined assessment by these professionals is used to devise a comprehensive approach to allow the patient to benefit maximally, reintegrate fully into life, and have as few restrictions as possible.
- Patients with acute or chronic pain may be referred for physical medicine evaluation and treatment as a component of a multidisciplinary management approach or for certain specific treatments.
- Electrodiagnostic testing encompasses nerve conduction studies and electromyography, which provide information about the peripheral nerves and muscles, and evoked potentials, which is used mainly to assess the central nervous system. Electrodiagnosis can play an important role in identifying an underlying problem
KEY POINTS—cont’d

- in a patient with a pain disorder. Electrodiagnostic testing helps not only in diagnosis but also in determining the chronicity and severity of the condition and can even assist in prognosis.
- Pain commonly limits participation in a physical therapy or rehabilitation program. Adequate pain management is an important component of rehabilitation.
- Physical modalities and techniques commonly used to relieve pain include therapeutic heat and cold, hydrotherapy, ultrasound, electricity, and traction. They are best used as adjunctive treatments to an active exercise program.
- Manual medicine refers to hands-on therapy and includes gentle joint stretching or mobilization to improve joint mobility and muscle dysfunction in the spine or adjacent structures based on the concept that joint restriction contributes to pain.
- Various types of manual therapy exist: the biomechanical model, manipulation, the Norwegian approach, the Maitland approach, the McKenzie approach, and myofascial release.
- Massage is a general term that refers to application of the hands to soft tissues (e.g., skin, muscles, ligaments, tendons) to produce a therapeutic effect. Massage can be subcategorized as classic massage, sports massage, reflexology, shiatsu, and acupuncture.
- In physiology, we learn that regular exercise may increase strength, muscle bulk, and stamina. Reports on the efficacy or benefit of therapies are mixed, but most physicians agree that being more active rather than less active is more beneficial for most pain patients.
- There are three main types of therapeutic exercises—stretching, strengthening, and endurance activities. Strengthening exercises involve the application of weights or resistance to a muscle group during several repetitions at maximal effort to increase the force of the muscle. Stretching involves sustained static lengthening of a muscle to increase the flexibility of that specific muscle.
- We suggest that physical medicine techniques performed in conjunction or along with a behavioral modification approach should produce a better outcome, especially in patients with chronic pain.

REFERENCES

Ideally, patients with pain-related disability resulting from chronic pain are treated by a team of health professionals, commonly consisting of physicians, psychologists, physical and occupational therapists, social workers and nurses, to address the biopsychosocial nature of pain. Within the interdisciplinary team, the physical therapist is responsible for a comprehensive assessment with emphasis on the musculoskeletal system, including assessment of impairments, limitations in activities, restrictions in participation, environmental and personal factors that may influence physical functioning, as well as the management of the physical rehabilitation process. Physical therapists are thus intimately involved in pain management and, where possible, pain treatment.

Patients come to our clinics with certain expectations of evaluation and treatment. One study investigated the expectations of patients with chronic pain of their first outpatient visit to a pain management program. In that study, most patients expected an explanation or an improved understanding of their pain problem. The most common satisfying outcome was relief or control of pain and the understanding of their pain problem. The most common disappointing outcome was being told nothing could be done. The majority of patients expected further medical investigations and changes to the prescribed medication. There was no mention of patients expecting a referral for pain management, and only a small percentage of patients wanted advice on coping with pain, or self-management of pain. Although this study needs to be duplicated in other centers, it has a great deal of face validity. Many patients with chronic pain resist referral to physical rehabilitation. Part of the difficulty lies in the history of treatment failures with which patients often present. A number of factors may be responsible for past treatment failures, including persistent failure of physical therapists to recognize and treat the differences between acute and chronic pain states, past treatment that did not address the emotional and cognitive aspects of chronic pain, and an inability of the patient to recognize anything less than total pain relief as success. It is therefore important to identify patient expectations at the initial visit to prevent disappointment with referrals to physical rehabilitation for pain management.

### PHYSICAL THERAPY EVALUATION

In evidence-based practice, clinical decisions must include consideration of, first, the patient’s clinical and physical circumstances to establish what is “wrong” and what treatment options are available to address this problem. Second, the latter need to be tempered by research evidence concerning the efficacy, effectiveness, and efficiency of the treatment options. Third, given the likely consequences associated with each option, the clinician must consider the patient’s preferences and likely actions (in terms of what interventions she or he is ready and able to accept). Clinical expertise is needed to bring these considerations together and recommend a treatment that the patient agrees to accept. Accordingly, the purposes of a physical therapy evaluation are to establish a baseline from which to plan and begin interventions, assist in the selection of appropriate interventions, and evaluate the efficacy of interventions.

As described in the biopsychosocial model of pain introduced by Fordyce, contributing factors to disability can be biologic, psychological, as well as social. Essential in this model is the idea that factors maintaining the pain problem are not necessarily the same as those initiating pain. To establish a baseline, therefore, a thorough inventory of all factors contributing to a patient’s perceived level of disability is important. The International Classification of Functioning, Disability and Health (ICF) provides a biopsychosocial model that identifies three concepts described from the perspective of body systems, the individual, and society. Within the context of health, the ICF defined bodily functions and structures as physiologic functions of body systems or anatomic elements, such as organs, limbs, and their components. Activity is defined as the execution of specific tasks or actions by an individual, whereas participation is envisioned as encompassing involvement in a life situation. In the ICF, functioning refers to all body functions, activities, and participation. Disability is the ICF umbrella term for impairment, activity limitation, and participation restrictions. Contextual factors are provided within the ICF framework (Fig. 47.1), consisting of external environmental factors (such as significant others, employers, medications, and health care providers) and personal factors (such as age, education, income, worry that activity will exacerbate pain or injury resulting in avoidance of activity to prevent anticipated negative consequences).

Qualifiers for the Activities and Participation classification make it possible to clearly separate the patient’s inherent capacity to perform actions within a domain and performance in his or her actual environmental context. Capacity refers to the environmentally adjusted inherent ability of the individual or, in other words, the highest probable functioning of a person in a given domain at a given point in time, in a standardized environment. Capacity can be measured by physical tests or by questionnaires that ask, “Can you?” Performance describes what a person actually does in her or his current environment and thus describes...
the person’s functioning as observed or reported in the person’s real-life environment with the existing facilitators and barriers. Performance can be measured by direct observation. As this is often highly impractical, self-report measures can be substituted that ask, “Do you?”

The Rehabilitation Problem Solving (RPS) form is based on the ICF and is a practical tool to use to visualize the patient’s state of functioning and disability. The form is used to specify precise and relevant target problems, discern factors that cause or contribute to these problems, and plan the most appropriate intervention. In addition, the form was designed as a tool to facilitate both intra- and interprofessional communications and improve the communication between health care professionals and their patients. The form is divided into three parts: (1) the header provides basic information, (2) the upper part is used to describe the patient’s perspective, and (3) the lower part is used for the analysis of the health care professionals.

The form can visualize the current understanding of the patient’s state of activities and participation, his or her target problems, and how the health care team relates them to hypothetical mediators and contextual factors (Fig. 47.2).

From the information obtained through carefully selected questionnaires, an interview, the physical examination, and physical tests, most of the information needed to develop an appropriate treatment plan should be obtained.
PATIENT INTERVIEW

The Joint Commission on Accreditation of Health Care Organizations requires that all patients have the right to an adequate pain assessment, including documentation of pain location, intensity, quality, onset/duration/variability/rhythms, manner of expressing pain, pain relief, what makes it worse, effects of pain, and a pain plan. In addition to questions about the location, intensity, frequency, and duration of pain, questions such as “What do you think causes your pain?” and “What is the worst thing you think might happen to you because of your pain?” will give insight into the patient’s belief system—especially important if the patient comes from a different culture—and the presence of catastrophizing. In addition, physical therapists focus on determining how much the pain interferes with activities and participation: activities of daily living such as housework, grocery shopping, and getting around in the community; recreational and social activities; and the ability to do work and sleep. The number of hours lying down and changes in the level of activity because of pain during a day is noted. Patients are further asked about significant others, partners, parents, and children; do they help out, ignore the patient, or prevent the patient from doing things as they fear the patient might “harm” him- or herself.

Unfortunately there are no perfect measures of physical activity or activity limitations. Comparison measures include both “subjective” measures (based on self-report) and “objective” measures (based on direct measurement). Self-report measures can be self-administered or interviewer administered, both in person or on the telephone. However, self-report of physical activity can reflect a difference between how active patients really are and how active they perceive they are, resulting in a difference between self-reported physical activity level and the actually observed active behavior. Studies including both self-report and objective measures on activity and activity-related disability indicated a gap between self-report and objective measurement.

In rehabilitation practice, there is a tendency to use objective as well as self-report measures to assess physical activity. Objective measures include functional capacity tasks, markers of movement (accelerometers or activity monitors), and observed or videotaped activity (direct observation). Self-reported status often involves outcomes of most relevance and importance to patients and their loved ones because they capture patient experience and perspective. Therapists should be aware of these differences during their assessment. In addition to assessing a patient’s level of activity, labeling a patient’s activity-related behavior style seems of additional value when choosing the most appropriate ingredients for treatment: Will this patient avoid activities because of pain (avoider), or will he or she persist in the performance of activities regardless of pain (persister)?

Psychosocial factors have been found to have a significant impact on perceived disability, particularly among persons with chronic pain. The physical therapist’s observations of a patient’s behavior during the interview or functional testing as a part of a screening procedure can deliver valuable information and should be communicated clearly to the rest of the team, which can then direct appropriate psychological and psychiatric treatment. Psychological screening by means of history taking has been shown to have low sensitivity and predictive value for identifying distressed patients. Thus, formal screening of some sort, such as with a questionnaire, is recommended. Psychosocial factors contributing to a patient’s disability level that can be assessed by a questionnaire are, for instance, fear of movement (Tampa Scale of Kinesiophobia), catastrophizing (Pain Catastrophizing Scale), and depression (the Beck Depression Inventory). Consideration of the patient’s views is associated with greater satisfaction with care, improved compliance with treatment programs, and maintenance of continuous relationships in health care.

As previously mentioned, particularly important are questions about what the patient expects from treatment. Patients’ beliefs and expectations play a large role in treatment compliance and eventual treatment outcome. Studies have shown that high patient expectations may positively influence clinical outcome independent of the treatment itself. Treatment of chronic pain is often complex and may be further complicated when patients and health care providers have differing goals and attitudes concerning treatment. Difficulties in engaging in collaborative treatment decision making may result. A negative expectation on treatment outcome can influence treatment compliance. For instance, a patient, who is looking for pain relief only and insists on medication management as the sole treatment for the pain is not likely going to comply with a rehabilitation program. Efforts to enhance patient-provider communication as well as to systematically examine nonspecific treatment factors are likely to promote effective management of chronic pain.

PHYSICAL EXAMINATION

The traditional rehabilitation-oriented physical examination assesses impairments in joint range of motion (ROM), strength, neurologic integrity, and gait. Diagnostic procedures should focus on identifying potentially serious “red flag” conditions that require prompt medical evaluation. The main objective is to determine whether there is a relationship between pain reports and objective physical findings or whether the patient presents with intractable pain (chronic pain syndrome). In the former, rehabilitation might focus more specifically on impairments related to pain that interfere with the ability to function, whereas in the latter case rehabilitation might focus on improving physical functioning in general and have a more significant behavioral approach.

Patient anxiety may complicate the physical examination. Catastrophic cognitions, behavioral displays of pain, and somatic sensations measured during examination have been shown to uniquely predict anxiety experienced during examination. Muscle guarding and pain behaviors are often displayed during physical examination and include moaning, sighing, rubbing, reluctance to perform any active movement (ROM), and the presence of giveaway weakness and nonphysiologic signs. Waddell’s nonphysiologic or behavioral signs in patients with back pain can be assessed through palpation and simulation tests including axial loading (pressure applied to the top of the patient’s head), simulated rotation (moving shoulders and hips together so that no rotation occurs in the trunk), inconsistency between the straight leg raise in a sitting versus supine position, giveaway
weakness with resisted muscle testing, and regional sensory change. One study examined the cross-sectional construct validity of the Waddell score and found evidence that it measures a combination of pain intensity, illness behavior, physical dysfunction, and psychological functioning. However, the associations with the different domains were, in general, weak, which underscores the complexity of illness behavior as measured with the Waddell score.29

Recognizing that studies in patients with chronic pain have identified discrepancies between self-report of physical activity and actual level of physical activity, capacity testing is performed in addition to traditional impairment examination. This involves direct observation of patient performance on specific tasks and assessment of whether the patient is willing to move or fears performing specific tasks. Baseline functional ability assessment can provide objectively verifiable information about a patient’s quality of life and ability to participate in normal life activities.

Functional tests can be used to focus on performance in basic daily life activities, such as walking, stair climbing, and lifting. Various specific tasks or sets of tests that intend to represent daily functioning are available for this purpose. Simple tasks such as 5-minute walking, 50-foot walking, sit-to-stand, 1 minute stair climbing, loaded forward reach, or various lifting tasks are available to assess a patient’s capacity during one specific activity. However, the ability of the tests to reflect the level of functioning in patients with pain have to be taken with caution. The test-retest reliability and responsiveness27 appeared to be only moderate for most of the tests. In addition to single tests, test batteries have been introduced to represent functioning in patients with pain. For example, the Back Performance Scale is a condition-specific performance measure of activity limitation in patients with back pain and includes five tests of daily activities requiring mobility of the trunk: sock test, pickup test, rollup test, fingertip-to-floor test, and lift test. The psychometric properties of this test battery have been demonstrated.28,29 A second example of a test battery is a generic test battery that includes nine physical performance tests: the time taken to complete various tasks (e.g., picking up coins, tying a belt, reaching up, putting on a sock, standing from sitting, a 50-foot fast walk, a 50-foot walk at preferred speed), the distance walked in 6 minutes, and the distance reached forward while standing. The reliability and discriminant ability of this battery have been confirmed.30

In the assessment of work-related performance, a functional capacity evaluation (FCE) is often used.31 An FCE is an evaluation of capacity of activities that is used to make recommendations for participation in work while considering the person’s body functions and structures, environmental factors, personal factors, and health status.32 The purpose of an FCE is to test a person’s physical abilities to the maximum in order to produce objective documentation regarding work and activities of daily life. The FCE has become part of the accepted practice in work injury prevention and rehabilitation.33 During an FCE, the patient has to complete a standard protocol of physical tasks while a trained observer records the capacity and limitations. Assessment includes ability to lift weights from floor to waist and from waist to overhead, carry, crawl, squat, sit, stand, walk, climb stairs, and push and pull weights. Aerobic capacity may be determined from a maximal bicycle or treadmill test. Additional specific tests may be performed, such as those used to evaluate fine motor skills for the hands and handgrip strength. Practical data on the use of FCEs to determine an individual’s physical capacities have been available since the early 2000s and normative data have now been established.34 Biopsychosocial factors may influence FCE test results, although it is not quite clear to what extent and which factors are important. A systematic review concluded that there is conflicting evidence for the influence of psychological factors and absence of evidence for the influence of social and biologic/physiologic factors in patients with nonspecific chronic low back pain (CLBP) that influence capacity test results.35 Interpretation of FCE test results is therefore not fully objective because the observer has to decide if a patient performed maximally or submaximally during the test.

A number of studies have shown that self-report and performance and capacity tests, although related, appear to tap into different aspects of the physical functioning domain.36 For instance, patients with CLBP showed considerable differences in limitations when comparing self-report, clinical examination, and functional testing for assessing work-related limitations. Professional health care workers should be aware of these differences when using them in daily practice.37,38

**THERAPY FOR CHRONIC PAIN**

An important difference between patients with acute pain and those with chronic pain is the variation in relationships between pain, activity limitations, and participation restrictions. For patients with acute pain, nociception, perceived pain, activity limitations, and participation restrictions often have a close relationship. Therefore, treatment in the acute phase focuses on eliminating the causal factor of the pain, resulting in a reduction of activity limitations and the prevention of disability. For patients with chronic pain, however, this treatment strategy is often insufficient. Patients with chronic pain may never return to work even when the only impairment identified is pain. Treatments that address chronic pain as a warning of tissue damage do not alter the illness and disability behavior of patients with chronic pain, nor will they improve their health-related quality of life. The focus of therapy should be to help these patients regain control over their lives by active participation in their pain management program and learning to cope with pain. To achieve this goal, an active partnership is needed between the patient and the therapist. Like other patients, patients with chronic pain want a confidence-based association that includes understanding, listening, respect, and being included in decision making.39

Patients with chronic pain are not a homogeneous group and there is no magic bullet that fits all. Because each patient has a unique set of circumstances, psychosocial issues, and physical findings, treatment is individualized and based on the comprehensive assessment of the patient and the patient’s individual goals.

In general, chronic pain management should include the following, as noted by Von Korff and colleagues:40

- Collaboration between physical therapist and the patient
- A personalized rehabilitation plan
• Tailored education of the patient on the nature of the problem
• Resolution of treatable barriers related to functional goal attainment
• Tailored instruction in independent management of pain
• Instruction in methods to prevent future problems
• Monitoring of outcome (achievement of patient goals)
• Monitoring of adherence to treatment
• Planned follow-up

COLLABORATION BETWEEN PHYSICAL THERAPIST AND PATIENT

Implementing patient-centered approaches in caring for individuals with chronic pain and using principles drawn from the chronic disease management model to improve care systems may improve both patient and provider satisfaction with chronic pain care. For instance, significant positive associations were found between a positive therapeutic alliance and the patient’s global perceived effect of treatment, change in pain, physical function, patient satisfaction with treatment, depression; and general health status in patients with chronic musculoskeletal pain in physical rehabilitation. Contributing to a positive therapeutic alliance are (1) therapist-patient agreement on goals of treatment, (2) therapist-patient agreement on intervention, and (3) the affective bond between patient and therapist.

Coming to mutual agreement on goals and intervention can be a challenge. To decrease the negative impact of chronic pain on functioning and health-related quality of life, patients must adopt self-management skills. In order to do so, patients have to be ready to stop focusing on further medical diagnostics in order to find a definite medical solution for pain and change to an active orientation regarding self-management. Not all patients are ready for this. For a good collaboration between the physical therapist and the patient, the patient must at least be planning to take an active orientation toward self-management, and the therapist should support and encourage this goal. Motivational interviewing (MI) techniques can be applied to support patients in enhancing behavioral change and finding an active orientation toward self-management. MI, originally developed in the field of addiction, has recently been introduced in various health care domains, including the care for patients with chronic pain. In the treatment of patients with chronic low back pain, an MI-adapted intervention added to physical therapy effectively enhanced motivation and exercise compliance compared to physiotherapy alone.

Patients with chronic musculoskeletal pain who followed an exercise program containing an additional motivation program were more likely to attend the exercise classes. Further research is, however, needed to study whether these positive effects on motivation and adherence will eventually improve treatment outcomes.

Not only do patients bring expectations about treatment but the provider does as well. Treatment decisions are often heavily influenced by personal beliefs of the provider. Results of several studies indicate that the personal attitudes and beliefs regarding pain of physiotherapists and other health care providers are associated with their advice to patients regarding regaining activities and return to work. Practitioners with a more biomedical orientation are more likely to use a pain-contingent treatment approach and focus on “curing” impairments, whereas practitioners with a more biopsychosocial orientation will more likely use a time-contingent treatment approach and focus on increasing activities. Linton and associates investigated the level of fear-avoidance beliefs in practicing general practitioners and physical therapists. Compared to providers with low fear avoidance, providers with high levels of fear-avoidance belief had an increased risk for believing sick leave to be a good treatment, not providing good information about activities, and being uncertain about identifying patients at risk for developing persistent pain problems. The combination of a high fear avoidant provider with a high fear avoidant patient seems a recipe for disaster in chronic pain management and should at all cost be avoided.

Different assessment tools are currently available to measure practitioners’ beliefs toward pain, such as the Attitudes to Back Pain scale for musculoskeletal practitioners (ABS.mp), the Health Care Providers’ Pain and Impairment Relationship Scale (HC-PAIRS), and the Pain Attitudes and Beliefs Scale for Physiotherapists (PABS.PT).

It can be concluded that for optimal interaction with his or her patient, a physical therapist should have (1) a dynamic, multidimensional knowledge base that is patient centered, (2) a clinical reasoning process that is embedded in a collaborative, problem-solving venture with the patient, (3) a central focus on movement assessment linked to patient function, and (4) consistent virtues seen in caring and commitment to patients as has been shown to be central to expert physical therapy care.

PERSONALIZED REHABILITATION PLAN

To win the collaboration of patients and their families, physical therapists need to negotiate and agree on a definition of the problem they are working on with each patient. They must then agree on the targets and goals for management and develop an individualized collaborative self-management plan. The patient and physical therapist need to agree on the goals of treatment to prevent confusion and disappointment on both sides and to establish a collaborative relationship. Adopting a shared decision-making approach to goal and treatment setting may be useful. Training and support for both health professionals and patients may facilitate a shared decision-making approach. Establishing specific but attainable goals can facilitate task performance. In contrast, unrealistic goals can lead to decreased motivation and a sense of failure. Self-efficacy facilitates goal setting. People with high self-efficacy choose to perform more challenging tasks. They set themselves higher goals and stick to them. Self-efficacy can be understood as the confidence one has in one’s ability to deal with certain life stressors. High self-efficacy is related to better treatment outcomes, such as higher levels of physical functioning and the use of pain coping strategies related to better adjustment to chronic pain.

Goals must be measurable so that treatment can be time limited and have an observable end point. Return to a pain-free state is a good example of an unrealistic goal. Common (realistic) goals are associated with a reduction of the impact of pain on the patient’s life (i.e., increased level of activities and participation), independent pain management, and the attainment of functional goals. Examples of functional goals
are being able to walk for an hour, sitting through a meal or a movie, being able to carry and lift a certain amount of weight, playing with the kids, going out with the family, and being able to perform essential job components. Return to work or vocational rehabilitation should be part of the treatment plan when appropriate. Goals must be realistic and attainable within a reasonable time. A gauge such as the Canadian Occupational Performance Measure (COPM) can be helpful during the process of goal setting and goal attainment during treatment.\(^5,^6\) It is helpful to determine the number of treatments per week and the number of weeks of treatment before initiating treatment (i.e., treatment will occur 3 times per week for 6 weeks). Having a definite end point increases patient adherence and provides a framework to the patient and the treatment team in which to achieve goals. A treatment contract that includes goals, the intensity and frequency of treatment, and expected compliance with treatment can be helpful.

During treatment, the use of goal-setting charts is recommended. Patients set a target for activities each week, record their achievements on the chart, note the nature of any difficulties and how these will be tackled next time, and make other comments. Patients may comment on their performance or on the appropriateness of the goals they had set. In this manner they can monitor their progress and improve their accuracy in goal setting.

**EDUCATION ON THE NATURE OF THE PROBLEM**

A number of studies have shown that most patients expect an explanation or an improved understanding of their pain problem, a clear diagnosis of the cause of their pain, information, and instructions. They expect confirmation from the health care provider that their pain is real.\(^5,^6\) For patients attending pain clinics, the explanation of their pain problem is rated as important as the cure or relief of their pain.\(^5,^6\) Education on the neuropathology of pain seems therefore quite important and may be considered a precondition for pain management success.

The sensitization model can be used to explain pain as a physical cause related to changes in the nervous system and to explain how chronic pain exists without tissue damage. This explanation may improve the patient’s motivation to discuss the importance of psychosocial factors that contribute to the maintenance of chronic pain.\(^5,^6\) Unfortunately, the underestimation of patients’ ability to understand currently accurate information about the neuropathology of pain represents a barrier to reconceptualization of the problem in chronic pain within the clinical and lay arenas.\(^7,^8\) Most patients are quite capable of understanding the complexities of pain if explained well. The textbook *Explain Pain* can help to guide educational sessions with patients.\(^9,^10\) For chronic musculoskeletal pain disorders, there is compelling evidence that an educational strategy addressing the neuropathology and neurobiology of pain can have a positive effect on pain, disability, catastrophization, and physical performance.\(^7,^8\) The main goals of education are reassurance and empowerment for further treatment. When treating patients in a group, education comes from other patients as well. They may share solutions to functional problems, ways to better pace their activities, or independent pain management techniques they have found helpful.

**RESOLUTION OF TREATABLE BARRIERS RELATED TO FUNCTIONAL GOAL ATTAINMENT**

Barriers related to the attainment of functional goals in patients with chronic pain are usually due to a combination of physical factors and patient beliefs and cognitions. Physical conditioning programs that include a cognitive-behavioral approach plus intensive physical training (specific to the job or not) that includes aerobic capacity, muscle strength, endurance, and coordination; are in some way work related; and are given and supervised by a physical therapist or a multidisciplinary team seem to reduce the number of sick days for some workers with chronic back pain, when compared to usual care.\(^6,^7\) Ideally, exercise therapy is combined with a cognitive-behavioral approach in a chronic pain rehabilitation program.

**EXERCISE THERAPY**

The “deconditioning syndrome”\(^5,^7,^8\) was postulated in the mid-1980s as a factor contributing to the intolerance to physical activities and subsequent (further) loss of function and disability in patients with chronic pain. Physical disuse has been presented as one factor that perpetuates chronic pain in theoretical pain research models. Although current evidence does not support the disabling influence of a deconditioning syndrome in chronic pain syndromes,\(^9\) reconditioning is still used as a fundament for various pain rehabilitation programs. Enhancing physical activity and fitness can, however, indeed have a beneficial effect in patients with chronic pain. For example, meta-analyses have demonstrated strong evidence for the efficacy of muscle conditioning and aerobic exercise to lessen symptoms in persons with arthritis, other rheumatic diseases,\(^10\) and shoulder pain.\(^11\) There is evidence (although the studies have been classified as low quality) for the effectiveness of exercise therapy compared to usual care in patients with back pain.\(^12\)

Exercise therapy encompasses a heterogeneous group of interventions, and a number of studies have found beneficial effects of exercise on pain and function; however, there continues to be uncertainty about the most effective exercise approach. Most studies had insufficient data to provide useful guidelines on optimal exercise type or dosage, although some evidence exists that “sicker” patients may benefit from more intensive treatment. Haldorsen and associates,\(^13\) for instance, showed that patients with a poor return-to-work prognosis returned to work at significantly higher rates when they completed a more intense multidisciplinary treatment program, whereas patients with a good return-to-work prognosis benefited equally from ordinary treatment and multidisciplinary treatment. Patients thus do not all benefit from the same exercise program. Exercise programs therefore need to be designed and tailored to the individual needs of the patient. In addition, the mechanisms by which physical treatment supports improvement in patients with chronic pain may not only be based on changes in muscle strength or fitness. In a study of Smeets and coworkers, it appeared that pain catastrophizing mediated results in both cognitive-behavioral treatment and in physical treatment.\(^14\) Changes in the level of catastrophizing, instead of changes in physical fitness, were associated with changes in disability during treatment.

There is little evidence that supports the use of passive modalities in the treatment of patients with chronic pain.
High-quality evidence suggests that there is no clinically relevant difference between spinal manipulative therapy and other interventions for reducing pain and improving function in patients with chronic low-back pain. There is currently insufficient evidence to draw a firm conclusion on the clinical effect of low-level laser therapy, massage, traction, superficial heat/cold, and lumbar supports for patients with chronic low-back pain.62

Published literature on transcutaneous electrical nerve stimulation (TENS) lacks the methodological rigor or robust reporting needed to make confident assessments of the role of TENS in chronic pain management.65 Passive modalities (TENS, ultrasound, massage, corsets, traction, acupuncture) should be limited and used only in combination with an active exercise program.

COGNITIVE-BEHAVIORAL APPROACH
Cognitive-behavior therapy (CBT) is a combination of cognitive and behavioral therapy. Behavioral therapy addresses the connections between situations and patients’ habitual reactions to them (i.e., walking with a limp because it gets positive attention from the spouse). Cognitive therapy addresses patients’ thoughts or beliefs that cause them to feel and act the way they do (“If I use my back I will become paraplegic, so the safest thing to do for me is to lie on the couch and do nothing”). Therefore, if patients exhibit unwanted behaviors, it is important to identify the beliefs that cause the behaviors and to teach patients how to replace or modify the beliefs so that more desirable behavior might ensue.

Cognitive-behavior modification can be accomplished in a number of ways: by talking about beliefs, by gaining exposure to avoided activities, by increasing the number and duration of usual activities, by participating in a “reward system” in which healthy behavior is rewarded and encouraged and nonhealthy behavior is ignored, and by listening to feedback from other patients on their behavior.

Pain-related fear has been consistently associated with initiation and maintenance of chronic pain disability.66 For patients with high levels of pain and activity-related fear who avoid activities, behavioral methods such as graded activity and graded exposure treatment have both been shown to be effective in reducing disability.67 Repeated exposure to avoided activities decreases anxiety and fear about them. In graded exposure, patients are challenged to actually perform the specific physical activities that they believe will harm them. Most of the time exposure treatment is performed in combined therapy with a physical therapist and a behavioral therapist.

Although multidisciplinary programs have shown effectiveness in patients with chronic pain, it is still unclear which component is most effective. In a study in which the effectiveness of three rehabilitation interventions (an active physical, a cognitive-behavioral, and a combined treatment) for patients with chronic low back pain was compared with that for a waiting list control group, it appeared that all three active treatments were effective in comparison to no treatment, but no clinically relevant differences between the combined and the single-component treatments were found.21 A new approach in CBT, or the third-wave CBT, has been introduced in pain treatment. An example of a third-wave CBT approach is acceptance commitment therapy (ACT). ACT differs from traditional CBT in that instead of trying to teach people to better control their thoughts, feelings, and sensations, ACT teaches them to “just notice,” accept, and embrace personal life events. ACT aims to help individuals clarify their personal values and take action on them in order to bring more meaning to their lives.

SELF-MANAGEMENT TECHNIQUES
Self-management ensures active patient participation in managing pain and achieving reasonable goals of functional restoration. Self-management ensures active patient participation and includes the following:

- The use of pain-control modalities (e.g., ice, heat, self-massage, relaxation, cognitive-behavioral techniques)
- A graded, gradually progressive exercise program to encourage overall fitness, activity, and a healthy lifestyle

There is emerging evidence that interactive online self-management programs are helpful in reducing pain intensity, psychological distress, and disability.68,69

INSTRUCTION IN METHODS TO PREVENT FUTURE PROBLEMS
It is almost inevitable that a patient with chronic pain will experience an exacerbation of the pain problem at some time. Relapse may be due to an individual physical event or it may result from cumulative physical and psychological stresses that challenge patients’ coping resources. The physical therapist can help to identify situations that are challenging and develop strategies to cope with them. Strategies may include setting criteria to visit health professionals, using pain medication, or briefly resting and relaxing. Plans for resuming activity following an exacerbation are critical.70 Technological applications, such as the online self-management programs described previously, or telephone-based interventions may help patients maintain the skills they learned in their pain management programs and prevent relapse.

If returning a patient to work is an important goal, a job description with as much detail as possible provides important ergonomic information. Patients can then practice components of the job description with the physical therapist and at home.

The goal of ergonomics is to ensure that the workplace is designed to prevent work-induced injuries. Non-neutral postures, forceful exertions, constrained or static postures, repetitive work, use of pinch grip, work over shoulder height, prolonged periods of time with the trunk inclined forward, heavy lifting, twisting while lifting, and whole body and vibration are all risk factors for work-related musculoskeletal disorders. A common type of ergonomic instruction during physical therapy is educating the patient on manual handling and lifting, optimal seated postures and activities, and the relationship of the seat to the workbench or desk. The patient is taught to take “stretch breaks” during work or to alternate job components.

At the end of treatment, a vocational assessment is advised, which preferably includes an FCE assessment. Then the FCE is matched with the job description. Recommendations for return to work are based on this evaluation. Changes in the job that would enable the patient to return to work may be suggested. If possible, a worksite analysis also should be performed to help identify risks to the patient and to suggest changes to the work environment to accommodate the patient.
For return to work, a “light duty” job or a gradual increase in the hours worked per day is usually recommended. Some therapists offer a “work hardening” program in which a pain patient gradually “works” up to a simulated 8-hour workday. In workers with chronic back pain, pooled results of five physical conditioning studies showed a small effect on sickness absence at long-term follow-up. The addition of cognitive behavioral therapy to physical conditioning programs was not more effective than the physical conditioning alone. Workplace involvement might improve the outcome. After discharge from these programs, full-time return to work is appropriate.

**MONITORING OF OUTCOME (ACHIEVEMENT OF PATIENT GOALS)**

Generic and disease-specific measurement tools have been developed. Recommendations based on the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) can be helpful for designing sets for routine assessments in order to monitor treatment progress. Important domains to consider for assessment as advised by IMMPACT are pain, fatigue, disturbed sleep, physical functioning, emotional functioning, patient global ratings of satisfaction, and health-related quality of life. In addition, patients’ treatment goals can serve as outcome measures to determine treatment efficacy. A simple visual analog scale (VAS) can visualize progress, for instance:

**In the past week were you able to walk a mile?**

Completely unable_________________Completely able

**MONITORING OF ADHERENCE TO TREATMENT**

As early as 1991, Turk and colleagues reported that nonadherence with therapeutic recommendations during treatment and subsequent to treatment termination are neglected topics in the treatment of patients with chronic pain. The topic remains under-researched.

Besides outcome domains as mentioned earlier, IMMPACT focuses also on participant disposition (e.g., adherence to the treatment regimen and reasons for premature withdrawal from the trial). Adherence to pain management treatment recommendations and the number of “no shows” should be monitored in clinical practice as well. Physical therapists need to offer an appropriate behavioral framework by maintaining a clear structure, consistent rules, and rewards for positive patient response during treatment. When a patient is persistently nonadherent, the problem should be addressed and the reasons for nonadherence explored. Reasons for nonadherence can include poor satisfaction with treatment results or a patient-provider relationship that does not work well.

**PLANNED FOLLOW-UP**

There is a paucity of literature on planned follow-up after multidisciplinary treatment. Planned follow-up can be done on an individual basis or in group settings and serves to prevent crisis management. It can also serve as an external motivator (they are going to know I did not do my exercise/ self-management techniques). To date, there is no evidence as to the optimal frequency or duration of follow-up visits.

**CONCLUSION**

Generally, the evaluation and treatment of chronic pain patients are difficult tasks that are best performed in an interdisciplinary team setting, because both biomedical and psychosocial aspects related to the pain problem have to be addressed. The role of the physical therapist is to form a close partnership with patients, help patients set and attain individual goals at activities and participation level, and teach patients self-management skills. Ultimately, patients should become experts on managing their own chronic pain in order for them to enjoy the best health-related quality of life possible.

Acupuncture is an ancient medical modality of traditional Chinese medicine. It was described in the Huang Di Nei Jing (Yellow Emperor’s Internal Classic) in 100 BC. Called jin jiao, acupuncture generally consists of the practices of needling and moxibustion. Moxibustion is a warming sensation produced by placing smouldering moxa (Artemisia vulgaris) over the acupuncture points. The practice of acupuncture also includes electroacupuncture, laser acupuncture, cupping, Chinese tui na massage, Gua Sha, and acupressure. With the advances in biochemical and biophysical technology, the mechanisms of acupuncture analgesia have been elucidated as being a consequence of peripheral acupuncture point stimulation, mobilization of central neural peptides, and triggering of the central inhibitory pathway for modulation of pain sensation.

**THEORIES OF ACUPUNCTURE**

The concept of yin and yang is one of the essential theories of traditional Chinese medicine. The principle is simple, but its implication is philosophical. It was first mentioned in The Book of Changes and Simplicity (Yi Jing), a text from about 700 BC. Yin and yang are natural phenomena that exist within the body. They are interdependent and can be transformed into each other. They exist in a constant state of dynamic balance. Yang is related to bright, hot, activity, light, above, outward, increase, dry, and male. Yin is present in the qualities of dark, cold, rest, passivity, below, inward, decrease, wet, and female. Yin and yang define aspects of a whole and are therefore dependent on each other. For example, “bright” is difficult to define without “dark.” “Above” is meaningless without “below.” Yin-yang interdependence is the relationship between structure and function. Optimal physical condition requires a balance of yin and yang within the body. Disease is associated with a dis-harmony or imbalance between yin and yang. Acupuncture can be used to balance and promote yin and yang energy within the body.

There are more than 365 identifiable acupuncture points in the human body. There are also pathways, called meridians, connecting acupuncture points to each other. Qi (pronounced “chee”) is the energy flow through these meridians. Difficult to define, qi represents power and movement, similar to energy. Qi is a functional, dynamic force that resides in living creatures. It is a result of the interaction between heaven and earth, an energy that is manifested concurrently in the physical and spiritual levels of human existence. Qi flows throughout the meridians of the body to maintain life and health. These meridians are not defined by physical structures such as blood or lymphatic vessels, but by their function. The body is viewed as a dynamic system of organs connected by the flow of qi through the meridians.

When there is stagnation or inadequate flow of qi through the meridians, pain or illness may result. The flow of qi may be restored by the insertion of very fine needles into a combination of appropriate acupuncture points along the meridians. Manual twirling of these needles produces a sore, heavy, or numb sensation known as “de qi” (obtaining qi). Acupuncture practitioners have observed that stimulating specific acupuncture points results in predictable responses in patients with a given pattern of signs and symptoms. Practitioners of acupuncture routinely request the patient’s detailed history of the present illness in pursuing the diagnosis. Physical attention is also focused on disposition of the pulse and appearance of the tongue. In traditional Chinese medicine, there are six pathologic factors that cause disease—wind, cold, heat, dampness, dryness, and fire. The goal of the history and physical examination is to assess the patient’s balance of yin and yang and to gain insight into other symptoms.

There are eight principal classifications of symptoms, which include yin or yang, external or internal, cold or hot, and deficient or excess. The aim of acupuncture therapy is to restore deficiencies or correct excesses in qi, thus restoring health. It is frequently used for preventive care, as well as for therapeutic purposes.

A Treatise on Acupuncturation, written by James Morss Churchill in 1823, was the first text about acupuncture published in English. Dr. Churchill described his success in using acupuncture for rheumatic conditions, sciatica, and back pain. Sir William Osler’s Principles and Practice of Medicine, first published in 1892, recommended the use of acupuncture for the treatment of sciatica and lumbago. Public awareness and use of acupuncture increased in the United States following New York Times writer James Reston’s account of his emergency appendectomy in a Chinese hospital. His article described how physicians eased his postsurgical abdominal pain with acupuncture.¹

**ACUPUNCTURE POINTS**

Acupuncture points are generally located in the deep depressions of muscles, joints, or bones and are often sensitive to pressure. The unit of measurement used to determine the locations of acupuncture points on the body is called a tsun, and measurement of a tsun is relative to the patient’s own body. One tsun (approximately 1 inch) is equal to the space
between the distal interphalangeal joint and the proximal interphalangeal joint on the middle finger.

• CV 12 (zhong guan; “central venter”)—located in the midline, 4 tsun above the umbilicus (Fig. 48.1)
• CV 17 (tan chung; “chest center”)—located in the midline of the sternum, between the nipples, at the level of the fourth intercostal space (Fig. 48.1)
• LR 13 (zhang men; “camphor wood gate”)—located on the lateral side of the abdomen, below the free end of the 11th rib, 2 tsun above the navel and 6 tsun on either side of the midline (Fig. 48.2)
• GB 34 (yang ling quan; “young mound spring”)—located in the deep depression 1 tsun anterior and 1 tsun inferior to the head of the fibula (Fig. 48.3)
• GB 39 (xuan zhong or jue gu; “suspended bell or severed bone”)—located 3 tsun directly above the tip of the lateral malleolus in the depression between the posterior border of the fibula and the tendons of the peroneus longus and brevis (see Fig. 48.3)
• BL 11 (da zhu; “great shuttle”)—located 1.5 tsun lateral to the lower border of the spinous process of the first thoracic vertebra (Fig. 48.4)
• BL 17 (ge shu; “diaphragm shu”)—located 1.5 tsun lateral to the lower border of the spinous process of the seventh vertebra (Fig. 48.4)
• LU 9 (tai yuan; “great abyss”)—located at the transverse crease of the wrist in the depression on the lateral side of the radial artery (Fig. 48.5)
• **LI 4** (he gu; “union valley”)—located between the first and second metacarpal bones in the deep depression of the web space (Fig. 48.6)

• **PC 6** (nei guan; “internal gate”)—located 2 to 3 tsun above the transverse crease of the wrist, a deep depression between the tendons of the long palmar muscle and the radial flexor muscle of the wrist (Fig. 48.7)

• **ST 36** (zu san li; “leg three miles”)—located 3 tsun below the patella and 1 tsun lateral to the crest of the tibia (Fig. 48.8)

• **SP 6** (san yin jiao; “three yin intersection”)—located 3 tsun above the tip of the medial malleolus on the posterior border of the tibia (Fig. 48.9)
Numerous reports confirm that acupuncture has reproducible neurobiologic effects. Acupuncture inhibits the transmission of pain according to the gate control theory.\(^2\) It may act by stimulating sensory Aβ fibers and directly inhibiting the spinal transmission of pain by smaller Aδ and C fibers.\(^3\) Researchers have also been paying attention to the relationship between acupuncture and the production of endogenous opioid peptides, such as the endorphins and enkephalins, and stimulation of the endogenous descending inhibitory pathways. In an analysis of human cerebrospinal fluid, Sjolund and colleagues\(^4\) determined that endorphin levels in subjects become elevated following electroacupuncture. Acupuncture analgesia is caused mainly by activation of the endogenous antinociceptive system to modulate transmission of pain and the pain response.\(^5\)

Electroacupuncture at 2 Hz accelerates the release of enkephalin, β-endorphin, and endomorphin, whereas at 100 Hz it selectively increases the release of dynorphin. A combination of the two frequencies produces simultaneous release of all four opioid peptides, thereby resulting in a maximal therapeutic effect.\(^6\) Peripheral stimulation of the skin or deeper structures activates various brain structures, the spinal cord, or a combination via specific neural pathways.\(^7\) A human study by Mayer and associates indicated that acupuncture analgesia can be reversed by naloxone.\(^8\) Several serotonin antagonists inhibit the effects of electroacupuncture. Electroacupuncture attenuates behavioral hyperalgesia and stress-induced colonic motor dysfunction in rats.\(^9\) It also attenuates behavioral hyperalgesia and stress-induced colonic motor dysfunction in rats via serotonergic pathways.

Neuronal correlation to acupuncture stimulation in the human brain has been investigated with functional magnetic resonance imaging (fMRI). Acupuncture needle manipulation on the LI 4 (he gu) point modulates the fMRI activity of the limbic system and subcortical structure.\(^10\) Acupuncture stimulation at analgesic points involving the pain-related neuromatrix have been studied. Acupuncture stimulation at the GB 34 (yang ling quan) acupuncture point has elicited significantly higher activation than has sham acupuncture over the hypothalamus and primary somatosensory motor cortex and deactivation over the rostral segment of the anterior cingulated cortex.\(^11\)

**SIDE EFFECTS**

The use of disposable sterile acupuncture needles avoids the risk of cross-contamination. Occasionally, the patient may experience bruising at the acupuncture site. Mild transient drowsiness may also occur. Pneumothorax is the most frequently reported serious complication related to acupuncture.\(^12\)\(^13\) In a study of the cases of 78 acupuncturists involving 31,822 acupuncture treatments in the United Kingdom, the most common adverse events reported were bleeding (310/10,000 consultations) and needling pain (110/10,000 consultations).\(^14\) The York acupuncture safety study surveyed 34,000 treatments by traditional acupuncturists. Aggravation of symptoms occurred in 96 of 10,000 cases, but none of these events were serious. There was subsequent improvement in the main complaint in 70% of cases.\(^15\) Major adverse consequences of acupuncture appear to be extremely rare.\(^16\) Acupuncture can be considered safe when performed by a competent and experienced acupuncturist,\(^17\) including appropriately trained practitioners in the pediatric population.\(^18\)

**CLINICAL USE OF ACUPUNCTURE**

Acupuncture as a therapeutic intervention is currently practiced widely in the United States. In 1997, the National Institutes of Health\(^19\) concluded that there are promising results supporting its efficacy for adult postoperative and chemotherapy-related nausea and vomiting and for postoperative dental pain. There are reasonable studies concluding that the use of acupuncture results in satisfactory treatment of addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma. Depending on the situation, acupuncture may be used as an adjunctive treatment or acceptable alternative therapy or be integrated into a comprehensive management program.

Clinical research on the use of acupuncture for the treatment of pain has consisted primarily of uncontrolled trials. Although beneficial results have frequently been demonstrated, the flawed design of many of the studies places limited value on the outcomes. Systematic reviews of randomized controlled trials (RCTs) have provided the best evidence and the least bias in assessing the efficacy of any medical intervention. Several difficulties are inherent in designing valid, blinded RCTs of acupuncture.\(^20\)\(^21\) An appropriate placebo for the acupuncture control group is difficult to determine. Various studies have used placement of needles at nonmeridian sites, called “sham” acupuncture, to model acupuncture in control group patients.

Thirty percent of study subjects may respond positively to placebo. There are very few criteria in the current literature for the use of placebo in acupuncture research. Sham acupuncture is frequently used as the control treatment in research trials involving acupuncture; however, it presents a unique problem as a placebo. The well-outlined energy channels of the acupuncture meridian systems cover the entire body and link wei-qi (defense qi), rong-qi (growth and development qi), and yuan-qi (the original qi inherited at birth). Because the meridian systems affect the entire body, sham acupuncture still does provide some acupuncture effect and therefore cannot be considered to produce a true placebo effect. In an attempt to address this problem, a placebo acupuncture needle that retracts back into the handle of the acupuncture needle and does not penetrate the skin has been developed.\(^22\)

Richardson and Vincent\(^23\) reviewed 27 controlled studies of acupuncture for the treatment of acute and chronic pain, as well as several large uncontrolled studies. In 50% to 80% of the patients studied, they noted that it was difficult to assess the long-term effectiveness of acupuncture based on the collected data. In a meta-analysis of 14 RCTs of acupuncture for chronic pain in adults, Patel and coworkers\(^24\) found that although few of the individual trials demonstrated statistically significant benefit from acupuncture, the pooled
results for several subgroups did, in fact, attain statistical significance in favor of acupuncture.

**POSTOPERATIVE PAIN**

Acupuncture may be most useful in predictable situations involving acute pain, such as dental procedures and postoperative pain, or in the setting of medical conditions characterized by recurrent episodes of acute pain, such as sickle cell crisis and recurrent abdominal pain. Although effective treatment is available in many cases (e.g., local anesthetics for dental procedures, opioids for severe postoperative pain), side effects such as respiratory depression may occur. Taub and colleagues used acupuncture for the treatment of dental pain in a single-blind RCT in which 39 adult patients underwent dental restoration for cavities. Patients were randomized between real and sham acupuncture groups. Seventy percent of the experimental group and 53% of the control group reported good or excellent pain reduction. The results for the two groups showed no statistical significance. A systematic review has suggested that acupuncture is effective in relieving dental pain. Also, a study of the effect of acupuncture for pain after lower abdominal surgery revealed that preoperative treatment with low- or high-frequency electroacupuncture reduced postoperative analgesic requirements and decreased the side effects of systemic opioids.

Acupuncture has been shown to reduce postoperative opioid dose requirements in patients and to decrease discomfort. In a randomized, controlled, double-blind study of patients scheduled for elective upper and lower abdominal surgery, acupuncture was found to reduce postoperative pain. Consumption of supplemental intravenous morphine was reduced 50%, and the incidence of postoperative nausea was reduced 20% to 30%. Plasma cortisol and epinephrine concentrations were reduced 30% to 50% in the acupuncture group. In an RCT of electroacupuncture in 100 women undergoing lower abdominal surgery, the incidence of nausea and dizziness during the first 24 hours after surgery was significantly reduced in the electroacupuncture group when compared with the control and sham groups. Preoperative treatment with low- and high-frequency electroacupuncture reduced postoperative analgesic requirements and associated side effects. A study of 27 patients with operable non–small cell lung carcinoma who underwent either electroacupuncture or sham acupuncture for control of post-thoracotomy pain revealed that electroacupuncture may reduce narcotic analgesic use in the early postoperative period. In a study of 36 patients undergoing thoracotomy, epidural and intradermal insertion of acupuncture needles was well tolerated by the patients and did not interfere with standard preoperative care.

In a study of pediatric patients undergoing bilateral myringotomy tube placement, acupuncture treatment provided a significant benefit in alleviating pain and reducing agitation. The median time until the first postoperative administration of an analgesic, acetaminophen, was significantly shorter in the control group. The number of patients who required analgesia was considerably smaller in the acupuncture group than in the control as well. No adverse effects related to the acupuncture treatment were observed. A systematic review was performed to quantitatively evaluate the efficacy of acupuncture and related techniques as adjunctive analgesics for the management of acute postoperative pain. Fifteen RCTs compared acupuncture with sham control for the management of acute postoperative pain. The acupuncture treatment group had a lower incidence of opioid-related side effects, such as nausea, dizziness, sedation, pruritus, and urinary retention. Perioperative acupuncture may thus be a useful adjunct for acute postoperative pain management.

**NAUSEA AND VOMITING**

Acupuncture performed with acupuncture needles, an electrical apparatus, pressure, or magnets is commonly used for the management of nausea and vomiting after surgery or chemotherapy. Stimulation of the PC 6 (nei guan) acupuncture point is also used to treat nausea and vomiting caused by sea sickness or pregnancy and to treat side effects from surgery or chemotherapy. A systematic review revealed that beneficial results were achieved in 27 of 33 RCTs of acupuncture, acupressure, or both for the treatment of nausea and vomiting. An RCT of pediatric patients undergoing tonsillectomy in whom electroacupuncture was used for control of nausea showed a significant reduction in the occurrence of nausea when compared with the sham and control groups. This study demonstrated that the efficacy of acupuncture for prevention of postoperative nausea and vomiting is similar to that achieved with commonly used pharmacotherapies. These results have been most consistent with its use for postoperative nausea and vomiting. In 26 trials studying the care of more than 3000 patients, stimulation of the PC 6 acupuncture point was superior to sham acupuncture for the treatment of nausea and vomiting in both adults and children.

**LOW BACK PAIN**

In a meta-analysis of 12 RCTs, acupuncture was found to be superior to various control interventions for the management of low back pain. An RCT of acupuncture versus transcutaneous electrical nerve stimulation for chronic low back pain in the elderly revealed that both were equally effective, with acupuncture improving spinal flexion. An RCT of 50 patients with low back pain showed a significant decrease in pain intensity at 1 and 3 months in the acupuncture groups in comparison to the placebo group. Acupuncture treatment significantly shortened the time that patients were out of work, improved their quality of sleep, and decreased analgesic intake. An RCT revealed significant improvement in chronic low back pain with traditional acupuncture versus physiotherapy, but not versus sham acupuncture. Benefits included decreases in pain intensity, pain disability, and psychological distress at the end of 12 weeks of treatment. At the 9-month follow-up, the superiority of acupuncture over the control group had lessened. An RCT of 298 patients with low back pain revealed that acupuncture was more effective than no acupuncture treatment in improving pain, but there were no significant differences between acupuncture and minimal acupuncture.

A meta-analysis of 33 RCTs of acupuncture for low back pain indicated that acupuncture effectively relieves chronic low back pain. An RCT of 241 patients with low back pain revealed that a short course of treatment by a qualified traditional acupuncturist is a safe and acceptable method of pain
management. Additionally, acupuncture care for low back pain is a cost-effective therapy in the long term.

HEADACHE

Several studies have shown acupuncture therapy to be efficacious for migraine headache. In an RCT of 168 women with migraine, acupuncture was found to be adequate for migraine prophylaxis. When compared with flunarizine therapy, acupuncture treatment exhibited greater effectiveness in the first months of therapy and superior tolerability. A prospective, randomized, double-blind study has shown the efficacy of acupuncture for migraine prophylaxis. The reduction of migraine days in patients receiving acupuncture treatment was statistically significant in comparison to baseline. Treatment outcomes for migraine do not differ between patients treated with acupuncture or standard therapy. A systematic review of 22 trials involving a total of 1042 patients concluded that acupuncture has a role in the treatment of recurrent headaches. In an RCT of 179 patients with acute migraine, acupuncture and sumatriptan were more effective than placebo injection for the early treatment of an acute migraine attack. An RCT of 114 patients with migraine compared acupuncture with the use of metoprolol and determined that acupuncture might be an effective and safe treatment option for patients unwilling or unable to use drug prophylaxis.

Supplementing medical management with acupuncture can result in improvement in health-related quality of life, as well as the perception by patients that they suffer less from their headaches. A Cochrane Database Systematic Review of acupuncture for migraine prophylaxis involved 22 trials with 4419 participants. The available studies suggested that acupuncture is at least as effective as or possibly more effective than prophylactic drug treatment and has fewer adverse effects. Acupuncture should be considered as a treatment option for patients with migraine headaches. A Cochrane Database Systematic Review of 11 trials with 2317 participants also indicated that acupuncture can result in at least a 50% reduction in headache frequency, headache days, pain intensity, and analgesic use. Acupuncture could be a valuable nonpharmacologic tool for patients with frequent episodic or chronic tension-type headaches.

TEMPOROMANDIBULAR JOINT DYSFUNCTION

Three RCTs of acupuncture treatment involving 205 patients with temporomandibular joint dysfunction revealed positive results. Acupuncture appears to be an effective treatment of painful dysfunction of the temporomandibular joint, but the results still require confirmation from more rigorous trial methods.

NECK PAIN

Several clinical reports have suggested that acupuncture can be useful for the treatment of patients with neck pain. However, 14 RCTs involving 724 subjects with various causes of neck pain did not provide significant evidence in support of acupuncture for the treatment of neck pain. There have been too few studies of sufficient quality and homogeneity to be able to draw conclusions about its effectiveness as treatment. A scoring system to gauge the effects of acupuncture on neck pain has been proposed, but there are problems with its use. In an RCT of 177 individuals with chronic neck pain, patients were randomly assigned to treatment with acupuncture (56 patients), massage (60 patients), or “sham” laser acupuncture (61 patients) over a period of 3 weeks. The patients received five acupuncture treatments during this 3-week period, and acupuncture was found to be an effective short-term treatment. An RCT of acupuncture in 123 patients with chronic neck pain revealed that at 6 months of follow-up, acupuncture was more effective than placebo treatment. Acupuncture treatment improved the patient’s quality of life from a physical aspect, improved active neck mobility, and reduced the need for rescue medication. There is some evidence that acupuncture relieves neck pain more effectively than sham treatment or no treatment does.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is one of the most common causes of chronic musculoskeletal pain. Melzack and colleagues reported a 71% correlation between acupuncture points and trigger points used for the treatment of myofascial pain. An uncontrolled study, Lewit reported immediate relief in 87% of cases and long-term benefit in at least 92% of 288 patients.

KNEE PAIN AND OSTEOARTHRITIS

Osteoarthritis of the knee is a common joint disorder, especially in women older than 50 years. In a randomized controlled trial of 570 patients with osteoarthritis of the knee, patients underwent 23 weeks of acupuncture treatment. Acupuncture seemed to provide improvement in function and pain relief as an adjunctive therapy when compared with sham acupuncture and education control groups. A systematic review and meta-analysis of 13 RCTs of acupuncture for knee pain revealed acupuncture to be significantly superior to sham acupuncture in both pain control and regaining function. The differences were still significant at long-term follow-up.

LOW BACK PAIN

Low back pain limits daily activities and is a common reason for physician visits. Acupuncture is widely used by patients with low back pain. A meta-analysis of 33 RCTs of acupuncture for low back pain indicated that acupuncture is significantly more effective than sham treatment and no treatment. A study of 298 patients with chronic low back pain compared acupuncture, minimal acupuncture (superficial needling at nonacupuncture points), and a waiting list group as the control. Low back pain was shown to improve after acupuncture treatment for at least 6 months. The effectiveness of acupuncture, either verum or sham, was almost twice that of conventional therapy.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is a common entrapment neuropathy of the median nerve. Eleven patients with mild to moderate carpal tunnel syndrome were randomized into groups receiving real or sham laser acupuncture treatment.
Significant decreases in the McGill Pain Questionnaire score, median nerve sensory latency, and Phalen’s and Tinel’s signs after the actual laser acupuncture treatment series were observed, but not in the placebo group. A study of fMRI in patients with carpal tunnel syndrome revealed that hyperactivity in the contralateral sensorimotor cortex diminishes after acupuncture treatment.

NEUROPATHIC PAIN

The efficacy of acupuncture in patients with peripheral neuropathy is unclear. Peripheral neuropathy is common in patients infected with human immunodeficiency virus (HIV). Neither acupuncture nor amitriptyline was found to be more effective than placebo in relieving pain caused by HIV-related peripheral neuropathy. Reports are available on the benefits of traditional acupuncture therapy and auricular therapy in treating complex regional pain syndrome, formerly known as reflex sympathetic dystrophy. However, each of these reports involved only one to five patients in uncontrolled studies.

REFERRING PATIENTS FOR ACUPUNCTURE TREATMENT

Differentiating between disease and illness is important. A disease is what physicians diagnose, whereas an illness is what the patient feels or suffers. There are many diseases for which there is no cure, but acupuncture can be used as a complementary intervention for the associated illnesses or for the side effects related to conventional medical therapies. Licensing guidelines for the practice of acupuncture are determined by each state. The National Commission for the Certification of Acupuncturists has developed standards for training and certification of licensed acupuncturists, and the American Board of Medical Acupuncture has established guidelines and qualification requirements for physicians to practice medical acupuncture.

Over the past several years the use of traditional Chinese medicine has become more common and accepted in the United States. Some health maintenance organization insurance plans have begun to cover acupuncture treatments for their patients. Some workers’ compensation boards and personal injury insurance policies will also cover acupuncture. If there is an increase in the number of insurers willing to reimburse acupuncture therapy, patients will be more likely to seek acupuncture treatment in the future.

How can we best advise patients with pain-related disorders who are interested in acupuncture? The pain service practitioner should discuss with patients what their treatment preferences and expectations of outcome are. It is also essential to review the safety and efficacy of the therapy thoroughly with patients. Patients should be referred to qualified acupuncture providers, and follow-up appointments should also be scheduled to monitor response to treatment.

Acupuncture is steadily becoming an integral part of the health care delivery system. Research on acupuncture has allowed its integration into conventional Western medical practice. More prospective, randomized, and controlled studies on acupuncture are needed to better understand its mechanisms, efficacy, and side effects.

KEY POINTS

- Acupuncture is part of traditional Chinese medicine. The practice of acupuncture includes electroacupuncture, laser acupuncture, moxibustion, cupping, Chinese tui na massage, Gua Sha, and acupressure.
- The theory of yin and yang is essential in traditional Chinese medicine. Yin and yang are natural phenomena that exist within the body. They are interdependent and can be transformed into each other. They exist in a constant state of dynamic balance.
- Optimal physical condition requires a balance of yin and yang within the body. Disease is associated with a disharmony or imbalance between yin and yang.
- Acupuncture can be considered safe when performed by competent and experienced licensed providers.
- Acupuncture as a therapeutic intervention is widely practiced in the United States. There are promising results supporting its efficacy for adult postoperative and chemotherapy-related nausea and vomiting and for postoperative dental pain. There are reasonable studies that conclude that the use of acupuncture results in satisfactory treatment of addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma.
- Acupuncture may be used as a complementary treatment or acceptable alternative therapy or be integrated into a comprehensive management program.
- The LI 4, he gu, acupuncture point is located between the first and second metacarpal bones in the deep depression of the web space.
- The PC 6, nei guan, acupuncture point is located three fingerbreadth proximal to the transverse crease of the wrist, a deep depression between the tendons of the long palmar muscle and the radial flexor muscle of the wrist.

44. Radcliffe M. Acupuncture compared to the other alternative therapies. Nurs Times. 2006;102:124.

Integrative medicine is a philosophy of care that integrates conventional allopathic medical therapies with modalities not typically included in conventional care and addresses the physical, emotional, and spiritual needs of the patient. This field of medicine is sometimes referred to as complementary medicine or complementary and alternative medicine (CAM). However, these terms refer more precisely to modalities such as acupuncture, meditation, nutritional supplements, and massage, all of which may be included in the integrative medicine “tool box.” In 2005 the Consortium of Academic Health Centers for Integrative Medicine defined integrative medicine as follows:

“The practice of medicine that reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, health-care professionals and disciplines to achieve optimal health and healing.

The use of complementary medicine modalities in the United States is increasing. One study found that 62% of adults had used some form of complementary therapy in the previous 12 months. The most commonly used CAM therapies were prayer for the improvement of health, natural products, deep breathing exercises, meditation, chiropractic care, yoga, massage, and diet-based therapies. It is estimated that in 1997, between $36 and $47 billion was spent on CAM therapies in the United States.

Pain syndromes, such as chronic back pain, appear to be increasing and are associated with significant health care costs. Unresolved pain has a wide-reaching impact in that it affects physical, emotional, and spiritual wellness and has a negative impact on social and occupational functioning. Integrative medicine, which adopts a mind-body approach to the treatment of pain and uses multiple effective CAM modalities, is well suited to address chronic pain syndromes. In 2002, 6% of the U.S. population used complementary medicine modalities for the treatment of back pain and 60% of respondents who used CAM for back pain perceived a “great deal” of benefit.

Perception of pain is multifactorial and involves a complex interplay between the peripheral and central nervous systems. As pain signals reach the brain from the periphery, the brain can modify these signals by activating inhibitory pathways and releasing substances such as endorphins and neurotransmitters. Alternatively, the brain can magnify nociceptive signals if they are perceived to be threatening, thus increasing the perception of pain. Connections between the cerebral cortex and the limbic system allow the brain to give meaning to the pain experience. It is this connection between emotions and pain perception that forms the basis of the mind-body approach to pain. Psychological factors such as the tendency to catastrophize have been associated with chronic pain, and the literature suggests a clear link between psychological variables and neck and back pain. Life stress in childhood or adulthood can be associated with adult pain syndromes, and anxiety and chronic pain often coexist. Depression and pain are related, with each negatively affecting the other and negative emotional states of any kind can increase the severity of pain. Even brief interventions designed to address the emotional components of pain have been effective in decreasing its severity.

Using real-time functional magnetic resonance imaging (fMRI) to guide training, subjects were able to learn to control regions of the brain involved in pain perception and regulation, specifically, the rostral anterior cingulate cortex (rACC). When activation of the rACC was intentionally increased or decreased, there was a simultaneous change in the perception of pain from an experimentally induced pain. Subjects who trained with sham real-time fMRI did not show a similar change in pain perception. In addition, chronic pain patients who were trained to control activation of the rACC reported decreased levels of chronic pain after training. This experiment illustrates that patients can learn to control specific regions of the brain that are involved in pain perception, thus learning to exert control over their own pain. This is a form of biofeedback and contributes to scientific understanding of the mind-body connection.

Neuroimaging studies have shown that social pain and physical pain are reflected similarly in the brain. In one study, subjects played a virtual game that elicited feelings of being excluded. The rACC showed an increase in activity during exclusion—physiologic changes that are similar to those seen with physical pain. In addition, hypnotic suggestion of pain has been shown to create changes on fMRI in the rACC, thalamus, insula, prefrontal cortex, and parietal cortex, which are also influenced by pain originating in peripheral tissues. This suggests that pain initiated by the brain has significant similarity to pain originating in the periphery. This concept highlights the mind-body connection and is important for understanding and treating patients with acute and chronic pain.
INTEGRATIVE MEDICINE MODALITIES AND PAIN

Varied complementary medicine techniques have shown benefit in the treatment of pain. Domains such as traditional Chinese medicine (TCM), mind-body medicine, manual medicine, and others have an increasing body of evidence supporting their use for management of pain. The most commonly used and well-supported modalities are discussed in the following sections.

ACUPUNCTURE AND TRADITIONAL CHINESE MEDICINE

TCM is an inclusive medical system based on 3000-year-old ancient texts. It incorporates varied treatment modalities, including acupuncture, acupressure, Chinese herbal medicine, meditative movement such as tai chi and qi gong, moxibustion, cupping, and specialized massage techniques referred to as tui na.

Acupuncture and TCM are based on the theory that health is determined by the balance of vital energy flow, called qi (pronounced “chi”), which is thought to be present in all living creatures. TCM uses concepts such as yin and yang and dampness and wind, which have no equivalents in conventional medicine and are therefore difficult to explain in standard medical terms. "Yin” represents the concept of cold, slow, and passive, whereas “yang” represents energy that is hot, fast, and active. Health is believed to be based on a balance of these and other opposing forces, such as dampness and dryness, and to require free flow of qi. Disease is thought to arise from an imbalance in these forces. Imbalance leads to blockage of qi (vital energy) along specified pathways. In all organisms, qi is believed to flow through particular channels called meridians, and TCM therapies are used to unblock the flow of qi. Unlike conventional medicine, treatment plans are highly individualized and based on an individual’s constitution, as assessed by the TCM provider, as well as on the individual’s symptoms. Thus, two patients with identical complaints might receive entirely unique treatment plans based on their baseline characteristics.

Acupuncture points are located along the recognized meridians, and the process of acupuncture involves the insertion of thin needles into these points. Although meridians cannot be visualized anatomically, acupuncture points often correspond to depressions in muscles, bones, or neural foramina and may have their own neurovascular bundle that distinguishes the acupuncture point from surrounding tissue. They are often palpable and may be tender to palpation.

The mechanism of action of acupuncture, from a conventional medicine point of view, has not been unequivocally determined. Theories on the efficacy of acupuncture include release of endorphins and neurotransmitters, enhanced local immune response, enhanced circulation and smooth muscle relaxation, stimulation of tissue growth and repair, and spinal and peripheral nerve stimulation. Substantial evidence supports the theory that acupuncture creates physiologic change at the site of needle insertion, in the cerebral cortex, and in the release of hormones and endorphins. Endorphin levels in cerebrospinal fluid have been shown to rise after acupuncture treatment.

Despite abundant evidence supporting the use of acupuncture for varied medical conditions, there are particular challenges in conducting research on acupuncture that may affect the results. Acupuncture has no true placebo control, and sham acupuncture has sometimes been shown to be as effective as true acupuncture. Inserting needles in “sham” acupuncture points might elicit physiologic changes, and even sham acupuncture needles that press but do not puncture the skin may approximate the effects of acupressure if they are used at specified acupuncture points. In addition, standardized acupuncture treatments are often used in research in an effort to provide a standardized and replicable approach. That is, all patients with back pain would receive acupuncture at the same acupuncture points. However, this does not replicate the individualized treatment approach to acupuncture used in practice, thus creating a research environment that does not reflect real-life conditions.

Acupuncture is used for a wide variety of health conditions and is also used by those without specific symptoms to maintain optimal health. It is most commonly used for relief of musculoskeletal pain. A 2001 review on acupuncture safety found that minor adverse events were common but serious adverse events were rare. The most commonly reported adverse events were needle pain (1% to 45%), tiredness (2% to 41%), nausea or vomiting (0.01% to 0.2%), and slight bleeding or bruising (0.03% to 38%). Feeling faint was very rare (0% to 0.3%), and pneumothorax was extremely rare—occurring only twice in nearly a quarter of a million treatments.

Laws concerning the practice of acupuncture are defined by each state. Practitioners may include licensed acupuncturists who have completed more than 1000 hours of training at a college of Oriental medicine or masters-level program, chiropractors who may receive some training within their professional course of study and may choose to pursue additional postgraduate training, and physicians and dentists who pursue acupuncture training after completing their professional programs. Most programs targeted to physicians, chiropractors, and dentists include approximately 200 to 400 hours of training. Board certification is available to physicians through the American Board of Medical Acupuncture. Acupuncture styles differ and can include traditional Chinese acupuncture, five-element acupuncture, Korean or Japanese acupuncture, and auricular acupuncture. Evidence of superiority of one form over the others is not available.

A Cochrane review on acupuncture for pain found that it was effective for migraines, neck disorders, tension-type headaches, and peripheral joint osteoarthritis. One well-designed randomized controlled trial of acupuncture for the treatment of knee osteoarthritis involved 507 patients recruited from two university outpatient clinics. The patients were randomized into one of three groups: true acupuncture, sham acupuncture, or education control. The primary outcomes measured were changes in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain and function scores at 8 and 26 weeks. Secondary outcomes were patient global assessment, 6-minute walk distance, and physical health scores on the 36-Item Short-Form Health Survey (SF-36). Participants in the true acupuncture group experienced significantly greater...
improvement in the WOMAC function score than did both the sham acupuncture and education groups at 8 weeks, but not in the WOMAC pain score or patient global assessment. At 26 weeks, the true acupuncture group experienced significantly greater improvement than did the sham and education groups in the WOMAC function score, WOMAC pain score, and patient global assessment. The authors concluded that acupuncture can be used as adjunctive therapy for the treatment of knee osteoarthritis. Another randomized controlled trial in which acupuncture was added to advice and exercise in patients with osteoarthritis showed only small improvements in pain and no superiority of true acupuncture over sham acupuncture.

A recent Cochrane review of acupuncture revealed that sham-controlled trials show statistically significant benefits; however, these benefits are small and may be due partly to placebo effects from incomplete blinding. Acupuncture has been shown to improve chronic low back pain symptoms in some studies, but not in others. However, another Cochrane review of acupuncture for the treatment of chronic tension-type headache suggested that acupuncture could be a valuable nonpharmacologic tool for patients with frequent episodic or chronic tension-type headache. A recent meta-analysis using individual patient data evaluated the efficacy of acupuncture for the treatment of chronic pain. Data from 29 studies of back and neck pain, osteoarthritis, chronic headache, and shoulder pain were evaluated, and true acupuncture was found to be more effective than either sham acupuncture or nonacupuncture control in decreasing pain.

Thus, although the evidence is suggestive that acupuncture is beneficial for the treatment of varied pain syndromes, the picture is not entirely clear. Expectation of benefit, possible physiologic action of supposed sham controls, different styles of acupuncture, and acupuncture research protocols that may not match the “real-life” practice of acupuncture all create some uncertainty regarding the effectiveness of acupuncture for the treatment of pain. On the other hand, a mounting body of evidence suggests acupuncture to be beneficial when added to conventional care, with clear evidence of safety.

MIND-BODY MEDICINE

The term mind-body medicine does not refer to a specific treatment modality; rather, it refers to a group of modalities that are unified by the underlying concept of an intricate connection between the mind and the body. The physical, emotional, spiritual, and social aspects of our lives have an impact on health and well-being, and dysfunction in one domain can lead to dysfunction in another. Mind-body medicine asserts that the mind can positively affect the body in the pursuit of health and wellness. Our daily experience makes it clear that the mind can affect physiology. Blushing from social embarrassment results from increased blood flow to the face, frightening movies can increase cardiovascular vital signs, and sexually stimulating visual material can increase blood flow to the penis. Similarly, psychological stress can lead to clear physiologic changes, most of which are potentially harmful. Chronically elevated blood pressure, muscular tension leading to headaches or neck pain, and the increased incidence of chronic pain syndromes may all be associated with stress. Pain and stress are interconnected, and a vicious cycle is often generated in which pain causes stress and subsequently stress causes more pain. Mind-body techniques can provide an improved ability to cope with pain, decreased perception of pain, and an increased sense of well-being and relaxation. The psychological tendency to catastrophize has been associated with increased pain perception, and mind-body techniques can help temper this anxious state.

The relaxation response is a physical state or reaction that counteracts the physiologic and emotional responses to stress and is essentially the opposite of the fight-or-flight response. It was first described by Herbert Benson and colleagues at Harvard Medical School in the 1970s. Just as eliciting the stress response can generate unhelpful physiologic changes, eliciting the relaxation response can result in health-inducing physiologic effects. The relaxation response is different from simply relaxing with a book or in front of the television. Although these activities may be considered “relaxing,” they do not generate the physiologic changes associated with the relaxation response. The relaxation response is elicited by focusing the mind on a particular word, phrase, breath, image, or action and adopting a passive attitude toward one’s thoughts. Modulation of cardiovascular parameters, muscular relaxation, and normalization of stress hormones such as cortisol, epinephrine, and norepinephrine are all associated with the relaxation response.

Mind-body techniques are varied and become easier to do with practice. Techniques include abdominal breathing, meditation, guided imagery, biofeedback, yoga, tai chi, qi gong, therapeutic arts, and even prayer. No mind-body technique is intrinsically more effective than another, and all can be used to decrease stress and elicit the relaxation response. Some involve movement and stretching, whereas others are practiced in seated or recumbent positions. They can be performed in groups, with an individual instructor, or alone. Patients may choose to try different mind-body techniques to find one, or several, that they prefer. Mind-body techniques have been shown to be helpful for varied conditions such as osteoarthritis, rheumatoid arthritis, headaches, procedural pain, and stress management. Specific mind-body techniques are described in the ensuing paragraphs.

PROGRESSIVE MUSCLE RELAXATION

Progressive muscle relaxation is a technique commonly used for eliciting the relaxation response and relieving muscular tension. It is easy to learn and is accessible even to people who may not be familiar with or interested in meditation. It involves sequentially relaxing various muscle groups, often starting at the head and moving down the body to the feet. Participants may tense a muscle before relaxing it (for example, clenching the jaw and then releasing it) or simply bring their attention to a muscle group and intentionally relax it. A sample progressive muscle relaxation script is provided in Appendix A.

MEDITATION

The term meditation refers to a broad variety of practices that are similar in form but may be quite distinct in intention. Depending on the culture and tradition of the meditator, meditation may be used to induce relaxation, increase
vital energy ("qi" or "prana"), attain closeness to God, or induce a state of contemplation or ultimate consciousness. Many religious faiths, both Western and Eastern, include meditative practices within their traditions, and in the past 40+ years, more secular versions of meditation have gained popularity. These forms of meditation are generally considered relaxation techniques, and they involve an intentional focus on the act of breathing, a sound, an object, a phrase, or a movement. The goal of these forms of meditation is generally to increase awareness of the present moment, elicit the relaxation response, reduce stress, and enhance personal growth.

Two common forms of meditation used in the West are mindfulness meditation and concentrative meditation. In mindfulness meditation, participants direct their full attention to their breathing by focusing on each inhalation and exhalation. When thoughts, feelings, or sensations arise, the meditator simply notices and accepts them non judgmentally and brings attention back to the breath. In concentrative meditation, attention is focused intensely on one thing such as an object (a candle) or a sound or on a word or phrase, which is repeated silently with each breath cycle. Common words and phrases might include "peace" with inhalation and "love" with exhalation or "all will/be well."

Practicing focused attention in the present moment and nonjudgmental acceptance of experiences or thoughts decreases the mind’s tendency to worry about the future or ruminate about the past. It has also been found to be useful in pain conditions. In one interesting study of experimental pain, subjects were taught mindfulness meditation, which they practiced 20 minutes daily for 3 days. The investigators measured pain sensitivity before and after meditation training and found decreased sensitivity after 3 days of meditation. The authors believed that the increased ability to tolerate pain was related to decreased anxiety and an increased ability to focus on the present moment.

Mindfulness meditation has also been used successfully in older adults with chronic low back pain. Patients were randomized to an 8-week mindfulness meditation group or a wait-list control. The meditators had statistically significant improvements in pain acceptance, activity engagement, and physical functioning. Qualitative assessment of the same subjects revealed that meditation was beneficial for pain, sleep, attention, and well-being. It has also been shown to decrease the severity of bowel symptoms in women with irritable bowel syndrome, with benefits lasting for at least 3 months after mindfulness training.

GUIDED IMAGERY

Guided imagery is the generation of specific mental images to evoke a state of relaxation or physiologic change. It takes advantage of the communication links between the mind and the body and uses the imagination to generate intentional physiologic states, such as relaxation or relief of pain. It can be performed with a therapist and patient in person or by a patient alone listening to a recording.

One study of fibromyalgia patients randomized subjects to either 6 weeks of daily guided imagery audiotapes or usual care. People in the guided imagery group had statistically significant improvements in their ability to cope with fibromyalgia, with a decrease in the Fibromyalgia Impact Questionnaire (FIQ) score and increased self-efficacy in managing pain. Interestingly, the imagery dose was not significantly associated with outcome. This lack of dose-response relationship suggests that even using guided imagery infrequently might be beneficial. Guided imagery has also been shown to be beneficial for tension-type headache, recurrent abdominal pain in children, and musculoskeletal pain, although large, higher-quality studies are needed to confirm these results.

There is suggestive evidence that guided imagery is helpful in the perioperative period. It has been shown to reduce length of hospital stay and pharmacy costs and to decrease postoperative pain. A study of patients undergoing colorectal surgery showed that guided imagery significantly reduced postoperative pain, anxiety, and narcotic requirements while increasing patient satisfaction.

HYPNOSIS

Hypnosis involves leading the patient into a focused, trance-like state. By concentrating attention intensely on one specific thought, memory, feeling, or sensation and blocking out all distractions, patients become calm, relaxed, and open to hypnotic suggestion. Health-inducing suggestions can be offered, including a decrease in anxiety or pain. Patients’ free will remains intact during hypnosis, and they cannot be led against their will to actions that are dangerous to themselves or others.

There is evidence supporting the use of hypnosis for various pain syndromes such as chronic pain, cancer, osteoarthritis, sickle cell disease, temporomandibular disorder, fibromyalgia, non–cardiac-related chest pain, and disability-related chronic pain. In a review of hypnosis for procedure-related pain in children, hypnosis was consistently found to be more effective than control conditions in alleviating the discomfort of bone marrow aspiration, lumbar puncture, voiding cystourethrogram, the Nuss procedure, and postsurgical pain. Hypnosis decreased anxiety and depressed mood in patients about to undergo excisional breast biopsy.

YOGA

Yoga originated in India but is now widely practiced throughout the world and is generally used to improve relaxation, strength, and flexibility. Yoga’s combined focus on mindfulness, breathing, and physical movements is health inducing for the mind and the body. Several styles of yoga are commonly practiced in the United States, including Hatha, Vinyasa, Ashtanga, Iyengar, Anusara, and Bikram, and each has unique intentions and techniques. Hatha yoga may be more appropriate for beginners, whereas Ashtanga yoga tends to be more physically demanding. “Power yoga” classes are appropriate for people seeking aerobic exercise, and they are often modifications of the Ashtanga style. Bikram yoga, often referred to as “hot yoga,” is practiced in a room heated to between 95° F and 100° F, and Iyengar yoga is particularly concerned with bodily alignment.

Yoga is often used as a relaxation practice, but it has also been shown to be helpful for pain conditions. In one study, yoga was found to be more effective than a self-care book but equal to a stretching regimen in relieving chronic low back pain. The benefits lasted for several months. Iyengar yoga was also found to reduce pain intensity, functional disability, and depression, and patients with chronic low back pain were found to have increased pain tolerance and self-efficacy after practicing yoga.
pain showed a trend toward decreased use of pain medica-
tion when compared with controls.\textsuperscript{45} Six months after
the intervention, the yoga group still showed decreased func-
tional disability, pain intensity, and depression when com-
pared with the control group.

In a systematic review of yoga interventions, 9 of 10 ran-
donized controlled trials suggested that yoga leads to a
significantly greater reduction in pain than do the various
control interventions, such as standard care, self-care, thera-
peutic exercises, touch and manipulation, or no interven-
tion. The authors noted, however, that study quality was less
than ideal and definitive judgment was not possible.\textsuperscript{46}

TAI CHI AND QI GONG

Tai chi and qi gong are ancient meditative movement tech-
niques that combine standardized physical movements
with meditation and relaxation breathing techniques. They have been used for thousands of years in China and
as part of TCM theory and are thought to unblock and bal-
ance vital energy (“qi”). In the United States, tai chi and
qi gong are often used to relieve stress, improve balance,
and reduce pain. These techniques use conscious, often
slow movements and focus on goals different from those
of conventional Western exercise, such as developing con-
sciousness within the body and enhancing the smooth flow
of energy.

One study found that tai chi improves immunity and
resistance to the virus that causes shingles in older adults,\textsuperscript{47}
and several have shown benefits in alleviating osteoarthritis
symptoms.\textsuperscript{48-50} A Cochrane review of the medical literature
showed that tai chi may be helpful in rheumatoid arthritis
patients by increasing range of motion of the ankle, hip, and
knee. Patients enjoyed the exercise and reported subjective
improvement.\textsuperscript{51}

Practice of qi gong has been shown to decrease weight,
wast circumference, and insulin resistance and to increase
leg strength.\textsuperscript{32} It might therefore be useful for patients with
weight- and deconditioning-related painful conditions such
as knee osteoarthritis, although in a meta-analysis of inter-
nal qi gong it was not shown to improve chronic pain syn-
dromes.\textsuperscript{53} Very few high-quality studies of qi gong for pain
have been published, and thus more evidence is needed to
evaluate the utility of qi gong for pain conditions.

A recent review of the medical literature found significant
beneficial health effects of tai chi and qi gong. The authors
reviewed 77 articles reporting the results of 66 random-
ized controlled trials of the health effects of tai chi or qi
pong in more than 6000 patients. Control groups included
nonexercise controls, exercise controls, or both. The most
convincing evidence of health benefits in this review was for
bone density, cardiopulmonary fitness, prevention of falls,
balance, quality of life, and self-efficacy.\textsuperscript{54}

Tai chi has also been shown to benefit patients with fibro-
myalgia. A single-blind, randomized trial of tai chi versus an
attention control was recently published in the \textit{New England
Journal of Medicine}.\textsuperscript{55} The intervention group received tai
chi instruction and practiced twice per week for 12 weeks,
whereas the control group received an equivalent amount
of wellness education and stretching. Subjects who prac-
ticed tai chi had highly statistically significant decreases in
FIQ scores, and the benefit was maintained at 24 weeks. No
adverse events were noted.

THERAPEUTIC ART AND MUSIC

Creative arts can be used in the therapeutic environment to
relieve stress, anxiety, and pain in patients and caregiv-
ers.\textsuperscript{56,57} Art therapy has been used to stimulate relaxation
in the palliative care setting, as distraction from the nega-
tive side effects of bone marrow transplantation\textsuperscript{58}
and to increase patient empowerment.\textsuperscript{59}

Music therapy was more effective in decreasing anxiety
in ventilated patients in the intensive care unit than was
an uninterrupted period of rest,\textsuperscript{60} and it was more effective
than treatment as usual or scheduled rest in decreasing
anxiety, pain, and pain-related distress in patients after open
heart surgery.\textsuperscript{61} Patients randomly assigned to music during
colposcopy had decreased pain and lower anxiety than did a
non–music therapy group.\textsuperscript{62}

A Cochrane review of music therapy in people with can-
cer assessed 30 trials with a total of 1891 participants. They
used music from multiple sources, including recorded music
and music provided by trained music therapists, and found
that music interventions may have beneficial effects on pain,
anxiety, mood, and quality of life in people with cancer.\textsuperscript{64}

ENERGY MEDICINE

Energy medicine modalities, sometimes called biofield ther-
apies, are based on the idea that all living creatures have
energy that can be manipulated in the pursuit of health by
a trained practitioner.

A recent 3-year study of 118 chemotherapy patients inves-
tigated the role of Reiki in the management of anxiety, pain,
and global wellness in cancer patients. Pain and anxiety
were evaluated with a visual analog scale (VAS). In patients
who received the full treatment course (four Reiki sessions),
mean VAS anxiety scores decreased from 6.77 to 2.28, which
was a highly significant result. Mean VAS pain scores also
decreased from 4.4 to 2.32, but this did not reach statistical
significance.\textsuperscript{63} Another small study of the use of Reiki in
community-dwelling older adults found significant improve-
ments in pain, depression, and anxiety in patients who
received Reiki,\textsuperscript{65} whereas another found a highly significant
reduction in pain of varied causes after Reiki treatment.\textsuperscript{66}

A Cochrane review of touch therapies for pain evaluated
the evidence for the efficacy of therapeutic touch, healing
touch, and Reiki. Randomized controlled trials or controlled
clinical trials evaluating the effect of touch on any type of
pain were included. Twenty-four studies involving 1153 par-
ticipants met the inclusion criteria, and only studies using
a sham placebo or a “no treatment” control were included.
Small, but statistically significant effects were found in
patients receiving touch therapy. Interestingly, experienced
practitioners of Reiki appeared to be slightly more effective.
Two of the five studies evaluating analgesic use suggested
that touch therapies minimized analgesic use.\textsuperscript{68}

Despite the presence of evidence suggesting that Reiki
and related therapies are effective in controlling pain, the
evidence is contradictory. Distant Reiki was not found to be
effective in controlling pain in women after cesarean sec-
tion.\textsuperscript{69} A review of the Reiki literature found that most trials
suffered from methodologic flaws such as small sample size,
inadequate study design, and poor reporting. The authors
concluded that the evidence is insufficient to suggest that
Reiki is an effective treatment of any condition.\textsuperscript{70} In another
systematic review, 9 of the 12 trials detected a significant therapeutic effect of the Reiki intervention. However, using the Jadad quality score, 11 of the 12 studies were ranked “poor.” Thus, although Reiki is probably safe and may be effective in relieving pain and anxiety, higher-quality studies are needed to clarify its clinical indications.

**MANUAL THERAPIES**

The term *manual therapy* is nonspecific and refers to techniques that use the hands to diagnose and treat disorders of the musculoskeletal system. It is often used to treat a variety of painful musculoskeletal conditions, and several studies have demonstrated its effectiveness. Many studies show a significant effect on pain and improvement in outcome measures, although in some cases the effect size is small. Manual therapy may be performed by physical therapists, chiropractors, massage therapists, osteopathic physicians, and others and may include techniques such as craniosacral therapy and osteopathic manipulative techniques (OMTs).

Practitioners of manual therapy generally believe that musculoskeletal problems arise from abnormal movement patterns or postures, which lead to asymmetrical musculoskeletal forces and subsequent pain. Examples of musculoskeletal asymmetry that can lead to painful conditions include chronic elevation of one shoulder when carrying a heavy purse, abnormalities in tissue texture after prolonged immobilization, and forward head carriage associated with desk work, computer use, and prolonged sitting causing intervertebral disk deformation.

Several models attempt to explain the mechanisms by which manipulation or manual therapy modulates pain. There are three primary models:

**Structural model**: Misaligned structures impinge on nerves and stress soft tissues, thereby stimulating nociceptors. Common terminology includes “subluxation,” “pelvic obliquity,” “leg length inequality,” and “torsion.” It is believed that correction of these misalignments via manual methods eliminates pain.

**Functional model**: Muscular imbalance leads to abnormal joint loading, which in turn causes loss of joint function at the level of accessory motion. Terminology includes “somatic dysfunction,” “biomechanical lesion,” “blockage,” “muscular inhibition/facilitation,” and “instability/stabilization.” Syndromes include upper and lower crossed syndromes, each characterized by specific patterns of muscular facilitation (tightness) and inhibition (weakness). For example, upper crossed syndrome is characterized by facilitation or “tightness” of the upper trapezius, levator, sternocleidomastoid, and pectoralis muscles, whereas the deep cervical flexors, lower trapezius, and serratus anterior muscles are inhibited and weak. Practitioners use rehabilitative exercise and manipulation with the intention of correcting the imbalance and reducing nociceptive input.

**Neurophysiologic model**: This model is consistent with the emerging concept that the pain experience is a central nervous system output that is modulated by multiple factors such as stress, anxiety, fear avoidance, experience, and context in the brain’s “neuromatrix.” Wellens proposed that manual therapy introduces a novel stimulation into the central nervous system that may help the brain downregulate the perceived threat of nociceptive stimuli, thereby decreasing the pain by descending inhibition and other peripheral and central mechanisms. This in turn may stimulate a change in the maladaptive motor responses produced by the brain in response to pain. Other reflexive reactions at the spinal cord level may affect temporal summation and downregulate the value (threat) of the nociceptive input even more. Even though this model is hypothetical, there is an impressive emerging body of supportive literature.

It is likely that manual therapy provides pain relief through an interplay of all three models. Future research may help determine each model’s relative contribution.

Myofascial pain syndrome is a chronic musculoskeletal pain condition with a poorly defined and somewhat controversial pathophysiology. It may emerge after tissue injury, chronic stress-related muscular contraction, or excessive strain on a muscle, tendon, or ligament. Tender regions of hyperirritable, contracted muscle fibers, called trigger points, may form in the affected muscle group and cause local and referred pain. Myofascial trigger points are palpable, tender nodules within skeletal muscles that have characteristic referred pain patterns and physiologic activity that are different from those in normal muscle tissue. Trigger points may be treated with physical therapy, massage, transcutaneous electrical stimulation, selective voluntary contraction of antagonist muscles or muscle groups, injection of saline or local anesthetic medications, dry needling, or application of coolant spray combined with focused muscular stretching. Botulinum toxin has also been used.

**MASSAGE**

Massage refers to the application of varied techniques to the muscles, ligaments, tendons, and related structures in the pursuit of health and wellness. Massage may be performed with the hands, elbows, forearms, or feet, as well as with appliances such as warmed stones. There are many types of massage, each with unique techniques and goals, such as Swedish massage, trigger point massage, reflexology, and lymphatic drainage.

Massage is often used to address pain syndromes such as back pain, neck pain, and sports injuries, as well as to aid in stress reduction and generation of the relaxation response. It has been found to improve symptoms of osteoarthritis of the knee and chronic low back pain, decrease medication use and medical costs, and decrease perception of cancer pain.

It is not clear whether some forms of massage are superior to others or whether all are equally effective. One recent study randomized 401 patients with nonspecific low back pain to relaxation massage, structural massage, or usual care and assessed their symptoms with the Roland Disability Score and the Symptom Bothersome Score. Participants were blinded to the type of massage but not to massage versus usual care. At 10 weeks, both massage groups had statistically significant improvements in both outcome measures when compared with those receiving usual care.

Although massage is generally safe for healthy populations, it can be dangerous in certain circumstances.
Contraindications include, but are not limited to metastatic lesions, severe osteoporosis, thrombosis, infections or wounds, active inflammatory conditions, and bleeding disorders.

CHIROPRACTIC

Doctors of chiropractic focus primarily on the interaction between the structure and the function of the body, with particular attention paid to the spine. Historically, the primary goal was to correct musculoskeletal misalignments (subluxations) to relieve nerve pressure and thus alleviate pain and improve the body’s innate self-healing capability. The primary modality of chiropractic manipulative therapy is high-velocity, low-amplitude (HVLA) thrust manipulation (spinal adjustment). Adjustments generally involve use of the hands or a device to apply an intentional, controlled, rapid force to a joint or body segment thought to have impaired alignment or restricted motion. Restored intersegmental motion or joint position is believed to improve both function and general health. There are multiple chiropractic techniques, each with its own unique set of diagnostic and treatment protocols. Some use very little force, whereas others can be quite aggressive. The most common technique encountered is termed “diversified” and encompasses HVLA maneuvers for all joints of the spine and extremities. In addition to manual therapies, chiropractors may incorporate relaxation techniques, dietary guidance, nutritional supplements, physical therapy modalities, and rehabilitative exercise into their treatment plans. The combination of HVLA manipulation and rehabilitative exercise appears to provide the best outcomes.94

Most patients who choose chiropractic care do so because of back and neck problems. Patients are generally satisfied with their chiropractic care.95 Although some have expressed concern that chiropractic treatment of the neck increases the risk for stroke, a large study that included more than 100 million person-years showed that these concerns are unfounded.96 Debate on this topic persists.97,98

A systematic review of randomized clinical trials of manual therapies evaluated the evidence for spinal manipulation or mobilization in treating several different conditions, including 13 musculoskeletal conditions and headaches. The authors reviewed 49 systematic reviews, 16 evidence-based clinical guidelines, and an additional 46 randomized clinical trials not yet included in systematic reviews and guidelines. They found spinal manipulation to be effective in adults for acute, subacute, and chronic back pain, migraine and cervicogenic headache, and cervicogenic dizziness, and thoracic manipulation or mobilization was determined to be effective for acute and subacute neck pain.77

Research is inconsistent regarding the efficacy of spinal manipulation or mobilization for the treatment of neck pain. One study found spinal manipulation or mobilization to be effective in improving neck pain symptoms when combined with exercise but not when used alone.99 but a literature review found chiropractic spinal manipulation to be ineffective for neck pain.100 A more recent Cochrane review detected a suggested benefit but also noted the need for higher-quality studies to confirm the result.75 A 2011 study provided evidence suggesting that HVLA manipulation of the cervicothoracic and upper cervical segments is superior to mobilization techniques for the relief of neck pain.101

OSTEOPATHIC MANIPULATION

Doctors of osteopathy earn their DO degree from 1 of 26 osteopathic medical schools in the United States and are approved for the unlimited practice of medicine in all 50 states, the District of Columbia, and U.S. territories. Their scope of practice includes the ability to prescribe medications and perform surgery. Osteopathic medical education is similar to that found in allopathic medical schools, with the added focus on a holistic and preventive approach to medicine. In addition, osteopathic physicians learn OMT, which is not included in the allopathic medical school curriculum. OMT is a hands-on practice that attempts to restore normal movement and function and decrease pain.

Osteopathic physicians may choose any specialty and can earn board certification from both osteopathic and allopathic medical boards. Some osteopathic physicians complete allopathic residencies and practice indistinguishably from allopathic physicians, whereas others remain committed to osteopathic principles and practices.

Osteopathic principles include working in partnership with patients to facilitate wellness and prevent disease and the concept that structure influences function. That is, a structural problem in one part of the body may affect function in that region and possibly others. Osteopaths generally believe that the body has an innate ability for self-healing, and OMT techniques are thought to support this process.

OMT procedures are directed at increasing mobility in restricted areas of musculoskeletal function and reducing pain. Some practitioners focus on pain relief, whereas others are more interested in the influence of increased mobility within the system. The stated goal of OMT is to restore maximal, pain-free movement of the musculoskeletal system in postural balance.102 Techniques include a muscle energy technique, mobilization with and without impulses, indirect technique, myofascial release, and integrated neuromusculoskeletal technique.102

OMT has been demonstrated to be effective for neck pain103 and migraine headache symptoms, with pain intensity, functional disturbance, and days of disability all showing improvement when compared with control.104 A systematic review and meta-analysis of OMT for low back pain concluded that OMT significantly reduces low back pain symptoms, with the effect lasting at least 3 months.105

Orthopedic manual therapy is the name given to manual therapy as practiced by physical therapists. Manual therapy has only recently been introduced as part of the core physical therapy curriculum, with most practitioners gaining knowledge and skills through continuing education or fellowships. Physical therapists trained in manual therapy use techniques such as stretching, mobilization, manipulation, and muscle energy–related techniques to increase range of motion, improve function, modulate pain, decrease tissue inflammation, and facilitate tissue repair.

Practitioners of manual medicine may be trained as physical therapists, osteopathic physicians, chiropractors, and to some extent, massage therapists, and strict distinction between practice styles and techniques is lacking. A standardized knowledge base with certification available to all relevant practitioners would be valuable. It is not clear
whether one profession will eventually “own” manual medicine or whether a new specialty will emerge. One suggested model is to offer fellowships in manual medicine with board certification that would be available to physical therapists, chiropractors, osteopathic physicians, allopathic physicians, and massage therapists.

**HOMEOPATHY**

The field of homeopathy was developed by the German physician Samuel Hahnemann at the end of the 18th century in an effort to find a way to trigger the body’s natural ability to heal disease. Homeopathic medicines, called “remedies,” are made at homeopathic pharmacies by using a specialized process of dilution and shaking, called succussion. Remedies, which are often in tablet form, are individualized, and patients with the same symptom may be given very different remedies. Homeopathy is based on two principles that may be challenging for conventional health practitioners to accept: the “law of similars” and the “law of minimum dose.” The “law of similars” suggests that the substance that is most helpful for a disease or symptom is one that causes these same symptoms in a healthy person. For example, if a substance causes sleeplessness when taken at full strength, it might be used to treat insomnia homeopathically.

The “law of minimum dose” is based on the principle that the efficacy of a remedy increases as the dose is decreased. Homeopathic remedies are serially diluted, often until the remedy no longer contains any molecules of the original medication. The diluent, frequently water, is thought by homeopaths to be “imprinted” by the original substance, thus imparting therapeutic efficacy.

Most rigorous clinical trials and systematic analyses of the research on homeopathy have concluded that there is little evidence to support homeopathy as effective treatment of any specific condition. However, some reviews have found suggestions of positive results, and a randomized, controlled study of homeopathic treatment of fibromyalgia showed significant decreases in tender points in the treatment group. One randomized, double-blind controlled trial of homeopathy for rheumatoid arthritis showed that it was the homeopathic consultation rather than the remedy itself that led to positive outcomes. Anecdotal claims of the efficacy of homeopathic treatments are common from both practitioners and users of homeopathy, and the remedies tend to be safe. Large, well-designed studies are needed to clarify the effectiveness of homeopathy for varied health conditions.

**BIOLOGICALLY BASED PRODUCTS: HERBS, NUTRACEUTICALS, AND NUTRITIONAL SUPPLEMENTS**

A large body of clinical evidence supports the use of biologically based natural products for the alleviation of pain. This supportive evidence for pain reduction spans a wide variety of herbs, nutraceuticals, nutritional supplements, and food-derived topical products. Although the majority of the evidence assessed the effects of these products on osteoarthritis pain, there is also evidence from well-designed clinical trials supporting the use of natural products for rheumatoid arthritis, neuropathy, persistent neck and back pain, dysmenorrhea, and inflammatory bowel disease. The following products have the strongest evidence supporting their use for the reduction of pain.

**CAPSAICIN**

Capsaicin is derived from chili peppers of the genus *Capsicum*, which includes the cayenne pepper commonly used in cooking. Topical application of gel ranging from a 2.5% to 8% concentration of capsaicin is used to provide pain relief. The primary mechanism through which capsaicin is believed to reduce pain is depletion of substance P, a neuropeptide involved in the transmission of pain signals from nerve endings to the brain, as well as the activation of inflammatory cytokines in joints.

Many high-quality, randomized, double-blind placebo-controlled trials have found that topical application of capsaicin is an effective treatment of osteoarthritis pain. A meta-analysis found that topical capsaicin in concentrations between 2.5% and 7.5% was four times as effective as placebo in reducing osteoarthritis pain. No serious side effects were noted in these trials, although a burning sensation following topical application of capsaicin at these concentrations is common. Motivated by the relatively common sensation of burning experienced at these concentrations, a recent trial assessed topical application of capsaicin at a concentration of 1.25% in 100 patients with osteoarthritis of the knee. Capsaicin at this lower concentration was effective in improving pain. Even though a mild burning sensation was common, no participants dropped out of the study for this reason. Consequently, lower concentrations of topically applied capsaicin appear to be an effective treatment option for mild to moderate osteoarthritis pain.

Although most capsaicin research to date has focused on osteoarthritis pain, several recent studies have assessed its efficacy for neuropathic pain. Transient application of a dermal patch containing 8% capsaicin has been shown to be an effective option for reducing neuropathic pain. The patch was applied for between 30 and 90 minutes in these studies and repeated, as required, every 90 days. The capsaicin patch was generally well tolerated in these studies. However, as has been the case in studies using capsaicin gel, irritation localized to the site of application was the most common adverse event.

**BOSWELLIA SERRATA**

Extracts of the *B. serrata* plant have been used as an important component of Ayurvedic medicine for thousands of years. Western science has validated the traditional use of *B. serrata* for pain inasmuch as its extracts elicit powerful anti-inflammatory activity through its inhibition of the 5-lipoxygenase (5-LOX) enzyme. Several forms of *B. serrata* have been studied and used clinically, including traditional 60% to 70% extracts of *B. serrata* gum resin, as well as the commercial preparations Aflapin and 5-Loxin.

Five randomized controlled trials have been conducted to assess the effects of *B. serrata* on the pain associated with osteoarthritis of the knee. All these trials found statistically and clinically significant reductions in pain. Symptoms improved as early as 5 days after treatment commenced. In one trial, the reduction in pain persisted 1 month after the conclusion of treatment. The lasting reduction in pain is a unique benefit of *B. serrata* when compared with traditional
pharmacologic therapies for pain. Daily dosages used in these studies were 333 mg of 65% standardized B. serrata extract, 100 mg of Aflapin, and 250 mg of 5-Loxin. B. serrata was well tolerated in all trials, and very few side effects were noted aside from minor gastrointestinal distress in some participants.

**GLUCOSAMINE AND CHONDROITIN**

Numerous meta-analyses have determined that glucosamine, either combined with chondroitin or alone, is an effective treatment of osteoarthritis pain. A meta-analysis of 16 randomized, double-blind studies found glucosamine to be significantly more effective than placebo and more effective than or equal to nonsteroidal anti-inflammatory drugs (NSAIDs) with minimal adverse effects. Another review of randomized trials of both glucosamine and chondroitin found moderate to large effect sizes (0.44 and 0.78, respectively). A large randomized controlled trial (N = 212) published since the aforementioned reviews found that patients taking 1500 mg of oral glucosamine sulfate daily for 3 years experienced no significant joint space loss and minimum joint space narrowing when compared with patients taking placebo.

Despite the abundance of positive evidence for glucosamine and chondroitin, the large Glucosamine/chondroitin Arthritis Intervention Trial (GAIT) found mixed results, which are often misinterpreted. This five-arm trial compared glucosamine alone, chondroitin sulfate alone, glucosamine/chondroitin sulfate, and celecoxib with placebo. Participants in the glucosamine/chondroitin group did not demonstrate a statistically significant improvement over placebo in the primary outcome (20% improvement in the WOMAC pain score) of the overall study sample of patients with osteoarthritis of the knee (mild [n = 1229] vs. moderate to severe [n = 354]). However, 67% of the overall study sample in the glucosamine/chondroitin group experienced at least a 20% improvement in pain with a trend toward statistical significance (P = 0.09). The lack of statistical significance at the P = 0.05 level was thought to be due to the unexpectedly high improvement in the placebo group (60.1%). Furthermore, among the 354 participants with moderate to severe osteoarthritis of the knee, 79% of those in the glucosamine/chondroitin combination group experienced at least a 20% improvement in the WOMAC pain score, which was statistically significant when compared with placebo (P = 0.002). Interestingly, participants with moderate to severe arthritis pain in the celecoxib group did not demonstrate statistically significant improvement when compared with placebo, a finding that is rarely reported. Although a statistical comparison between the glucosamine/chondroitin and celecoxib groups was not reported in the paper, glucosamine/chondroitin was shown to be more effective than celecoxib in patients with moderate to severe osteoarthritis.

Even though the findings from the more than 50 randomized controlled trials of glucosamine/chondroitin for osteoarthritis pain have not been universally positive, consideration of the body of evidence suggests that glucosamine/chondroitin is a safe and at least moderately effective treatment of osteoarthritis pain. A daily dose of 1500 mg glucosamine and 1200 mg chondroitin has been studied most frequently and is the typical recommended dosage.

**S-ADENOSYLMETHIONINE**

The reduction in joint pain provided by Sadenosylmethionine (SAM-e) was first observed as side effects in clinical trials for depression. Produced from L-methionine and adenosine monophosphate, SAM-e is a methyl donor involved in a wide variety of metabolic processes. Although its mechanism of action is not completely understood, SAM-e has been shown to possess anti-inflammatory and analgesic effects without causing gastrointestinal damage in animal models. SAM-e has also demonstrated chondroprotective effects through stimulation of chondrocytes and a subsequent increase in cartilage production.

A meta-analysis of 13 clinical trials revealed that SAM-e is comparable to ibuprofen and superior to placebo in reducing osteoarthritis pain. A large randomized controlled trial published subsequent to this review compared the efficacy of SAM-e with that of celecoxib in patients with osteoarthritis pain. This study found that SAM-e was as effective as celecoxib in relieving pain after 16 weeks of treatment. The onset of pain relief is slower than with some pharmacologic pain relievers, but SAM-e has no known side effects. Most clinical trials to date have used a daily dosage of between 400 and 1600 mg.

**ω-3 FATTY ACIDS**

Dietary ω-3 fatty acids, including α-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), can interrupt the production of inflammatory compounds such as prostaglandin E2, leukotriene B4, interleukin-1β, and tumor necrosis factor-α. ω-3 Fatty acids also inhibit the platelet-activating factor synthesis pathway, the cyclooxygenase pathway, and the 5-lipoxygenase pathway. Accordingly, ω-3 fatty acids are known to play an important role in modulating the inflammatory cascade and the pathophysiology of autoimmune conditions. Chief among the conditions affected by ω-3 fatty acids is rheumatoid arthritis.

ω-3 Fatty acids have been shown in numerous systematic reviews to reduce the pain and joint tenderness of rheumatoid arthritis. Multiple studies have also found that ω-3 supplementation can reduce dependence on NSAIDs and antirheumatic drugs. In addition to reduction of the pain associated with rheumatoid arthritis, ω-3 fatty acids have also been determined to be effective in reducing neck and back pain, neuropathic pain, and the pain from inflammatory bowel disease and dysmenorrhea. No significant toxicities have been associated with the use of ω-3 fatty acids, although patients taking anticoagulant medications should be mindful of the potential for interaction.

The ω-3 fatty acids EPH, DHA, and ALA are not produced endogenously in human beings and must be obtained through the diet. Dietary sources of ω-3 fatty acids include salmon, sardines, and other cold-water fish, fish and krill oil, and plant oil from flaxseed or walnuts. Although all forms of ω-3 fatty acids are important, EPA and DHA have direct anti-inflammatory effects and are more easily used by the body. Conversion from ALA to EPA and DHA is poor, particularly in men. Consequently, the optimal forms of ω-3 fatty acids taken for therapeutic purposes to relieve painful conditions are EPA and DHA. These studies show
that a minimum daily dosage of 3 g of EPA and DHA is required for clinical efficacy in pain conditions. Benefits in alleviating pain generally become apparent after a period of at least several weeks.

**SUMMARY**

An integrative approach to the treatment of pain that incorporates complementary medicine approaches into the care plan can provide clinical benefit with minimal additional risk. An understanding of the mind-body connection and its relevance to pain perception and treatment is important for the care of patients with both acute and, especially, chronic pain. Biologically active products, mind-body therapies, and manipulative and body-based treatments can all benefit patients with pain. Energy medicine and homeopathy have some evidence of benefit, although more research is needed. Large, well-designed studies of diverse complementary medicine modalities are needed to confirm which modalities are best suited to which conditions.

**KEY POINTS**

- The integrative approach to pain management takes into account the biopsychosocial etiology of pain and provides effective tools not conventionally used by allopathic physicians.
- Patients’ level of anxiety, psychological characteristics such as the tendency to catastrophize, and the meaning assigned to the pain experience can significantly affect the perception of pain.
- Acupuncture has shown efficacy in relieving migraines, neck disorders, tension-type headaches, and osteoarthritis and may improve chronic low back pain.
- The term “mind-body medicine” refers to a group of modalities, such as guided imagery, qi gong, and meditation, that are unified by the belief that the mind and body can positively affect each other in the pursuit of health and wellness.
- Mind-body techniques have been shown to be helpful in varied conditions such as osteoarthritis, rheumatoid arthritis, headache, procedural pain, and stress management.
- Guided imagery may be particularly helpful in the perioperative period to decrease pain, opioid use, and length of hospital stay.
- Manual therapy may be helpful in varied pain syndromes and may be performed by osteopathic physicians, appropriately trained allopathic physicians, chiropractors, physical therapists, and to some extent, massage therapists.
- Osteopathic manipulative treatment has been shown to be helpful for neck pain, migraine headaches, and low back pain.
- Biofield therapies and homeopathy have evidence suggesting benefit in patients with pain syndromes, but more robust studies are needed.
- Capsaicin, Boswellia serrata, glucosamine/chondroitin, Sadenosymethionine, and ω-3 fatty acids are the biologically based products with the strongest evidence supporting their use for the treatment of pain.

The references for this chapter can be found at www.expertconsult.com.
Find a comfortable position where you won’t be interrupted. You may sit up or lie down, however you are most comfortable.

You will be focusing your attention on your body for the next few minutes. If your mind wanders, simply bring your attention back to your body.

Take a deep breath into your abdomen while trying to push your belly button out as you breathe in. Hold your breath for a few seconds, and then slowly breathe out. Take another deep breath while trying to push out your belly button as you take in a healing breath. Hold for a few seconds... then slowly release your breath.

As you exhale, imagine the tension in your body being released and flowing out of your body. And again inhale... hold... and exhale. Feel your body beginning to relax.

Now tighten the muscles in your forehead by raising your eyebrows as high as you can. Hold for about 5 seconds. And abruptly release and feel that tension fall away.

Pause for about 10 seconds. Now smile widely and feel your mouth and cheeks tense. Hold for about 5 seconds, and release; noticing the softness in your face. Now just breathe slowly for about 10 seconds while feeling your face relax more and more with each breath.

Next, tighten your eye muscles by squinting your eyelids tightly shut. Hold for about 5 seconds and release.

Pause for about 10 seconds while breathing slowly, relaxing your breaths.

Now lift your shoulders up as though they could touch your ears. Hold for about 5 seconds and release quickly while feeling their heaviness. Pause for about 10 seconds; feel your arms getting heavy and warm as you continue to breathe slowly, relaxing your breaths.

Tense your upper back by pulling your shoulders back while trying to make your shoulder blades touch. Hold for about 5 seconds and release.

Pause for about 10 seconds while breathing slowly, relaxing your breaths.

Tighten your chest by taking a deep breath in, hold it for about 5 seconds, and exhale to blow out all the tension.

Breathe in... and out. In... and out. Let go of all the stress. In... and out.

Now, tightly but without straining, clench your fists. Hold for about 5 seconds and release.

Pause for about 10 seconds. Now, flex your biceps. Feel that buildup of tension. You may even visualize that muscle tightening. Hold for about 5 seconds, release, and enjoy that feeling of liminness. Breathe slowly in... and out.

Now tighten your triceps by extending your arms out and locking your elbows. Hold for about 5 seconds and release. Pause for about 10 seconds while imagining that all your stress and tension are leaving your body through your fingertips.

Now tighten the muscles in your abdomen by sucking your abdomen in. Hold for about 5 seconds and release. Pause for about 10 seconds while breathing slowly deep into your abdomen and notice your belly button moving away from your body with each inhalation.

Gently arch your lower back. Hold for about 5 seconds and relax. Pause for about 10 seconds.

Feel the liminess in your upper body letting go of the tension and stress, hold for about 5 seconds, and relax. Your arms are heavy and warm... the tension is leaving your body through your fingertips.

Tighten your buttocks. Hold for about 5 seconds, release, and imagine your hips falling loose. Pause for about 10 seconds while breathing slowly, relaxing your breaths.

Tighten your thighs by pressing your knees together. Hold for about 5 seconds... and release.

Pause for about 10 seconds. Now flex your feet, pull your toes toward you, and feel the tension in your calves. Hold for about 5 seconds and release; feel the weight of your legs sinking down. Pause for about 10 seconds.

Curl your toes and tense your feet. Hold for about 5 seconds and release. Pause for about 10 seconds.

Now imagine a wave of relaxation slowly spreading through your body beginning at your head and going all the way down to your feet.

Breathe in... and out... in... out... in... out...

Pain and Addictive Disorders: Challenge and Opportunity

Edward C. Covington | John A. Bailey

It is essential that pain specialists have an understanding of addiction since patients with both conditions are increasingly being encountered in pain clinics and are among the most challenging that we see. Addiction not only alters the experience of pain but also changes the reporting of it. Trough levels of opioids in addicts may create hyperalgesia, and reinforcing drugs may increase “pain behavior” (see Treisman and Clark). Addiction impairs function and thereby directly antagonizes efforts to promote functional restoration in pain management. Pain is also likely to be augmented by the dysphoria associated with addiction. The risk for trauma and medical complications of addiction have an impact on pain treatment and may worsen outcomes. Finally and perhaps of greatest concern to pain specialists, addiction carries the risk that misuse will cause our treatments to become harmful to patients.

The actual prevalence of addiction in those with chronic pain is unknown, and reports vary from 1% to 40%. Reasons for this variability include differences in time frame (past 30 days vs. lifetime, for example), different definitions, failure to obtain full information, and different patient populations, among others. It is clear that many patients with chronic noncancer pain (CNCP) have comorbid substance use disorders (SUDs), especially those receiving chronic opioid therapy (COT) for pain. In a recent comparison of Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), and proposed DSM-V criteria for addiction, Boscarino and coworkers found that 35% of patients receiving COT for pain had an opioid use disorder. Similarly, addiction treatment facilities have found that an increasing proportion of their admitted patients, up to 61%, suffer from chronic pain. Clearly, the extent of pain and addiction comorbidity requires that pain specialists be able to competently treat patients with both.

The presence of comorbid addiction complicates the treatment of pain in numerous ways. Patients can be argumentative and unpleasant, and providers unprepared to deal with them may either give in to unreasonable demands or inappropriately refuse to provide care. The former error not only leads to patient harm but also leaves the provider vulnerable to sanctions.

Addiction also complicates pain management because of the fact that individuals with previous addictions are the ones most likely to have problems when prescribed therapeutic opioids. The pain clinician has an obligation to screen for this risk before prescribing opioids and to be skillful in directing the patient to appropriate care if addictive behavior develops during treatment.

THE EPIDEMIC OF PRESCRIPTION OPIOID ABUSE AND ADDICTION

Media attention has created general awareness that there has been a “dark” side to the liberalization of opioid prescribing, which began in the late 1980s. The epidemic of prescription analgesic abuse now exceeds the use of cocaine and heroin combined. As opioid sales have increased, there has been a parallel increase both in admissions to addiction treatment facilities and in overdose deaths. Fatal poisonings involving opioids more than tripled between 1999 and 2006, from approximately 4000 to 13,800.

The relationship between opioid addiction and opioid treatment of pain is a complex one. A review by Minozzi and colleagues found that it is rare for pain treatment to result in opioid addiction, and the majority of abused prescription drugs are obtained from illicit sources rather than from a single, legitimate prescriber. However, in a sample of patients entering treatment for opioid dependence, Cicero and coworkers found that more than 80% had been exposed via a therapeutic prescription, which they then abused. Most had a previous SUD during their early or late teens and had received multiple treatments of substance use. Weisner and associates studied 4 million customers of two large insurance companies and found that those with an identified SUD were more likely to receive schedule II opioid prescriptions, received opioids in higher doses for longer periods, and were more likely to receive concomitant sedative-hypnotics than were those without an SUD.

These studies sound much more contradictory than they in fact are. Together, they portray a situation in which therapeutic opioids do not usually lead to addiction; however, they are commonly prescribed to people who have or have had an SUD. Furthermore, prescription recipients contribute heavily, intentionally or inadvertently, to drugs that are abused in society, often with disastrous results.

Thus, this epidemic is of concern to pain specialists for three reasons: (1) a large percentage of patients being prescribed COT suffer from comorbid addiction (often unknown to the prescriber) and are therefore at increased risk for harm; (2) the abused drugs are frequently diverted from legitimate prescriptions, thereby creating an obligation for the prescriber to be vigilant for signs of diversion, to
be responsible in performing and responding to toxicology screens, and to educate patients regarding the necessity for secure handling and storage of prescription medications; and (3) patients with previous SUDs are at high risk for “transferring” their addiction to prescribed opioids.

DEFINITIONS

There is disagreement concerning the optimal definition of addiction. The American Psychiatric Association and the World Health Organization both wished to avoid stigmatizing patients with the label “addict” and therefore substituted the word dependence. Unfortunately, this had the effect of creating ambiguity. The problem is the inevitable confusion between the terms dependent and physically dependent (which refers to the normal development of the potential for a withdrawal syndrome in nearly all continuous users of dependence-producing drugs). This chapter uses the terms “addict” and “addiction” for the sake of clarity and brevity. We recognize addiction as a disease that arose not because the patient intended it, but despite efforts to avoid it. The individual is thus the victim of the disease, not a perpetrator, and the term is not used disparagingly.

ADDICTION AND SUBSTANCE DEPENDENCE

In an effort to use a common taxonomy, the American Society of Addiction Medicine, the American Pain Society, and the American Academy of Pain Medicine formed a consensus panel to define tolerance, physical dependence, and addiction. They adopted the following definition:

Addiction is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Since the biologic changes that are the essence of addiction are not clinically detectable, the diagnosis must be based on behavioral abnormalities and patient reports. The current standard criteria for substance dependence are those of the DSM-IV; however, these criteria will be obviated by the publication of DSM-V scheduled for May 2013. The DSM-IV term substance dependence disorder closely approximates what is generally considered to be addiction; nonetheless, accurate diagnosis is contingent on attention to the paragraph preceding the bulleted criteria, which requires “a maladaptive pattern of substance use” that leads to “clinically important distress or impairment.” Without this, many nonaddicted patients receiving COT would meet the criteria for a substance use diagnosis. These and other criteria not only risk diagnosing addiction in its absence but can also contribute to failure to diagnose the condition when present because the detrimental effects of drug use on lifestyle and psychosocial functioning may be less evident in pain patients and, when they do occur, are likely to be ascribed to pain rather than to drug use.

The proposed DSM-V criteria for “opiod use disorder” will require a maladaptive pattern of use leading to significant impairment or distress, as manifested by at least two of the following occurring within a 12-month period (the criteria have been abbreviated):

1. The opioid is often taken in larger amounts or over a longer period than intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control use.
3. A great deal of time is spent on activities necessary to obtain, use, or recover from the effects of the opioid.
4. Recurrent use results in failure to fulfill major role obligations.
5. Use is continued despite persistent or recurrent social or interpersonal problems caused or exacerbated by the substance.
6. Important social, occupational, or recreational activities are reduced because of use.
7. Use occurs in situations in which it is physically hazardous.
8. Use is continued despite knowledge of a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by the opioid.
9. Tolerance is present (not counted for those taking medications under medical supervision).
10. Withdrawal occurs (not counted for those taking medications under medical supervision).
11. There is craving or a strong desire or urge to use the opioid.

There are many idiosyncratic definitions created by governmental and health-related organizations. For example, the Controlled Substances Act defines an “addict” as a person who “habitually uses any narcotic drug so as to endanger the public morals, health, safety, or who is so far addicted to the use of narcotic drugs as to have lost power of self-control with reference to his addiction.”

PHYSICAL DEPENDENCE

It must be emphasized that “drug dependence” is not synonymous with “physical dependence,” which is normal and to be expected with prolonged use of opioids and does not indicate the presence of any disorder. In fact, physical dependence, as manifested by withdrawal on administration of naloxone, can be elicited in normal subjects following a single dose of morphine, which confirms that this phenomenon is not useful as a diagnostic criterion in patients taking prescribed opioids.

Physical dependence is neither necessary nor sufficient for the diagnosis of SUD. It commonly occurs with substances that lack addictive potential and is universal in those taking significant doses of prescribed opioids or benzodiazepines on a continuous basis. It is said to be present if a withdrawal syndrome occurs on cessation of use, dose reduction, or administration of an antagonist. Physical dependence can be a major issue in addiction to opioids and alcohol, is minimal with cocaine and amphetamines, and is absent in addiction to hallucinogens and inhalants. It can be a major problem with discontinuation of such nonreinforcing substances as paroxetine, venlafaxine, some antiepileptics, clonidine, and baclofen.

TOLERANCE

Tolerance is a state of adaptation in which exposure to a substance induces physiologic changes that diminish its effects.
It develops more rapidly in some individuals than in others. It develops with effects such as sedation from antiepileptics, nausea from serotonin-norepinephrine reuptake inhibitors, and hypotension from clonidine. Tolerance usually develops rapidly to opioid-induced sedation, itching, and nausea and more slowly to analgesia and may not develop at all to constipation. Because of tolerance, patients who take a stable dose of opioids on a scheduled basis can usually safely return to work and drive.31,32

Analgesic tolerance is one of the reasons that opioids are more effective for acute than for chronic pain.33-37 Clinically, patients who have severe pain despite high doses of opioids often report that low to moderate doses of opioids initially produced satisfactory analgesia. It is important to explain tolerance to patients. They should understand that efforts to regain initial analgesia through repeated dose escalation can lead to falls, fractures, and fatalities, as well as side effects such as low testosterone and opioid-induced hyperalgesia. Strategies for reducing tolerance include opioid rotation and the addition of adjunctive medications that are opioid sparing.

PSEUDOADDICTION

Pseudoaddiction describes a state in which inadequate analgesia leads to behavior that mimics addictive behavior. This drug-seeking behavior improves when the pain is controlled. Although the concept is simple, in practice, both undermedicated patients in pain and patients with actual addiction may be drug seeking, and both cease drug seeking, at least transiently, when their needs are met. So the distinction is often made with difficulty and usually in retrospect (i.e., when the patient’s behavior normalizes for an extended period after adequate pain control is provided).36,39

DRUG MISUSE

Drug abuse and misuse are defined in various ways that have in common the fact that the drugs either were not prescribed or were used in a manner different than instructed. They differ from addiction in that those who abuse drugs can choose to quit in the event of adverse consequences. The term chemical coping has been used to describe persons who use opioids to ameliorate uncomfortable emotion. For example, opioids may reduce fear of cancer. They temporarily decrease depression, anxiety, anger, and symptoms of post-traumatic stress disorder (PTSD). In fact, there is some evidence that PTSD may share a common neurobiology with addiction, which in part accounts for their high comorbidity40 (for review, see Logrip and colleagues41).

NEUROBIOLOGY OF ADDICTION

Increased understanding of the neurobiology of addiction has had both medical and cultural benefits as the traditional views of addicts as people who were immoral or lacking in willpower have become untenable.42 It is established that neural mechanisms evolved that link behavior necessary to survival (e.g., acquisition of food, sex, and nurture) to dopaminergic (DA) activity in the ventral tegmental area and the nucleus accumbens. These areas are involved in salience, reward, expectation of reward, and habit.43 In other words, important or pleasurable activities increase midbrain dopamine. Importantly, all rewarding drugs also act in the ventral tegmental area and nucleus accumbens to increase DA function, a remarkable fact given that some are sedatives, others stimulants, and others analgesics. Since reinforcing drugs increase dopamine even more than natural rewards do, our brains are hardwired to experience pleasure from and attach importance to these drugs. Thus, recreational drug use in essence hijacks neurologic systems that are essential for survival. Evidence that release of dopamine with opioid use is attenuated in animals that have chronic inflammatory or neuropathic pain may explain the observation that people are less likely to become addicted after opioid use for pain than after use for euphoria.

Imaging also implicates dysfunctional activity in the prefrontal cortex (PFC) in addiction. This functionally heterogeneous structure plays a crucial role in regulating limbic reward regions and higher-order executive functions, including self-control, judgment, salience attribution, and awareness. In addiction, PFC dysfunction is thought to impair impulse control. PFC dysfunction could also explain patients’ lack of awareness of their addiction in the face of overwhelming evidence.44 This decreased awareness, or “denial,” is a hallmark of addiction and a barrier to treatment acceptance.

It has become clear that addictive behavior has other driving forces. For example, negative reinforcement results from both withdrawal anhedonia and the anxiety driven by sympathetic rebound.4 Important insights have been provided by study of what have been called opponent processes.45 Many drugs elicit homeostatic mechanisms that antagonize some or all of their effects; in fact, withdrawal symptoms typically consist of processes that oppose a drug that is no longer present. Thus, sedative withdrawal is characterized by stimulation, stimulant withdrawal is associated with lethargy, withdrawal of constipating drugs causes diarrhea, and stopping anticonvulsants (e.g., benzodiazepines) can produce seizures.

It has been shown that processes are engendered by euphorogenic drugs that oppose euphoria and create dysphoria. As drug use continues, euphoria diminishes, whereas dysphoria increases, can be intense, and is relieved only by the substance of abuse. Thus, the transition from drug use to addiction involves stages. Recreational users are initially motivated by positive reinforcement (i.e., substance use generates a pleasurable state). However, after the transition to addiction, negative reinforcement is increasingly determinative; people use substances not so much to feel good as to avoid feeling bad. With continued use, release of dopamine in response to dosing is reduced, whereas release of corticotropin-releasing factor (a “stress hormone”), adrenocorticotropic hormone, corticosterone, norepinephrine, and neuropeptide Y during periods of abstinence is increased. It is believed that the decrease in reward function combined with the recruitment of antireward systems provides a powerful negative reinforcement that contributes to compulsive drug seeking and addiction.46,47 Furthermore, the transition from controlled use to compulsive drug seeking seems to be associated with the migration of control neural circuitry to the more dorsal areas of the striatum that are involved in habit and compulsion.48
Heroin addicts often report that they have spent years trying without success to recapture the highs that they experienced when they initiated use or, more commonly, that they no longer use heroin to get high but only to stop feeling bad. In this way, recreational addicts are similar to those with chronic pain—their use is motivated primarily by a desire to end suffering, not to achieve euphoria. The brain changes result in an increase in the perceived importance of drug-related issues, a reduction in the perceived importance of other things, and diminished impulse control over use.

It is well known that marked physical and emotional distress can result from abrupt drug discontinuation; however, it is less commonly appreciated that subsequent to the resolution of obvious symptoms, during the so-called post-acute withdrawal period, there may be persistent anhedonia and depression. The endogenous opioid systems may take months to normalize, during which time patients may experience insomnia, anxiety, depression, inability to concentrate, clumsiness, and disturbing dreams. Recent studies suggest that a specific set of genetic transcriptional regulations may underlie protracted abstinence symptoms from compounds as disparate as nicotine, alcohol, tetrahydrocannabinol (THC), and morphine. This could in part explain the vulnerability of abinent addicts to the development of addiction to an unrelated substance.

Some of the neuroplastic changes associated with addiction are thought to be permanent, which may explain why addiction is associated with a lifelong vulnerability to relapse. Fortunately, the likelihood of relapse decreases with time, as well as with continued participation in an ongoing recovery program.

**DEVELOPMENT OF ADDICTION**

Addictive behavior is heavily influenced by genetic factors. Selective breeding easily produces animals that have a strong baseline propensity to self-administer rewarding drugs and other animals that require high doses and prolonged exposure to develop evidence of “drug liking.” These studies, as well as twin studies and family hereditary patterns, support the belief that vulnerability to addiction is partially genetic. Animal and human imaging suggests that those more vulnerable to addiction have decreased baseline DA activity and may therefore attach even more importance to dopamine-elevating drugs. Vulnerability to addiction is also influenced by life events. Childhood physical, sexual, and emotional trauma, as well as major adult stress, is important in this regard.

Previous exposure to a rewarding substance can increase consumption of subsequent substances and previous drug abuse or addiction increases the likelihood of future SUDs; for example, those who have smoked tobacco or marijuana may have increased vulnerability to other SUDs.

Factors that promote addiction should be distinguished from those that trigger relapse in individuals with prior addiction. Common triggers include drug exposure, environmental stimuli (people, places, and things associated with drug use), and stress. Many people incorrectly attribute addictive behavior to psychiatric comorbidity and believe that if the underlying psychiatric disorder is corrected, the addiction will go away. In fact, although patients may believe that their substance use would cease if they were relieved of their anxiety, depression, panic, or stress, experience shows that such is rarely the case.

**CROSS-ADDICTION**

A tenant of most addiction treatment and education is the concept that a person addicted to one reinforcing substance is at high risk for addiction to all such substances and should therefore abstain even from substances that have never been problematic. This caution is based on two considerations: (1) a person who takes an intoxicant is less able to resist other temptations (e.g., a person working on nicotine abstinence is more likely to relapse after a few drinks), and (2) the neurologic changes that occur with addiction appear to be common to most substances (i.e., the changes in people with alcohol dependence and those with opioid dependence are similar). Thus, it makes sense to caution those attempting to recover from opioid dependence to avoid alcohol, benzodiazepines, carisoprodol, and illicit substances. Unfortunately, there are few data to confirm these beliefs other than the high prevalence of polysubstance abuse or dependence, which shows that people who develop one SUD often develop several (see Compton and colleagues).

**IATROGENIC ADDICTION**

Although COT can cause physical dependence, trigger relapse in those recovering from addiction, and elicit addiction in some, it is clear that preexisting vulnerability plays a critical role in this process. Early in the last century it was often believed that anyone who used opioids chronically became addicted. However, the distinction between physical dependence and addiction was not appreciated and therefore addiction rates were probably exaggerated. Until recently, many believed that addiction was rare in those who took long-term opioids to treat pain, unlike those who sought euphoria or relief from emotional distress. Now, concern is being raised that opioid therapy is causing a wave of addiction. Probably much of the uncertainty and disagreement relate to the distinction between those who have an addiction and are treated with COT versus those who have an addiction because they were treated with COT. The ambiguity surrounding triggering addiction versus triggering relapse is also a confounder.

Even though most pain specialists believe that iatrogenic addiction is uncommon, there are few data to determine its exact incidence. Extant studies are largely poorly done and brief. Accurate data are frequently difficult to obtain, and there is often ambiguity not only about the presence of addiction but also about the time of its onset. It is widely believed that the risk for inducing an addictive disorder with short-term opioid therapy is extremely low, around 3 per 1000. However, there seems to be no data on this question beyond two very old studies, both widely cited and widely criticized on methodologic grounds. Nonetheless, clinical experience supports their findings in that it is quite rare to see patients in whom iatrogenic addiction has developed as a result of brief treatment. Unfortunately, these early studies addressing acute opioid therapy have been cited as evidence of the safety of chronic opioid therapy, which they did not address.
IATROGENIC RELAPSE

Several studies suggest that the vast majority of patients who manifested addiction while being treated long-term with opioids had preexisting drug or alcohol disorders. For example, in a retrospective study of 48 patients hospitalized for addiction to oxycodone (OxyContin), Potter and associates found that 77.1% reported previous nonopioid substance use problems (including alcohol) and 48% had prior problems with other opioids. Similarly, an older study of 200 patients with chronic low back pain found that substance abuse preceded the pain in 94% of those with both conditions. In a highly selected group of patients undergoing pain rehabilitation, our group found that of those with an addictive disorder, medical exposure was responsible in 33%, recreational use in 64%, and undetermined causes in 3%. Needless to say, the proportion of patients in a pain clinic who became addicted medically would be much higher than the proportion in the community.

It seems that most patients thought to have iatrogenic addiction instead had a recreationally induced addiction that transformed into prescription use or were abstinence addicts who relapsed on re-exposure to opioids. The latter is predictable given that animal and human studies have demonstrated that one of the most powerful stimuli for eliciting resumption of dormant drug-seeking behavior is re-exposure to the drug of choice. A recovering heroin addict came to our attention who had maintained sobriety for longer than 1 year until exposed to intravenous midazolam for procedural sedation. He experienced an immediate onset of drug craving, subsequently obtained and injected heroin, to which he was no longer tolerant, and died. Studies are lacking to clarify the risk for relapse if, for example, a patient who has been sober from alcoholism for a number of years is exposed to COT. However, based on animal studies and observation, most addiction specialists believe that ingestion of alcohol or any reinforcing drug may increase craving for the addict’s drug of choice and other reinforcing drugs.

The brain changes that underlie addiction are multifactorial, and it appears that the development of addiction is a function of the molecule involved, dose administered, duration of use, genetic and personal vulnerability, and perhaps route and rate of administration. Thus, in a patient with no predisposition, COT would be unlikely to trigger addiction, whereas in those with high vulnerability, addiction might develop easily and early. Such patients would be likely to have a history of nicotine dependence or overdose of alcohol or other substances.

In addition to vulnerability and length of exposure, the substance itself plays a role. For example, drugs that rapidly and markedly increase dopamine (e.g., crack cocaine) often produce addictive behavior quickly. Other drugs, such as alcohol, seem to take much longer for most. Furthermore, the delivery system plays a role, with slow-onset preparations such as chewed tobacco or coca leaves producing addiction more slowly than cigarettes or smoked cocaine. This suggests that opioids that rapidly enter the central nervous system (CNS), such as fentanyl given by the intravenous or transmucosal route, may be more likely to trigger addiction or relapse than the same molecule administered transdermally.

DETECTING AND PREDICTING ABUSE AND ADDICTION

SCREENING AND UNIVERSAL PRECAUTIONS

Appropriate screening takes considerable time, which can lead providers to neglect it. A self-report questionnaire can facilitate this task and help ensure adequate information to guide the prescriber. If the state has an electronic prescription-monitoring program (42 of 50 do so as of this writing), this should be reviewed and compared with the patient’s information. One of the most valuable ways to detect addiction is by interviewing the patient’s relatives or significant others. They may be both more honest in revealing signs of addiction and more aware than the patient of such issues as drug-induced sedation, cognitive impairment, and changes in personality.

Legitimate patients (as opposed to scammers) generally understand that prescription opioids are a public health concern and that prescribers have a responsibility to mitigate societal risk. Patients should be informed of clinic rules and philosophies before the initial prescription. Some find it helpful to frame the first appointment as a screening and compatibility visit and to make it clear that controlled medications will not be prescribed on the first visit.

Gourlay and colleagues developed guidelines for opioid prescribing that they liken to the universal precautions used for infection control. The rationale is that providing the same standard of care to all patients minimizes risk to both the patient and provider. The guidelines recommend that such things as thorough assessment, documentation, testing, and follow-up standards be applied to all who are prescribed COT, regardless of perceived risk for aberrant behavior (Box 50.1).

SCREENING FOR LIABILITY TO ADDICTION

Instruments have been devised to alert the clinician to the likelihood that a patient has or is at risk for drug-related difficulties (Box 50.2). Positive screening does not necessarily exclude patients from opioid therapy; rather, it identifies

**Box 50.1 The Ten Steps of Universal Precautions in Pain Medicine**

1. Diagnosis with appropriate differential
2. Psychological assessment, including risk for addictive disorders
3. Informed consent
4. Treatment agreement
5. Preintervention/postintervention assessment of pain level and function
6. Appropriate trial of opioid therapy with or without adjunctive medication
7. Reassessment of pain score and level of function
8. Regular assessment of the “four As” of pain medicine (analgesia, activity level, adverse effects, and aberrant behavior)
9. Periodic review of diagnosis and comorbid conditions, including addictive disorders
10. Documentation
those who have a lower than usual benefit-to-harm ratio and who therefore require more thorough assessment, closer monitoring and accountability, and possibly referral for addiction treatment. Simple questioning may fail to reveal SUDs because of concealment, unawareness, or forgetfulness on the part of patients. 76 In a study of 109 patients with CNCP, Berndt and associates 77 found that 32% of the toxicology results were discordant with patients’ reports and that 21% concealed drug use.

The Screener and Opioid Assessment for Patients with Pain (SOAPP) comes in 5-, 14-, and 24-question versions, in addition to the Revised SOAPP (SOAPP-R). These questionnaires assess the risk for prescription opioid abuse. The test may be used in conjunction with other information to help assess patient suitability for COT, as well as to identify the need for more intense monitoring. The drug abuse screening test (DAST), though not developed for patients taking prescribed drugs, does contain several items that screen for opioid use behavior in patients being considered for a trial of COT. The ORT is a questionnaire that asks yes or no questions about risk factors such as family and personal substance abuse history, age, preadolescent sexual abuse, and psychological comorbidity. Though brief and easy, the questions are not disguised and stand out as screening questions and thus may invite dishonesty if the patient is seeking to obtain controlled medications.

Unlike these self-report instruments, the Diagnosis, Intractability, Risk, Efficacy (DIRE) score is a tool for use by clinicians to aid in determining the risks and benefits likely to accrue from COT. 82 A comparison of these screens suggests that all have value and are most useful when supplemented by clinical interview. 83

**Box 50.2 CAGE* Questions Adapted to Include Drugs (CAGE-AID)**

1. Have you felt that you ought to cut down on your drinking or drug use?
2. Have people annoyed you by criticizing your drinking or drug use?
3. Have you felt bad or guilty about your drinking or drug use?
4. Have you ever had a drink or used drugs the first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?

*G, cut down; A, annoyed; G, guilty; E, eye opener.

**LIKELIHOOD OF EXISTING ADDICTION**

- Previous drug-related treatment, arrests, driving under the influence
- Anger, arguing, bargaining
- Numerous emergency room visits for opioids
- Requesting highly abused medications, such as carisoprodol, barbiturates, stimulants
- Requesting rapid-onset opioids or those with easily defeated delivery systems
- Failure to bring requested medication bottles or amounts or dates that do not “add up”
- Statements such as “I have a high tolerance”
- Multisourcing/doctor shopping
- Wrong or no contact information
- Focus on opioids/disinterest in other treatment
- Extensive knowledge about abusable medications
- Previous noncompliance with other pain treatment programs
- Vernacular such as “oxy’s,” “roxy’s,” “bars,” “xanny bars,” “eating” versus “taking” pills
- Traveling long distances to the pain clinic
- Failure to produce medical records
- Obtaining medications from nonmedical sources
- Numerous allergies or intolerances to less reinforcing medications
- Positive, diluted, contaminated, or wrong temperature urine drug screen
- Failure to produce urine for drug testing
- Liver dysfunction, hepatitis B or C, or human immunodeficiency virus infection
- Physical findings: drug-related tattoos, track marks, needle bruising, “seed burns,” signs of withdrawal or intoxication
- Appearance discordant with professed dysfunction—muscular, tanned

**TOXICOLOGIC STUDIES**

It is necessary to verify that patients are taking prescribed medications and not using illicit drugs. Urine drug testing (UDT) and hair testing can help provide this information and assist the patient in maintaining compliance by providing accountability. Additionally, UDT results can be of value to patients who need to document treatment adherence for reasons that range from child custody to probation. An excellent primer of UDT is available in a monograph prepared for the California Academy of Family Physicians that is available online. 91 It is important to understand the limitations of the testing used, and most companies have experts available to assist in interpretation.

In clinical practice, UDT is the mainstay because it is relatively inexpensive and noninvasive and provides a reasonable window of detection. The initial office screening test is usually an immunoassay. These “dipsticks” are economical and consist of antibodies that react with the drug or its metabolite. A positive test can be confirmed with gas
Because it takes about 1 week for hair to grow from the scalp, detection is possible for about half an inch per month. Recent use will be missed by hair testing because the hair follicles that are already metabolized to morphine and therefore detected; however, synthetic and semisynthetic opioids are not. Other screening tests are available that may include methadone, propoxyphene, benzodiazepines, barbiturates, and EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine)—a methadone metabolite.

UDT can lead to erroneous conclusions for several reasons. Immunoassays are vulnerable to cross-reactivity; for instance, decongestants may test as amphetamines. Misleading results can occur when a prescribed substance is converted to another nonprescribed substance (e.g., hydrocodone and morphine can be converted to hydroxcodeone and morphine). Spurious results can also occur from the consumption of legal substances; for example, poppy seeds contain morphine and some nasal inhalers contain l-methamphetamine.

In contrast, a finding of cocaine or THC is reliable and, in the case of THC, cannot be caused by being in a room in which a great deal of marijuana is being smoked. A urine screen that fails to contain a prescribed opioid may indicate diversion, but it can also mean that the patient exhausted the supply of medication several days before the test or that the patient used someone else's urine to conceal the use of illicit drugs.

It is helpful to have a breathalyzer available since alcohol is often not detected by urine drug testing. Ethyl glucuronide testing is widely available and can detect alcohol consumption for the previous 3 days; however, the test is so sensitive that exposure to alcohol from mouthwash or hand cleaner can produce a positive result. If levels exceed 500 ng/mL, deliberate alcohol ingestion is probable.

Drug testing should be performed before initiation of COT and randomly during treatment. Importantly, testing should not be limited to patients suspected of abuse because this strategy is open to bias (e.g., disproportionate testing of minorities) and has been shown to miss 50% of those using nonprescribed or illicit drugs.

Even though there are safeguards, urine drug screens can be defeated. “Clean” urine may be obtained via the Internet or from friends and delivered by ingenious worn devices that are difficult to detect even with direct observation. These devices can even maintain urine at an appropriate temperature, typically, 90°F to 100°F within 4 minutes of voiding.

The most common strategy for avoiding detection is to dilute the urine through aggressive fluid ingestion or by adding tap water. Therefore, reasonable care should be taken that the sample is not obtained in a room with access to water for dilution and that the color and temperature are appropriate. Urine creatinine, specific gravity, and pH should be determined.

Hair and saliva testing is now available. Hair testing is extremely accurate and virtually impossible to defeat and can detect use in the past 2 or more months since hair grows about half an inch per month. Recent use will be missed because it takes about 1 week for hair to grow from the follicle to a length at which it can be collected. THC levels are relatively low in hair follicles in comparison to most other drugs, and occasional use can be missed. Hair testing cannot be defeated by coloring or bleach since the chemicals tested are at the core. If scalp hair is absent, body hair may be used. The cost of hair testing is no longer prohibitive, and its use in monitoring is increasing. For example, the Florida Physicians Health Program has used hair testing to monitor recovering physicians since 2006.

It is reasonable for the clinician, without getting into a dispute about patients' rights to use substances or the benefits of “medical marijuana,” to make access to opioid therapy contingent on the patient’s willingness to produce urine that is free of illicit substances. This can be presented in a nonjudgmental manner as a way to ensure the patient’s access to treatment and the provider’s continued ability to prescribe. If the person is unwilling to relinquish recreational use, it suggests that the pain problem does not warrant COT. If the patient is unable to relinquish the drugs, addiction treatment is indicated.

### TREATING PAIN IN PATIENTS WITH ADDICTION

A number of authors in the past emphasized the importance of distinguishing pain patients from addicts (e.g., Ling and colleagues). The rub, obviously, is that the conditions are not mutually exclusive and, in fact, co-occur more frequently than would be expected by chance given that chemically dependent persons are at increased risk for trauma and painful illnesses and that pain patients have some finite risk for iatrogenic addiction.

Numerous authorities and professional organizations agree that it is unethical to withhold opioid analgesia from addicts. For example, the American Society for Pain Management Nursing has upheld this principle and described strategies for dealing with patients at different stages of the addictive disease process. The policy of the American Academy of Addiction Psychiatry is cautionary regarding COT in general. However, no one believes that patients should receive ineffective or harmful treatment, and all agree that opioids are not helpful in every case of chronic pain. Thus, there will be some patients with pain complaints who seek opioids and should be denied. Even though there are almost no data clarifying the risks and benefits of chronic opioid analgesia in addicts, it is clear that such therapy has hazards exceeding those of opioid therapy in nonaddicts given the potential for overuse and loss of control.

A patient's former drug of choice will have the most power to elicit cravings and relapse, which may explain the clinical impression (and pilot data) that COT in recovering alcoholics is often more successful than COT in recovering opioid addicts. Nevertheless, the concept of cross-addiction suggests that a patient with any prior addiction, including alcohol dependence, is at elevated risk for new addiction, even to unrelated substances. Thus, a chronic marijuana user may be at special risk for the development of an opioid use disorder. It is therefore essential that the clinician identify preexisting problems with all rewarding/reinforcing substances.
Treating pain in a person with an active SUD is complicated by several factors. Such patients are likely to believe that they are entitled to pain relief (regardless of whether this goal is attainable), and the prescriber is likely to suspect that some portion of the pain complaint represents drug seeking. Thus, the stage is set for conflict, which is further promoted by the previously mentioned adverse childhood experiences that predispose to both addiction and somatization. These experiences additionally engender mistrust, anger, and resentment of authority figures, who may be seen as betraying and withholding.

A distinction must be made between acute pain and chronic nonmalignant pain and between a patient who is actively engaging in substance abuse and a patient in recovery.

**ACUTE PAIN**

Substance abuse not only leads to trauma but also probably increases the pain associated with trauma based on the observations that addiction often leads to lower pain thresholds and tolerance, and that patients taking preoperative opioids have substantially greater postoperative pain and opioid requirements than those not taking opioids.

Therefore, acute injuries in addicts, even in those with sustained recovery, frequently require more aggressive analgesia than in patients with no addiction history because of the presence of tolerance. (It is commonly observed that a period of abstinence eliminates apparent drug tolerance; however, on resumption of use, tolerance is rapidly re-established in the previously tolerant person or animal.) The need of opioid-tolerant patients for more analgesia than expected can collide with staff desires to limit opioids in those with an addictive disorder. The result is likely to be a dissatisfied and uncomfortable patient—perhaps a vociferous one—and an unpleasant experience for staff. Management is facilitated by recognizing that a patient who is loudly demanding analgesia is unlikely to be overly medicated. It may be helpful to rotate opioids to identify a medication with incomplete cross-tolerance with the patient’s drug of choice. Methadone and buprenorphine may provide satisfactory analgesia in these conditions.

Difficulties arise in the treatment of acute (including perioperative) pain in a patient who is tolerant and physically dependent on opioids because of licit or illicit use. Not only may these patients require substantial doses of opioids simply to prevent withdrawal, but in addition they may require considerably more acute opioids for analgesia than a nontolerant patient.

**PATIENTS RECEIVING PHARMACOTHERAPY FOR ADDICTION**

Patients whose addiction is under treatment with opioid agonists (methadone, buprenorphine) require special consideration when they experience trauma or acute painful illness. Their maintenance dose of methadone will not provide analgesia but must be continued to prevent withdrawal. Doverty and coworkers found that blood levels of morphine typically adequate for relief of postoperative pain had minimal analgesic effect in patients maintained on stable doses of methadone. Thus, higher than usual doses of µ-opioid agonists may be required for acute pain. Administration of buprenorphine, a partial µ-agonist, to a patient taking full µ-agonists may produce an abstinence syndrome; however, the cautious addition of full agonists to a baseline dose of buprenorphine is effective.

Alcohol and opioid addiction may be treated with naltrexone, a long-acting µ-antagonist, as a relapse prevention strategy. When such patients require acute opioid therapy, much higher than usual doses are required. Close observation is necessary because these doses may become toxic as the naltrexone level decreases over time.

It seems counterintuitive, but acute analgesia with opioids may be more hazardous in tolerant than in nontolerant patients. Figure 50.1 is hypothetical but conveys the idea of what seems to happen clinically—as tolerance develops differentially to the analgesic versus the sedating and respiratory depressant effects of the drugs, the therapeutic window narrows, and the therapeutic dose begins to approach the lethal dose. (A part of this phenomenon may result from opioid-induced hyperalgesia since this would create the appearance of a high degree of analgesic tolerance without inducing tolerance to toxic drug effects.)

Rapp and colleagues compared the results of patient-controlled analgesia in tolerant and nontolerant patients, and although the former reported less nausea, vomiting, and pruritus than did opioid-naive controls, the incidence of moderate or severe sedation was 50.3% as compared with 19.0% in controls. We have seen postoperative patients who were highly opioid tolerant before surgery and in whom there seemed to be virtually no therapeutic window—careful bedside titration of intravenous opioids failed to reduce pain below a level of 9 to 10 out of 10 before the development of an unacceptable degree of sedation or respiratory depression.

Mehta and Langford reviewed recommendations for the treatment of acute or postoperative pain in patients maintained on opioid agonists. These recommendations included continuing maintenance opioids and supplementing them with additional analgesics, multimodal when possible, including short-acting opioids, local anesthetics, and adjuvant nonsteroidal anti-inflammatory drugs. They also recommended patient-controlled analgesia with higher than usual bolus doses and shorter than usual lock-out intervals. Transdermal opioids and implantable pumps were noted as alternatives. A review by Huxtable and associates supported recommendations for multimodal analgesia.
A special problem is created by the emergency department (ED) “frequent flyer”—a patient who is known to the staff of several local EDs and habitually shows up, often at night and on weekends, demanding opioids for a chronic (e.g., back pain), recurrent (migraine, sickle cell disease), or idiopathic pain condition. Fragmented care, as the person engages different shifts at different hospitals, presents a severe challenge to the development of a rational treatment plan; however, such a plan is mandatory. It is useful to establish liaison with a nonemergency provider in the relevant field of medicine and to arrange for consultation so that a plan of management for pain and addiction can be developed. Assessment for an addictive disorder should also be arranged. It is useful to recall that unrewarded behavior is not long repeated, so patients who resist daytime consultation should be limited, when possible, to noneuphorogenic medications in the ED (e.g., parenteral phenothiazines for migraine, ketorolac for other types of pain). ED guidelines on the administration and dispensing of opioids are essential so that house staff and faculty will have a consistent approach to provision of opioids for chronic pain. States and hospitals have developed guidelines that typically emphasize avoiding provision of opioids for chronic pain in the emergency setting, refusing to provide long-acting opioids or to refill lost or stolen prescriptions, avoiding parenteral opioids, using non-opioid–containing medications whenever possible, and creating a care plan for frequent patients that provides continuity of care with a nonemergency clinician (for examples, see the websites provided).115,116

PATIENTS IN RECOVERY

Patients recovering from an addictive disorder may face elective surgery with trepidation because they fear having to choose between unrelieved pain and relapse of their addiction. Some even refuse analgesia in an effort to preserve their hard-won sobriety. Experience suggests that this is unnecessary. They should be encouraged to advise the surgeon or anesthesiologist in advance of elective procedures that they are in recovery, will probably require higher than average doses of analgesics, but wish to preserve their sobriety by avoiding their previous drug of choice, transitioning to long-acting oral agents as soon as possible, and making arrangements for the safe use of opioids after discharge. The patients should increase their recovery work (12-step meetings, office sessions with an addiction counselor) and should notify their treating professionals and sponsor of their pending surgery so that support is in place. It is advisable to have a spouse, friend, or sponsor safeguard any home-going opioids and provide the patient a supply each day so that the patient is protected from the temptation of a bottle of opioids within easy reach.

CHRONIC PAIN

SAMHSA recently published a “treatment improvement protocol” that addresses the treatment of chronic pain in patients who have active or recovering SUDs (download available).117 Recommendations include avoidance of chronic opioid analgesic therapy in active addiction unless and until the person commits to a treatment/recovery program. Further recommendations include implementation of nonopioid therapies when effective (both pharmacological and nonpharmacological), avoidance of other reinforcing drugs (e.g., benzodiazepines, benzodiazepine receptor agonists, carisoprodol), and aggressive treatment of psychiatric comorbidity.

Optimal treatment of comorbid pain and addiction nonetheless remains controversial, and there are few data on which to base therapy.118 Current practice is largely guided by recommendations from clinicians in the field; however, we must recall how often “clinical wisdom” has been proved wrong when data became available. Among the most notable were the recommendations 50 years ago to minimize opioids for terminal cancer pain because of the risk for addiction.119

OPIOID-BASED TREATMENT

In a 1991 survey, Joranson and colleagues found that 58% of state medical board members considered it a probable violation of federal or state laws and regulations to prescribe COT to a person with a history of opioid abuse.120 A subsequent survey demonstrated marked liberalization of this attitude; however, many continue to doubt the wisdom of prescribing COT to those with SUDs, in part because of the paucity of data on the outcomes of such treatment. The lack of data may reflect a sense that the practice is hazardous. In fact, the use of chronic, home-going opioids in a person with an untreated addiction seems to be an invitation to abuse (altered routes of administration), diversion (exchanging therapeutic opioids for a different drug of choice), and death as a result of overdose and combinations of abused substances. Ironically, those with the least evidence of benefit from COT (most opioid studies excluded this population) and the most evidence of harm may be the ones most likely to receive it, as noted earlier.20

Studies of opioid analgesia in addiction are sparse. Dunbar and Katz treated 20 such patients with COT for longer than 1 year and found that those who abused treatment did so early. Those who did not were likely to be active in Alcoholics Anonymous, to have stable support systems, and not to be recent polysubstance abusers.102 Unsurprisingly, those who did not abuse opioid treatment were more likely to benefit from it. Kennedy and Crowley used methadone and weekly psychotherapy to treat four patients with chronic pain and comorbid SUDs.122 Three patients remained in treatment (19 to 21 months), stopped needle use or markedly decreased substance abuse, and demonstrated functional improvement. All three had significant psychopathology requiring psychotropics. Currie and coworkers treated 44 patients with comorbid chronic pain and addiction in cognitive-behavioral groups with an emphasis on substance abuse education and relapse prevention.123 Some chose to discontinue opioids. Those who continued opioids were transitioned to longer-acting medications (excluding methadone). “As-needed” opioids were prohibited, and once titrated to the optimal dosage, patients could not obtain additional medication. There were significant improvements in pain, emotional functioning, and medication reliance. At the 12-month follow-up, half the patients were opioid free and the remainder had reduced their use from 17 to 12 days per month. There was no significant difference in outcomes in opioid and nonopioid users, although those who continued to take opioids appeared to function better overall. It was suggested that long-acting opioids may provide both analgesia and reduction of cravings in this population.
From these studies, as well as clinical reports, it is reasonable to conclude that chronic opioid analgesic therapy will help some patients despite comorbid addiction if managed optimally. Ensuring concomitant addiction treatment is often key to management. For readers with interest in the treatment of addiction, the *Textbook of Substance Abuse Treatment*[124] provides detailed descriptions of psychosocial treatments, including psychodynamic, network, cognitive-behavioral, motivational, individual, group, and family psychotherapy, as well as 12-step–based approaches.

Several authors and publications have developed recommendations for opioid therapy in patients with SUDs. Most of these are not strictly data based; however, they are a reasonable guide given that patient management cannot be deferred until we have certainty. There is considerable overlap in recommendations; that is, experts tend to be in general agreement. This list is largely based on the sources listed.[118,125-127]

**Opioid Treatment of Patients with Substance Use Disorder**

1. Wean opioids and avoid COT if acceptable comfort and function can be maintained with nonopioid medications, behavioral methods, physical therapy, neuro-augmentation, or other therapies. Non-opioid–based treatments may be effective in this population.[128]
2. If a patient weaned from opioids continues to have craving and preoccupation, sublingual buprenorphine should be offered.
3. Require that the patient sign an agreement that constitutes informed consent (i.e., provides information regarding the risks and probable benefits of COT) and establishes the expected behavior of the patient and provider for continued management.
4. Make it clear that initiation of COT is always an “N of 1 experiment” and that it will be continued only if there is objective evidence of improved quality of life. “Taking the edge off” is not successful therapy.
5. Present COT as only one component of the treatment of chronic pain, which optimally includes education, fitness, and relaxation and coping skills training.
6. Ensure that the patient and family members understand that zero pain is not achievable with current technology and will not be pursued. Chasing this goal leads to indefinite dose escalation.
7. Frequent visits are necessary during dose finding (perhaps weekly) and initial treatment (at least monthly). Those who demonstrate the ability to use the medications appropriately may be seen less frequently and given multiple prescriptions with “do not fill until ___” instructions.
8. Avoid highly reinforcing opioids, primarily those with rapid onset and short action. Consider abuse-deterrent formulations that may impede crushing, injecting, and nasal insufflation.
9. A patient unable to maintain control of opioid use may respond to treatment with transdermal agents and an agreement that refills are contingent on return of used patches. This is also an option if the patient cohabits with a person who abuses substances.
10. Make it clear, in writing, at the onset that lost or stolen opioids or prescriptions will be treated like lost or stolen cash—it is not the prescriber’s role to replace them. It is clearly toxic to society to replace lost opioids since they lead to abuse and death, especially in young people.
11. Maintain accountability for medications with strategies such as pill counts.
12. Require permission to communicate with cohabitants, sponsors, pharmacies, and other providers.
13. Closely monitor the “four A’s”—analgesia, activity level, adverse effects, and aberrant behavior. In the event of poor outcomes, there is no defense for having continued an obviously ineffective treatment.
14. Obtain toxicologic verification that the patient is not taking unauthorized substances and is taking the prescribed opioid.
15. Do not combine opioids in this population with benzodiazepines, benzodiazepine receptor agonists, or carisoprodol. Instead, treat anxiety and insomnia with sedating antidepressants or antiepileptic drugs (AEDs).
16. If COT fails because of noncompliance, do not dismiss the patient; rather, dismiss the opioids and provide non-addicting treatments.

**Opioid Selection**

The goals in selecting an opioid are optimal analgesia with minimal risk for addictive relapse. Pharmacokinetic factors that promote inappropriate self-administration include rapid absorption and high bioavailability, rapid delivery to the CNS, low protein and peripheral tissue binding, small volume of distribution, short half-life, and high free drug clearance[129] (see also Quinn and colleagues[128]). Thus, drugs that are “fast in” with a bolus into the neuron and “fast out,” other things being equal, will be most subject to abuse. This is consistent with observations that delivery systems developed for euphorogenic effects are almost invariably in the direction predicted by these factors; for example, smoked cocaine is profoundly more rewarding than chewed coca leaves, and transdermal nicotine has little appeal to smokers.

Mironer and associates compared patients dismissed from treatment because of opioid misuse with those continuing to receive opioids.[131] They compared the frequency of prescription of various opioids with their frequency of abuse to generate a relative risk for misuse. The results, from highest to lowest risk for abuse, are as follows: butorphanol (4.4), propoxyphene (2.5), hydrocodone (1.61), codeine with acetaminophen (1.45), oxycodone immediate release (1.35), oxycodone delayed release (0.73), morphine 12 hour (0.66), transdermal fentanyl (0.23), and methadone (0.08). The conclusions are tentative given that patients were not randomly assigned to medications; however, they tend to support the clinical impression that patients are more likely to experience difficulty with some drugs than with others. Unfortunately, the study did not include many commonly prescribed opioids, and we lack good empirical data to guide opioid selection.

Brookoff asked prescription drug abusers to estimate the street price of various opioids. Of subjects who had tried controlled-release preparations, 60% found them to be of little use and estimated their street value to be lower than that of other opioids.[132] Reformulated OxyContin has a lower street price than the older, easy-to-crush formulation.[133] It seems reasonable to conclude that when abuse is
a concern, there should be a preference for opioids with delayed and prolonged action and avoidance of rapid-onset drugs and those that can be inhaled or injected.

**Abuse-Deterrent Drugs**

People abuse drugs in different ways—the most common is simple overuse of oral medications in an effort to become “high.” However, other methods to intensify the drug experience include crushing, grinding or chewing, dissolving, solvent extraction, nasal insufflation, and injection. Most strategies represent efforts to minimize \( T_{\text{max}} \) and achieve immediate neuronal entry of the substance.

In response, manufacturers have used a number of strategies to render drugs less abusable. Early “abuse-deterrent” formulations included Lomotil, which contains a subtherapeutic amount of atropine to discourage overuse, and Talwin-NX, in which naloxone was added to pentazocine in response to widespread abuse in the 1970s. The low dose of oral naloxone has no pharmacological activity; however, if injected, it antagonizes the action of pentazocine.

Currently, manufacturers are investigating a variety of techniques to impede rapid-onset preparations or routes (nasal, intravenous, smoked) or to limit the attractiveness of large doses:

- **Physical barriers**
  - Impede crushing, dissolving, chemical manipulation
  - Gel forming (difficult to inject, use by nasal insufflation)
  - Antagonist-agonist combinations
    - Typically release an antagonist if crushed or dissolved or contain an inactive oral dose of antagonist that is active if injected
- **Prodrugs**
  - Minimal effect until metabolized and thus little effect if injected or snorted
  - Lengthening of \( T_{\text{max}} \)
- **Aversive stimulus**
  - Niacin (induces flushing with overdose)
  - Capsaicin (painful nasally)
  - Sodium lauryl sulfate (irritates the nasal mucosa)
- **Depot drugs/implants**
  - Slow release rendering the drug inaccessible for manipulation

Although it seems that strategies that impede opioid abuse without reducing therapeutic use offer great promise, there are a number of barriers, including the difficulties associated with prescribing a proprietary abuse-deterrent drug when a cheaper generic is equally effective, the hurdle of convincing the Food and Drug Administration (FDA) that a new drug warrants an “abuse-deterrent” designation, and the fact that the benefit of the costly formulation will accrue more to society than to the recipient (purchaser) of the prescription.

Intrathecal analgesia has been used as a strategy for providing opioid therapy to patients who have difficulty controlling their use. Although this route impedes abuse, patients have withdrawn opioid from the pump and injected it intravenously, as well as injected illicit drugs into the port.134-136

**Buprenorphine**

The synthetic opioid buprenorphine is a partial \( \mu \)-opioid agonist with unusually high affinity for the \( \mu \) receptor.137 Because it is a partial agonist, there is a ceiling on both its analgesic and respiratory depressant effects, which may provide a considerable margin of safety in a population at risk for losing control of impulses to overdose.138 A sublingual form is available with naloxone that has little effect sublingually, but it antagonizes the opioid with parenteral use.139 Sublingual buprenorphine is approved only for use in the treatment of opioid addiction, but it is also an excellent analgesic and can be used to treat both conditions.138,140

The Drug Addiction Treatment Act of 2000 permits physicians to obtain a waiver that authorizes the prescription of approved medications (only sublingual buprenorphine at this point) for the treatment of opioid addiction. It is otherwise unlawful to prescribe opioids for the treatment of addiction except in a licensed methadone treatment program. The waiver is available from the Drug Enforcement Administration for physicians who have completed a small amount of training and meet other qualifications (details available online141).

Sublingual buprenorphine represents an appealing choice for patients with coexisting pain and addiction given its demonstrated benefit in both conditions and the reduced abuse liability of the naloxone-containing product. Transdermal buprenorphine is approved only for the treatment of pain. The packaging carries the warning of possible QT prolongation at dosages higher than 20 \( \mu g/hr \), and hepatic impairment may increase this risk. The FDA has mandated studies to determine whether sublingual forms also carry this risk since the dosages are higher.142

Because buprenorphine is only a partial agonist and has high receptor affinity, it can precipitate withdrawal in a patient taking a full \( \mu \)-agonist since the full agonist is displaced from the receptor by the partial agonist. If a patient maintained on COT is allowed to go into mild withdrawal and is then given buprenorphine, it relieves withdrawal symptoms.

Though used for the treatment of addiction, buprenorphine is also a drug of abuse. In Finland it has been the most misused opioid in recent years,143 and its illicit use has been increasing in the United States.144 The buprenorphine/naloxone combination is considerably less abusable as an intravenous preparation.145,146 Despite the relative safety of buprenorphine, it may be lethal when combined with benzodiazepines or other sedatives.146

**Methadone**

Methadone warrants special mention.147 It is approved for addiction treatment (by specially licensed facilities), is inexpensive and long acting, and seems less likely than other \( \mu \)-opioid agonists to promote dose escalation.148 Possibly because of \( N \)-methyl-D-aspartate (NMDA) receptor blockade by the \( \delta \)-isomer.149 However, it has many interactions with drugs and other substances (e.g., grapefruit, nicotine, antiretrovirals), has unpredictable kinetics leading to overdose fatalities, and prolongs the QT interval, which leads to a risk for torsades de pointes.151 Data from the American Association of Poison Control Centers demonstrated that the fatality rate per 100 exposures to methadone was several times that of other commonly prescribed analgesics.152 Therefore, it is best prescribed by those with expertise in its use.153

**Additional Reinforcing Medications**

The presence of comorbid psychiatric illness is typical in both individuals with disabling chronic pain and those with
addictive disorders. Thus, a preponderance of these patients will have psychiatric symptoms, most commonly anxiety or depression, which accounts for the frequent prescription of benzodiazepine anxiolytics in this population. Even though primary addiction to benzodiazepines is uncommon, its prevalence is increasing, and they are commonly abused by patients with other SUDs. There seems to be little justification for prescribing controlled substances for anxiety, muscle spasm, and insomnia given the availability of nonaddicting alternatives. Most antidepressants have anxiolytic properties and are not subject to abuse. This is also true of many AEDs commonly used for pain treatment. When needed, drugs from both categories (antidepressants and AEDs) that have sedative properties can be selected to minimize polypharmacy and unnecessary exposure of vulnerable patients to addicting substances. Chronic pain is also strongly associated with sleep disorders, which amplify the pain and should be addressed; however, the potentially habituating benzodiazepine receptor agonists are best avoided in those with addiction and tend to be of only transient benefit in any case. Most so-called muscle relaxants are not habituating, with the exception of carisoprodol, which should therefore be avoided in addicted patients.

NON-OPIOID–BASED TREATMENTS OF PAIN

It has been well demonstrated that some patients with chronic pain are more comfortable and functional without opioids, and there are a number of pharmacological and nonpharmacological options to opioids, as detailed in Chapters 38 to 43 and 45 to 49.

The role of fitness training and physical therapy is increasingly being recognized not only for improving pain and function in persons with CNCP but also for improving comorbid psychological distress. Cognitive-behavioral therapy and behavioral modification have well-demonstrated efficacy as well. Interdisciplinary pain rehabilitation programs that combine reconditioning, cognitive-behavioral therapies, and (usually non-opioid–based) pharmacotherapy have been shown to produce marked and lasting benefit in pain, mood, and function.

Since we lack accurate predictors of which patients will do well with opioids, we are essentially limited to a therapeutic trial to ascertain who will show improved pain, function, and mood and to assess side effects and aberrant behavior. It is likely that patients with addiction will be overly represented in the group who are better without opioids since their risks are clearly increased. It is noteworthy that most of the patients who improve with opioid elimination had believed that they were being helped by the drugs. We have compared treatment outcomes of CNCP patients who had comorbid addiction with those of nonaddicted patients and found that with nonopioid management of both conditions, outcomes were equally good. Since studies that extend beyond 18 months rarely show more than a 33% reduction in pain with COT (and a >50% dropout rate), it is apparent that even when opioids are necessary, they are rarely sufficient in patients with CNCP, and this is even more the case in those with comorbid addiction. Fitness, psychological counseling, and use of adjuvant analgesics are essential for most patients.

PROTECTING THE CLINICIAN

A medical text should properly be concerned primarily with the well-being of patients, which is the goal of health care. However, one impediment to such care is providers’ appropriate concern for their own protection and the protection of their livelihood. This concern has an impact on patient access to care.

Prescribers may face sanctions for treating addicts with opioids, and addicts may seek compensation from providers whom they claim caused their addiction. In a study of malpractice claims against anesthesiologists by patients with chronic pain, Fitzgibbon and colleagues found that medication management was responsible for 17% of the claims. Of the patients involved, 94% were prescribed opioids, which were combined with additional psychoactive medications in 58%. Eighty percent had at least one factor commonly associated with medication misuse, and 24% had three or more factors. Most claims involved patients who did not cooperate in their care (69%). Death was the most common outcome (57%), although iatrogenic addiction was the complaint in 24%.

The fact that addiction is much more likely to have arisen from recreational drug use does not alter the fact that iatrogenic addiction does occur and may constitute a compensable injury. A greater risk, however, is that a patient who had a preexisting addiction may falsely believe or claim that the prescriber caused it. Personal knowledge of physicians who have been sanctioned or sued for issues related to opioid prescribing suggests that the problems are most likely to occur during treatment of people with an addictive disorder. Although it is critical to recognize that addiction is a disease that no one chooses to have, it is associated with the emergence of antisocial behavior, to which the prescriber must not become vulnerable. Thus patients must be held accountable. Addicts making a sincere effort to recover will appreciate this because it helps reduce the likelihood of relapse (like being “weighed in” at Weight Watchers).

Protection of the provider’s interests is promoted by diligent documentation and diagnosis of any preexisting addictive disorder. Some states require that COT in those with a previous addiction be initiated only after consultation with an addictionologist. It is equally critical that the provider meticulously document treatment response (perhaps with spousal confirmation)—or the lack thereof—and terminate opioid therapy unless it is clearly beneficial.

Prescribers may assume that patients will accept a small risk for the development of addiction to have a substantial likelihood of pain relief. This should not be assumed because that decision belongs to the patient. It should be clearly documented that the patient understood the risk for potential addiction and opted for COT before its institution.

CONCLUSION

The pain/addiction interface is quite complex. It poses special challenges and requires special techniques. Accurate diagnosis is critical and often difficult. A guiding principle is that even though patients with addictive disorders are entitled to aggressive pain treatment, they are not all
entitled to opioids, which may be more of a liability than an asset. There is the potential for an excellent outcome in these cases since most patients with an addictive disorder and chronic pain can be restored to good function and comfort, sometimes with and sometimes without opioids. Such an outcome is unlikely unless the clinician exercises due diligence in identifying preexisting SUDs. A particular challenge is the apparent fact that excellent pain treatment or excellent addiction treatment will be of little value to these patients unless they have both. The pain specialist is in a unique position to ensure that this occurs.

Although addiction is generally described as a chronic relapsing illness, many sufferers are restored to fully normal and productive lives for prolonged periods, and some never relapse. In fact, it may be that those with iatrogenic opioid addiction have a better long-term prognosis than those who acquired the disease through recreational use. Thus, it is essential that pain specialists be able to understand patients who manifest addictive behavior as people with a bad disease rather than as bad people. By diagnosing addiction and facilitating treatment, pain specialists are in a position not only to decrease suffering but also to save lives.

**KEY POINTS**

- Addiction is a primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behavior that includes one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
- Physical dependence is normal and is expected after prolonged use of opioids; it does not indicate the presence of any disorder.
- Tolerance is a state of adaptation in which exposure to a substance induces physiologic changes that diminish its effects. Analgesic tolerance is one of the reasons that opioids are more effective for acute than for chronic pain.
- Pseudoaddiction describes a state in which inadequate analgesia leads to behavior that mimics addictive behavior.
- Heroin addicts often report that they have spent years trying without success to recapture the highs that they experienced when they initiated use or that they no longer use heroin to get high but only to stop feeling bad.
- A tenant of most addiction treatment and education is the concept that a person addicted to one reinforcing substance is at high risk for addiction to all such substances and should therefore abstain even from substances that have never been problematic.
- Although chronic opioid therapy can cause physical dependence, trigger relapse in those recovering from addiction, and elicit addiction in some, it is clear that preexisting vulnerability plays a critical role in this process.
- Several studies suggest that the vast majority of patients who manifested addiction while being treated with chronic opioids had preexisting drug or alcohol disorders.

**KEY POINTS—cont’d**

- The development of addiction is a function of the molecule involved, dose administered, duration of use, genetic and personal vulnerability, and perhaps the route and rate of administration.
- Drugs that rapidly and markedly increase dopamine, such as crack cocaine, often produce addictive behavior quickly.
- A positive screening test does not necessarily exclude patients from opioid therapy. Rather, it identifies those who have a lower than usual benefit-to-harm ratio and therefore require more thorough assessment, closer monitoring and accountability, and possibly referral for addiction treatment.
- Urine drug testing can lead to erroneous conclusions for several reasons. Immunoassays are vulnerable to cross-reactivity, misleading results can occur when a prescribed substance is converted to another nonprescribed substance, and spurious results can occur from the consumption of legal substances.
- Hair and saliva testing is now available. Hair testing is extremely accurate and virtually impossible to defeat and can detect use in the past 3 or more months. Recent use will be missed because it takes about 1 week for hair to grow from the follicle to a length where it can be collected.
- It has been shown that blood levels of morphine typically adequate for relief of postoperative pain had minimal analgesic effect in patients maintained on stable doses of methadone.
- Buprenorphine is a partial agonist with a ceiling on its analgesic and respiratory depressant effects, and this may provide a considerable margin of safety in a population at risk for losing control of impulses to overuse. Sublingual buprenorphine is approved only for use in the treatment of opioid addiction.
- Primary addiction to benzodiazepines is uncommon, but its prevalence is increasing. It is commonly abused by patients with other substance use disorders. There is little justification for prescribing controlled substances for anxiety, muscle spasm, and insomnia to patients with comorbid addiction given the availability of nonaddicting alternatives.
- The role of fitness training and physical therapy is increasingly being recognized not only for improving pain and function in persons with chronic noncancer–related pain but also for improving comorbid psychological distress.
- Reports of physicians who have been sanctioned or sued for issues related to opioid prescribing suggest that problems are most likely to occur during treatment of people with an addictive disorder. Protection of the provider’s interests is promoted by diligent documentation and diagnosis of any preexisting addictive disorder. Some states require that chronic opioid therapy in those with a previous addiction be initiated only after consultation with an addictionologist.

Chronic pain is a widespread, costly condition that influences every aspect of normal functioning; collectively, pain imposes a greater economic burden than any other disease, with estimates of annual cost near $300 billion. Opioids have been used to relieve pain for thousands of years, and prescription opioid medications continue to be a very common treatment modality for chronic non–cancer-related pain. Simultaneously, prescription opioid medications used for nonmedical purposes have rapidly become common drugs of abuse and the most likely cause of unintentional overdose. As a result, the relationship between pain and addiction is a complicated one that poses several challenges for both patients and physicians.

A large percentage of patients with chronic pain disorders have preexisting comorbid addiction disorders or such disorders develop after receiving treatment for pain. Studies have found rates as high as 15% to 28% for current substance disorders and 2% to 54% for lifetime prevalence in chronic pain patients, both rates significantly higher than in the general population. In one study of 200 patients with low back pain it was found that substance use and anxiety disorders seem to precede the onset of chronic pain. In the primary care setting it has been shown that substance use disorders precede the onset of chronic pain in 77% of patients who are actively using illicit substances and in 63% of patients with lifetime substance use disorders. Even though a significant proportion of patients seeking treatment of their pain may have a comorbid addiction problem, addiction problems can make it difficult to diagnose and treat pain. Chronic pain is more likely to develop in those with a preexisting history of substance abuse, and comorbid substance use disorders are more likely to develop in those with chronic pain and no history of substance abuse than in those without pain. It behooves the pain physician to have a good understanding of how pain and addiction are intertwined to skillfully manage these problems in an attempt to prevent worse outcomes.

Patients with chronic pain often have other psychiatric comorbid conditions (such as major depression or a generalized anxiety disorder), which may increase the risk for substance abuse and thereby create a more complex diagnostic and treatment conundrum for treating these patients’ pain. Some data suggest connections between chronic pain, mood disorders, and substance abuse. Moreover, it has been shown that patients who have chronic pain are not only at a higher risk for opioid abuse but also have higher rates of mood disorders. This constellation of diagnoses and problems compounds the difficulty that a physician will face when attempting to treat pain in patients who fall into this category.

This chapter covers the scope of these issues, from the neurobiology of addiction, to characterizing those at risk for opioid misuse and distinguishing opioid misuse without major negative consequences from prescription opioid addiction, to treatment considerations in patients with pain and substance use comorbidity. The topics are discussed primarily from the perspective of treatment of non–cancer-related pain with opioids. Even though those with cancer-associated pain are also at risk for substance use disorders, this phenomenon has not been well described.

Any drug addiction is now understood to be a disease that is very much brain based. This phenomenon is a consequence of repeated exposure to the addictive drugs that leads to behavior characterized by loss of control over the use of such drugs. The behavioral abnormalities are connected to physiologic underpinnings, which mutually reinforce each other, and substance use disorders can be thought of as disorders of motivated behavior. Effective treatment involves simultaneously changing behavior and addressing the underlying physiologic drives sustaining the aberrant behavior. Addiction can be conceptualized as a chronic neurobiologic disease and a model of the relationship between the brain and behavior.

There remains a great deal of uncertainty regarding the exact neural correlates of addiction. Nonetheless, it is believed that key brain regions constituting the brain networks for addiction are found within the mesocorticolimbic dopamine systems, which start in the ventral tegmental area and connect to the amygdala, prefrontal cortex, and nucleus accumbens (Fig. 51.1).

This pathway has been called the “dopamine reward pathway,” and all addictive drugs ultimately act through different mechanisms to potentiate euphoria or other positive reward symptoms that subsequently reinforce behavior for ongoing use of the drug. Opioids, in particular, work by inducing the release of dopamine in the ventral tegmental area and by binding to receptors in the nucleus accumbens. It has been postulated that the experience of withdrawal uses this same pathway to create the negative reinforcement that contributes to compulsive behavior and cravings.

Moreover, some of the biologic correlates connecting negative affect, increased pain, and opioid use have been described. These include the spinolimbic pathway, also known as the “medial pain system.” This pathway travels parallel to
much linked to genetic factors, as shown by genetic epidemiologic studies using twin, family, and adoption designs. Heritability can range from 0.3 to 0.5, depending on the concentration of opioid receptors.26,27

Vulnerability to the development of addiction is very much linked to genetic factors, as shown by genetic epidemiologic studies using twin, family, and adoption designs. Heritability can range from 0.3 to 0.5, depending on the drug of use.26-32 Although a specific “addiction gene” has not been identified, these studies point to a very strong biologic influence of addiction, whose assessment must be incorporated into the everyday clinical practice of addiction medicine and pain medicine. Thus, taking a detailed family history, including a family history of substance abuse, is valuable in providing data for comprehensive pain assessment. The different terminology used in the context of chronic pain with addiction and opioid misuse or abuse is summarized in Box 51.1.

**Box 51.1 Definition of Terms Used in Opioid Addiction**

- **Pain** is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.33
- **Addiction** is a chronic, relapsing brain disease characterized by compulsive drug behavior and use despite harmful consequences.34
- **Pseudo-addiction** is a condition in which patients taking opioids seek additional opioid medications because of inadequate dosing. These patients may exhibit behavior suggestive of addiction, but it resolves with an increase in opioid dose to provide adequate analgesia.35
- **Iatrogenic addiction** is a condition in which patients without a genetic predisposition for abuse are overly prescribed opioids, thereby leading to addiction.36
- **Physical dependence** is a state of adaptation that causes a drug class–specific withdrawal syndrome because of abrupt drug cessation, rapid reduction, or use of an antagonist.37,38
- **Tolerance** is an adaptation state that develops over time to a drug that requires increased doses to create the same drug effect or a reduction in one or more of a drug’s effect over time.39
- **Misuse** is the use of medications other than as directed whether willfully or unintentionally and regardless of whether harm results.
- **Abuse** is the use of illicit or licit substances intentionally for nonmedical purposes.
- **Diversion** is the intentional removal of a drug from legitimate distribution and dispensing channels. Much of the opioid medications “sold on the street” have come from pharmacies.10,40,41
- **Aberrant behavior** is a breach of mutually established medical boundaries by the patient.

For many pain medicine and addiction specialists, this definition of addiction is preferred in patients prescribed opioids for pain over the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), definition of substance dependence because physical dependence in these patients, as evidenced by tolerance and withdrawal, is normal. Although the DSM-IV definition does not require tolerance or withdrawal to make the diagnosis of substance dependence, these conditions do fulfill two of three major criteria required to make the diagnosis (Table 51.1). Thus, there are phenomenologic quandaries in applying the DSM-IV criteria for evaluation of substance dependence in patients prescribed opioids for pain. Given these issues, the AAPM and ASAM refer to **substance misuse** in this patient group as the use of any drug in a manner other than how it is indicated or prescribed.42 **Substance abuse** is defined as the use of any substance when such use is unlawful or detrimental to the user or others.

Hence, opioid misuse may indicate a treatment compliance issue or may signal a more serious addiction problem if accompanied by a lack of control over use despite negative consequences. These distinctions are somewhat blurry, and in a clinical pain medicine practice it is often unclear whether a patient is simply noncompliant with the medication or is truly dependent. The presence of craving is central to this distinction in applying the AAPM and

**Figure 51.1 Dopamine reward pathway.** (This slide is made available to the public through the National Institute on Drug Abuse Web page at www.nida.nih.gov/Teaching/largegifs/slide-9.gif.)

the spinothalamic tracts in the spinal cord and receives direct input from the dorsal horn of the spinal cord.25 This pathway will lead to regions in the brain, such as the anterior cingulate cortex, insula, and prefrontal cortex, that not only process both pain and affect but are also regions with a very high concentration of opioid receptors.26,27

Many terms are used to describe substance use disorders in patients with chronic non–cancer-related pain, and clarification of the terminology is important. The American Academy of Pain Medicine (AAPM), the American Pain Society, and the American Society of Addiction Medicine (ASAM) define **prescription opioid addiction** in patients with pain as “a primary, chronic, neurobiologic disease that is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.”42 As noted, the behavioral characteristics of prescription opioid addiction may be perpetuated by a physiologic drive that comes with using prescription opioids;18 in this case the mesolimbic motivational circuits are “hijacked” to perpetuate a disorder of motivated behavior.43,44

**NOSOLOGY OF PRESCRIPTION OPIOID MISUSE, ABUSE, AND ADDICTION**

Many terms are used to describe substance use disorders in patients with chronic non–cancer-related pain, and clarification of the terminology is important. The American Academy of Pain Medicine (AAPM), the American Pain Society, and the American Society of Addiction Medicine (ASAM) define **prescription opioid addiction** in patients with pain as “a primary, chronic, neurobiologic disease that is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.”42 As noted, the behavioral characteristics of prescription opioid addiction may be perpetuated by a physiologic drive that comes with using prescription opioids;18 in this case the mesolimbic motivational circuits are “hijacked” to perpetuate a disorder of motivated behavior.43,44
pain with opioids is associated with a 40% prevalence of opioid misuse. Clinicians have reported several types of aberrant drug-related behavior (ADRB) that may be indicative of opioid misuse. Although such behavior is problematic and indicative of nonadherence to opioid therapy at the very least, many have not been empirically tested to distinguish opioid misuse without negative consequences from prescription opioid addiction. Of course, certain types of extreme behaviors, such as injecting oral formulations or compulsive, uncontrolled use of medication, have face validity suggestive of addiction. According to Portenoy, there are three major types of ADRBs: loss of control over the drug, compulsive drug use, and continued use despite harm. He suggested the following sets of drug-related behavior that may cause suspicion about problematic use in opioid-treated pain patients:

**ADRB more predictive of addiction**
- Prescription forgery
- Stealing or “borrowing” drugs from others
- Injecting oral formulations
- Obtaining prescription drugs from nonmedical sources
- Concurrent abuse of alcohol or illicit drugs
- Multiple dose escalation or other noncompliance with therapy despite warnings
- Multiple episodes of prescription “loss”
- Repeatedly seeking prescriptions from other clinicians or from emergency departments (EDs) without informing the prescriber or after a warning to desist
- Evidence of deterioration in the ability to function at work, in the family, or socially that appears to be related to use of the drug
- Repeated resistance to changes in therapy despite clear evidence of adverse physical or psychological effects from the drug
- Selling prescription drugs (which is termed diversion and is not indicative of a substance use disorder per se but does signify a major ADRB)

**ADRB less predictive of addiction (may be more indicative of poorly controlled pain or misuse without significant negative consequences)**
- Aggressive complaining about the need for more drug
- Drug hoarding during periods of reduced symptoms
- Requesting specific drugs
- Openly acquiring similar drugs from other medical sources
- Unsanctioned dose escalation or other noncompliance with therapy on one or two occasions
- Unapproved use of the drug to treat another symptom
- Reporting psychic effects not intended by the clinician
- Resistance to change in therapy associated with “tolerable” adverse effects with expressions of anxiety related to the return of severe symptoms

Savage in 2002 also formulated a short list of patterns that may suggest addiction (“look for the four C’s”):

**Adverse Consequences/harm as a result of use**
- Intoxicated, somnolent, sedated
- Declining activity
- Irritable, anxious, labile mood
- Increasing sleep disturbances
- Increasing pain complaints
- Increasing relationship dysfunction
Impaired Control over use/Compulsive use
- Reports lost or stolen prescriptions or medication
- Frequent early renewal requests
- Urgent calls or unscheduled visits
- Abusing other drugs or alcohol
- Cannot produce medication on request
- Withdrawal noted at clinic visits
- Observers reporting overuse or sporadic use

Preoccupation with use because of Craving
- Frequently missed appointment unless opioid renewal expected
- Does not try nonopioid treatments
- Cannot tolerate most medications
- Requests medication with high reward
- No relief with anything else except opioids

It is important to remember that many of the types of behaviors listed may occur occasionally in isolation in patients using opioids appropriately, for the most part in the treatment of their chronic pain. However, a pattern of such behavior in the context of titrated pain therapy may suggest the need for further evaluation to determine the presence of prescription opioid addiction. It is still unclear exactly which constellations of symptoms or behaviors accurately distinguish misuse from abuse and addiction. These are thought to exist on a continuum, with the most severe form of nonadherence—addiction—characterized by the four “C’s.”

Early and proper identification, as well as careful monitoring for signs of problematic opioid use and ADRB, is warranted. Once identified, several measures may be taken by the prescribing physician to control for such aberrant behavior and reduce risk for the subsequent development of an addiction problem, including the following:

- Writing an opioid pain treatment agreement, if one is not available, in which expectations and conditions for termination of opioid prescription are clearly outlined
- Increasing the number of office visits and more frequent monitoring
- Decreasing the number of medication dispensed per visit
- Performing random pill counts on visits
- Recommending the use of only one pharmacy
- Using prescription drug–monitoring programs (PDMPs) to determine whether the patient has been getting prescriptions from multiple providers, EDs, or both
- Avoiding early prescriptions and excluding any replacement of lost or stolen prescriptions
- Requiring police reports for stolen medications
- Performing random urine drug screens and considering consultation with an addiction specialist if true addiction to the opioid medication is suspected

Careful assessment is essential to determine the underlying cause and co-occurring physical and mental comorbid conditions that may contribute to such behavior. Reliance on patient self-reports of medication use to determine inappropriate behavior has been shown to be notoriously unreliable and inaccurate since patients tend to underestimate their medication use. Cook and colleagues found that when patients’ self-reports were compared with urine toxicology screens, the actual prevalence rate of drug use was approximately 50% higher than the estimate produced by self-reports. Berndt and coauthors also reported that 32% of patients’ self-reports of their use of medication did not match with their urine tests.

In addition, “gut feelings” by some prescribers who are confident that they can identify vulnerable individuals should be avoided since empirical evidence has shown them to be ineffective. Wasan and associates found that even though prescribers had judged only 14% of their chronic pain patients to have ADRB, approximately 50% were found to have positive urine drug screens for illicit drugs and 8.7% had no evidence of any opioids in their urine.

In an attempt to decrease the risk for opioid misuse and iatrogenic addiction to prescribed opioid medications, Gourlay and coworkers recommended establishing a policy of “universal precautions” when prescribing opioid analgesics:

1. Making a diagnosis with appropriate differential
2. Psychological assessment, including risk for addictive disorders
3. Informed consent
4. Treatment agreement (previously called an “opioid contract”)
5. Preintervention and postintervention assessment of pain level and function
6. Appropriate trial of opioid therapy with or without adjunctive medication
7. Reassessment of pain score and level of function
8. Regular assessment of the “four A’s” of pain medicine (analgesia, activity, adverse effects, and aberrant behavior)
9. Periodic review of the pain diagnosis and comorbid conditions
10. Proper documentation

Screening for risk for addiction should be performed before chronic opioid therapy is initiated to provide the treating physician with clues about the necessity for increased monitoring in susceptible individuals and to assist in making the decision of whether to prescribe opioids at all. If opioid treatment results in good pain control, a better level of functioning, and improved overall quality of life, opioid treatment could reasonably be continued even in patients susceptible to addiction. However, the important point is that patients thought to be at greater risk for opioid misuse will require special attention with a focus on compliance and with proper communication about the potential risks and consequences if opioid treatment is getting out of control.

The ideal screening tool for medication misuse or abuse in patients with chronic pain should be easy to administer, reliable, and well validated. An outline of such different screening tools is summarized in Box 51.2.

Though conceptually distinct from instruments designed to detect existing addictive disorders, measures whose purpose is to predict aberrant prescription opioid–related behavior in pain patients are closely related, with identification of similar risk factors. As a whole, this body of research is remarkably consistent in identifying the most significant risk factors for predicting prescription opioid misuse: current reports of misuse, past or current history
of an addiction disorder to any substance (except perhaps for alcohol dependence in remission for several years), concurrent negative affective disorder (such as major depression or an anxiety disorder), previous or current history of sexual or physical abuse, family history of substance use disorders, and a history of illegal activities. Remarkably, ongoing pain levels have not been shown to be strong, consistent predictors of opioid misuse, albeit some misuse behavior may purely be a consequence of underdosing of opioids (pseudo-addiction).

URINE TOXICOLOGY SCREENING

Urine toxicology screens continue to be the most widely used and possibly the “gold standard” for detecting illicit substance use in chronic pain patients treated with opioids. Patients should be screened at baseline before starting opioids and then periodically throughout the course of treatment. However, the results of baseline screening should be interpreted with caution and not considered indicative of future aberrant behavior. Katz and Fanciullo found that 72% of patients with positive baseline screens (i.e., inappropriate results) did not have evidence of any aberrant behavior after initiation of treatment. Conversely, patients with an initial negative toxicology screen may later demonstrate behavior indicative of problematic drug use. Many types of urine toxicology screens and many testing technologies are available, so it is important to choose the type of screening that most closely and accurately identifies the substances of interest.

OPIOID THERAPY AGREEMENTS

As noted, it is important for clinicians to discuss their management plan regarding chronic opioid therapy with their patients before initiating treatment and on an ongoing basis during therapy. The management plan should include the goals of therapy, how opioids will be prescribed and taken, alternatives to opioid therapy, expectations for follow-up, monitoring, and use of concomitant therapies, as well as potential reasons for terminating opioid therapy, which may include failure to meet the therapeutic goals, serious side effects, or repeated ADRB.

Although evidence of the most effective methods to convey this management plan is lacking, written documentation through an opioid therapy agreement signed by both the patient and clinician may be an appealing tool for managing many of the potential difficulties related to chronic noncancer-related opioid therapy. Despite the widespread use of therapy agreements and some evidence of their effectiveness, their efficacy has not yet been proved (i.e., compared with a control condition in a prospective study). Nevertheless, multiple opioid therapy treatment guidelines appropriately emphasize the benefits of such an agreement in all patients prescribed opioids for noncancer pain. They can be particularly helpful for patients at higher risk for opioid misuse, to reinforce expectations about the appropriate and safe use of opioids, and to convey the consequences of violating such terms. The contents of signed opioid agreements may vary, and there is still insufficient evidence to guide specific recommendations on which provisions to include. Some common provisions include

- Obtaining opioids from one prescriber
- Filling opioid prescriptions at one designated pharmacy
- Random urine drug screens
- Office visits at a specified minimum interval
- Use of pill counts
- Limited prescriptions (in weekly or biweekly instead of monthly amounts)
- Description of behavior that may lead to discontinuation of chronic opioid therapy

Although the opioid agreement may be helpful in some ways, it may not be entirely benign for either the patient or clinician. There is always the potential of carrying some degree of stigma or even the appearance of punishment with such agreement forms, particularly in those with a history of addiction. It may also inappropriately reassure clinicians that patients are completely adherent to the treatment plan, which then results in less stringent monitoring of opioid use and treatment efficacy. Opioid agreements are still considered binding contracts and thus carry with them

Box 51.2 Screening Tools for Opioid Misuse or Abuse

<table>
<thead>
<tr>
<th>Well Validated Tools</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pain Medicine Questionnaire: high validity and reliability; patients answering the questionnaire may not feel opposed to or prejudiced against the questions since opioids are not specifically mentioned.</td>
</tr>
<tr>
<td>Current Opioid Misuse Measure (COMM): can identify aberrant drug-related behavior in patients who are currently taking opioids.</td>
</tr>
<tr>
<td>Screener and Opioid Assessment for Patients with Pain—Revised (SOAPP-R): consists of 24 items and a cut-off score of 14 or higher for classifying those at greater risk for opioid misuse.</td>
</tr>

an increased risk for liability should the clinician violate their terms or place patients at risk for reduced autonomy. Careful consideration should be given to restrictions placed on patients, such as limitations on driving or prohibiting pregnancy, since the literature is still inconclusive on these subjects.

PRESCRIPTION DRUG—MONITORING PROGRAMS

PDMPs are statewide electronic databases that collect data on controlled substances dispensed in the state. They are housed by specified statewide regulatory, administrative, or law enforcement agencies (most commonly state boards of pharmacy). Information is stored in a central database and can be accessed by authorized users, including prescribers, dispensers, law enforcement for drug investigations, licensing and regulatory boards, Medicaid programs, medical examiners, and research organizations. Their main goal is to identify and prevent drug abuse and diversion, as well as to facilitate the identification of, intervention in, and treatment of persons addicted to prescription drugs. The data collected can help provide information for public health initiatives about the use and abuse trends of different substances statewide, including prescription opioids. PDMPs also ensure patient privacy since law enforcement personnel cannot access patient-specific PDMP data unless an active investigation is ongoing and health care providers can access only the PDMP data relevant to their patients.

Several studies have shown that PDMPs are effective when fully used. A 2010 study found that when PDMP data were used in an ED, 41% of cases had altered prescribing after the clinician reviewed PDMP data; 61% of the patients received no or fewer opioid pain medications than had been originally planned by the physician before reviewing the PDMP data, and 39% received more opioid medication than previously planned because the physician was able to confirm that the patient did not have a recent history of controlled substance use. Another 2010 independent evaluation of Kentucky’s PDMP, KASPER, found that 90% of those surveyed believed that KASPER was effective in preventing drug abuse, diversion, and doctor shopping.

RISK EVALUATION AND MITIGATION STRATEGIES

In response to disturbing rises in prescription opioid abuse, the Food and Drug Administration proposed the implementation of aggressive risk evaluation and mitigation strategies (REMSs) that will require prescribers to obtain mandatory education, provide mandatory patient education, register patients into registries, and other measures before prescribing certain opioids. The first opioid to be subject to the new REMSs was the fentanyl buccal soluble film (Onsolis), and it has now been extended to include multiple opioids, including extended-release and long-acting forms. The applicability, usefulness, and acceptance of REMSs by prescribers remain controversial. A recent survey by Slevin and Ashburn found that 50% of surveyed primary care physicians reported being unwilling to prescribe opioids controlled by the new REMSs, which could have the unintended effect of decreasing access to these medications for legitimate medical purposes.

FACTORS PREDICTIVE OF OPIOID MISUSE OR ABUSE

As noted, the risk for addiction in the context of chronic non–cancer-related pain is believed to be due to a combination of factors, including genetic predisposition, brain reward mechanisms, psychosocial factors, and drug exposure. The most consistent risk factor in the context of opioid therapy as identified by several studies is a personal or family history of addiction, more so with multiple substances rather than a sole history of alcohol dependence. Turk and coworkers also identified other possible predictive factors, including a history of psychiatric comorbid conditions, especially unipolar depression, and a history of legal problems such as driving under the influence, previous motor vehicle collisions, or drug convictions. Dunbar and Katz identified not being members of a 12-step group such as Alcoholics Anonymous (for those with a past history of alcohol dependence) and having poor social support as additional risk factors. Michna and colleagues found that the presence of two or more risk factors, including a personal or family history of substance abuse or legal problems related to substance abuse, was significantly associated with clinical evidence of opioid misuse. Schiffer and associates also found that patients with a history of drug and alcohol abuse and patients with a prior psychiatric diagnosis (such as depression or an anxiety disorder) showed greater risk for medication misuse than did those without such a history. The results for other variables such as age, gender, and marital status are mixed.

TREATMENT OF PAIN IN HIGH-RISK PATIENTS AND THOSE WITH KNOWN ADDICTION

A number of authors have emphasized the importance of differentiating pain patients from addicts. However, realistically, the two conditions are not mutually exclusive and occur concurrently more frequently than would be expected by chance. Jamison and colleagues interviewed 248 patients at methadone maintenance centers and found that 61.3% reported chronic pain as a primary medical condition. Rosenblum and coworkers found that severe chronic pain was present in 37% of 390 methadone maintenance treatment patients and in 24% of 531 chemically dependent inpatients. On the other hand, reports regarding the prevalence of current substance use disorders in patients receiving opioids for chronic pain range from 3% to 43%, with a lifetime prevalence as high as 54%. Thus, documentation of the prevalence of pain in addicts and the prevalence of addiction in those with pain makes it clear that it is often necessary to treat persons with both conditions.

Pain, as well as pain management, in high-risk patients and those with substance dependence is a complex topic that sometimes leads to uncertainty or conflict between the patient and practitioner. It is important to remember that pain is more commonly undertreated in individuals perceived to have an addictive disorder secondary to fear of causing or exacerbating their addiction. However, this may increase the distress over and anxiety and craving for pain-relieving medications and thus potentially create more
potent factors for relapse. Treating physicians should inform patients with addictive disease that they are aware of their addiction and reassure them early that this will not be an obstacle to relief of their pain. Addiction counseling should be offered any time during treatment as long as the pain is adequately controlled. It is unclear to what extent this subgroup of patients can be adequately managed in a medical setting, such as a pain medicine clinic, or under what conditions these patients should have opioids prescribed only by an addiction medicine specialist.

CROSS-ADDICTION OF NONOPIOIDS

It is a truism in addiction medicine that a patient’s former drug of choice will have the most power to elicit cravings and relapse, which probably explains the clinical impression that opioid therapy in recovering alcoholics is often more successful and less likely to lead to adverse outcomes than such therapy in recovering opioid addicts. Nevertheless, the concept of cross-addiction suggests that a patient with any previous addiction is at heightened risk for new addiction, even to unrelated substances. Thus, a chronic marijuana user may be at special risk for the development of opioid addiction, even though the substances are unrelated. It is therefore essential that the clinician identify preexisting problems not only with opioid abuse but also with all rewarding or reinforcing substances. A distinction must be made between acute pain and chronic nonmalignant pain and between a patient who is actively engaging in substance abuse and one in recovery.

ACUTE PAIN

OPIOID ADDICTS

Acute injuries in addicts, even those with sustained recovery, often require higher doses of analgesia (about three times on average) than needed in patients with no addiction history because of higher tolerance levels to opioids. Research has shown that tolerance is rapidly re-established in a previously tolerant person or animal once opioid use is resumed. Care should be taken to educate the supporting staff well regarding tolerance and the higher analgesia requirements of such patients with a history of addiction to avoid possible collisions between the patient and staff.

Management of acute and postoperative pain in patients with addiction should include continuing the patients’ maintenance opioids, if any, to meet their baseline opioid requirements and supplementing them with additional analgesia, multimodal when possible, such as adjuvant nonsteroidal anti-inflammatory drugs (NSAIDs), neuropathic medications, local anesthetics, or short-acting opioids if needed. However, if opioids are to be used, they should be given on a scheduled or continuous basis rather than as-needed dosing. Giving the patient specific times for drug administration is also helpful. Intermittent, nonscheduled medications are appropriate when the individual has pain that is related only to specific activities or to help adjust the dosing schedule. If the individual has difficulty controlling medication use, a trusted other may help dispense the medications. The patient should always be included in the decision-making process regarding dosing and scheduling since this helps alleviate anxiety and may also give the physician valuable insight in designing an effective treatment regimen.

The use of patient-controlled analgesia (PCA) in individuals with addictive disease has been recommended by some to help provide more uniform pain relief at a lower total dose of medications and to eliminate the need for the patient to request opioids, thus avoiding conflicts between the staff and patient. However, others worry that because PCA requires self-administration, this may create ambivalence in recovering addicts who have difficulty limiting their administration of opioids to levels that provide analgesia without intoxication. It may also reinforce pain through pairing of pain with self-administration of opioids. Thus, as with all pain control measures, use of PCA should be considered on a case-by-case basis. If used, higher than usual bolus doses and shorter than usual lock-out intervals are generally recommended.

Transdermal opioids and implantable devices (discussed later in detail) have also been noted as alternatives. Other promising adjuvant analgesics that have been gaining more interest in controlling postoperative pain in patients taking long-acting opioids are ketamine and α2-agonists such as dexmedetomidine. Such agents may reduce opioid tolerance and attenuate opioid-induced hyperalgesia and have proven analgesic properties of their own. A recent meta-analysis of 37 trials that included more than 2200 patients by Bell and associates indicated that ketamine probably reduces postoperative opioid requirements, at least during the first 24 hours. In addition, Loftus and coauthors reported almost a 30% reduction in morphine consumption over the first 48 hours and a 25% reduction in visual analog pain scores in the postoperative care unit with the intraoperative administration of ketamine.

As a general rule, when there is doubt regarding whether a patient is in pain or is requesting drugs because of addiction, it is always more appropriate to err on the side of giving adequate pain relief, preferably with “nonopioid” interventions. In addition, associated symptoms such as sleep disturbance, anxiety, depression, or secondary physical problems should be identified and treated properly. Once the acute pain has completely resolved, the addiction problem can be addressed through detoxification, rehabilitation, therapy, or medications as deemed appropriate.

PATIENTS RECEIVING OPIOID AGONIST THERAPY

Both pain and addiction treatment issues should be addressed concurrently in patients with acute pain who are receiving opioid agonist therapy (such as methadone or buprenorphine).

First, in regard to their pain, it is crucial to relieve patients’ anxiety by discussing the plan with them in a nonjudgmental manner. Opioid tolerance and pain sensitization will often necessitate higher opioid analgesic doses administered at shorter intervals. Conventional analgesics, including opioids, should be used aggressively to treat the painful condition and should be given via continuous or scheduled dosing rather than as-needed dosing and for only a limited period. Mixed agonist-antagonist opioids such as pentazocine and nalbuphine should be avoided since they will displace the maintenance opioid from the μ-opioid receptor and precipitate acute opioid withdrawal. If the patient is receiving methadone maintenance treatment, methadone can be continued and its dose titrated slowly in 5- to 10-mg increments at least every 5 to 7 days to achieve proper analgesia. Short-acting opioid analgesics can be used
for breakthrough pain if needed. If the patient is receiving buprenorphine maintenance therapy and requires opioid analgesics, different options may be available:

1. Discontinue buprenorphine and titrate the opioid analgesics to effect to avoid withdrawal first and then to achieve analgesia.
2. Divide the buprenorphine dose to every 6 to 8 hours (although this by itself is usually insufficient to provide proper analgesia).
3. Convert buprenorphine to methadone at 30 to 40 mg daily (methadone binds less tightly to the µ-opioid receptor, and thus response to additional opioids will be as expected).
4. Buprenorphine can be continued and a short-acting opioid added and titrated to effect.

However, since dissociation of buprenorphine from the µ-opioid receptor is highly variable and high doses of opioids are usually required to over-ride buprenorphine secondary to its high receptor affinity, naloxone should be readily available at the bedside and the patient’s level of consciousness and respiration monitored closely.

Second, regarding their addiction issues, patients have to be reassured that their addiction history will not in any way prevent adequate pain management. The opioid agonist medication should be continued at the usual or equivalent dosing after being verified by the methadone maintenance clinic or prescribing physician. The addiction treatment program or prescribing physician should be notified regarding the patient’s admission and discharge from the hospital, and the time and amount of the last maintenance opioid dose have to be confirmed. Proper communication with the addiction treatment maintenance program or prescribing physician regarding any opioids or benzodiazepines given to the patient during hospitalization should be maintained since they may show up on routine urine drug screening.

**NONOPIOID ADDICTS**

Management of acute pain in patients with nonopioid addiction should entail providing effective analgesia with interventions that do not involve medication initially, such as local anesthetic blocks, thermal treatment, or transcutaneous electrical nerve stimulation. If ineffective, nonopioid analgesics as NSAIDs and neuropathic medications should be tried before opioids are used. Again, it is important to avoid as-needed dosing in such patients, and the opioid medication has to be tapered off immediately as the acute pain resolves. Sometimes withdrawal symptoms are misidentified by the patient and staff as reflecting pain, which may lead to increasing the opioid dose, often without relief of the symptoms. Thus, withdrawal symptoms should be properly identified and treated promptly to avoid such confusion. The underlying addiction should also be evaluated and treated.

**EMERGENCY DEPARTMENT PATIENTS (“FREQUENT FLYERS”)**

Approximately 11% of patients seeking treatment in the ED have chronic pain as their complaint, and a significant number of them are receiving opioids for non–cancer-related pain. A “frequent flyer” is a patient who is known to all the ED staff in the area and habitually shows up, usually on nights and weekends, demanding opioids for some chronic (e.g., pancreatitis) or recurrent (e.g., migraine, sickle cell disease) condition. Since the patient engages different shifts at different hospitals, the lack of continuity of care presents a severe challenge to the development of a rational treatment plan. However, such a plan is mandatory.

It is useful to establish a liaison with specialists in the relevant fields and to arrange for consultation so that a plan of management for both pain and addiction can be developed. It is useful to recall that unrewarded behavior is not repeated for long, so patients who resist daytime consultation should be limited, when possible, to noneuphorogenic medications in the ED (e.g., parenteral phenothiazines for migraine, ketorolac for other types of pain) until they accept appropriate consultation. Use of nationwide PDMPs can be very helpful in identifying frequent flyers.

**PERSISTENT (SUBACUTE) PAIN**

If pain persists beyond the expected time of healing, physical causes should initially be explored such as delayed healing, undetected trauma or abscess, disuse phenomena (muscle spasm, contractures), neuropathic pain (neuritis, neurouma, deafferentation), or sympathetic pain (complex regional pain syndrome). If no physical cause can be identified, possible pain-sustaining factors such as sleep disturbance, anxiety, depression, and secondary gain must be considered. Physical dependence on the opioid medication has to be ruled out. If this is the case, a slow taper of the current opioid or an equianalgesic dose of a long-acting opioid would be appropriate. Taper is preferably performed at a scheduled time contingent rather than at symptom contingent intervals, and associated withdrawal symptoms should be treated symptomatically if present. If addiction is suspected, consider obtaining an evaluation by an addiction specialist and referral to a recovery program if needed. Pain can be managed as a chronic problem at this time.

**CHRONIC PAIN**

Appropriate treatment of comorbid chronic pain and addiction remains controversial, and data on which to base therapy are still limited. However, it is important to remember that the goals of treatment of chronic pain in patients with and without an addiction history would be identical and should include reduction of pain, restoration of function, improved coping with pain, and improvement in associated symptoms such as sleep disturbance, depression, and anxiety if present. Both addiction and the physical components of pain have to be addressed concurrently through detoxification or substitution with a long-acting opioid if detoxification is not possible early in treatment. For pain management, non–medication-based approaches and the use of non–dependence-producing analgesics should take priority. Physical, social, and productive activity should be strongly encouraged to help improve the patient’s overall functional status. Chronic pain control in general in patients with addiction revolves mainly around opioid- and non–opioid-based therapies.
OPIOID-BASED TREATMENT

Use of chronic opioid therapy in patients with suspected ADRB or a history of substance abuse is challenging because such patients are more vulnerable to prescription drug misuse and abuse. In some patients, such as those actively using illicit drugs, the potential benefits from chronic opioid therapy are outweighed by the potential risks, and opioids should not be prescribed outside highly controlled and specialized settings such as an opioid treatment program with directly observed therapy. However, in other patients with no active substance use disorder, the potential benefits may outweigh the risks. Although evidence is still lacking on the best way to manage these patients, potential risks may be minimized by some of the measures mentioned previously, such as more frequent monitoring and scheduled visits, limiting the amount of dispensed medication, and clear communication with the patient regarding expectations and conditions for termination of opioid therapy. It is still unclear what degree of monitoring is needed and how effective these measures may be. However, as discussed below, some studies suggest that these measures are quite helpful and can readily be undertaken in a medical setting, such as a pain clinic.

Multiple guidelines for the treatment of chronic non–cancer-related pain have been developed, with some variability in their recommendations in regard to concurrent addictive disorder. Portenoy,97 among others, considered a history of alcohol abuse to be a relative contraindication to opioid therapy; whereas Kalso and coworkers98 considered it an absolute contraindication. Most guidelines emphasize the need for special attention in patients with a history of drug or alcohol abuse and recommend that such patients be referred to a multidisciplinary pain clinic99,100 or a specialized drug unit.97,101 All but one guideline101 recommend that opioid therapy be considered after all other reasonable attempts have failed or have been considered. Some guidelines recommend that a second opinion be sought at a multidisciplinary pain clinic before long-term opioid treatment is initiated.97-102 Another publication recommended that the final decision for initiating opioid treatment be made by a team of two or more practitioners.102 However, most guidelines recommend that only one physician should be responsible for the opioid prescribing. Sustained-release opioids taken by mouth and by the clock are recommended by all guidelines.97,102 and some consider transdermal fentanyl patches a useful alternative for patients with morphine intolerance who are at risk for inappropriate self-medication with oral opioid formulations.100,101 Again, all guidelines recommend close monitoring of patients to include adequate pain relief, adverse effects, functional capacity, and quality of life.

With such guidelines in place, many prescribers are still reluctant to prescribe opioids for patients with concurrent chronic pain problem and substance use disorder. A survey of physician attitudes across the United States103 found generalized reluctance regarding the prescription of opioids for chronic noncancer pain. Concerns about addiction, tolerance, and dependence were the most important cited, followed by regulatory pressure and finally side effects. Another survey by Joranson and colleagues104 found that 58% of surveyed state medical board members considered prescribing opioids for patients with a history of opioid abuse a probable violation of federal or state laws. Two subsequent follow-up surveys105,106 revealed some liberalization of this attitude in light of increased emphasis on pain management and educational programs for state medical boards; however, many still believe that federal and state law enforcement agencies have increased criminal investigations and prosecutions of physicians. It is important to remember that federal law prohibits the prescription of opioids to maintain addiction or prevent withdrawal but does not prohibit long-term prescription of opioids to persons with addictive disorders for the relief of pain.

Data on the outcome of opioid therapy in patients with chronic pain and addiction are very limited, and most studies conducted thus far have been small. In 20 patients with chronic non–cancer-related pain and a comorbid history of substance abuse who were treated for more than 1 year, Dunbar and Katz89 found that those who abused opioids did so early in treatment and those who did not were more likely to be active in 12-step meetings, to have stable support systems, and to be less likely to be recent polysubstance abusers. Those who did not abuse were more likely to benefit from the opioids. Currie and associates107 used cognitive-behavioral therapy with an emphasis on substance abuse education and relapse prevention to treat 44 patients with comorbid chronic pain and addiction who were receiving chronic opioid therapy. Some chose to discontinue opioids because they felt unable to control their use. Those who continued opioids were transitioned to longer-acting medications (excluding methadone). As-needed opioids were prohibited, and once titrated to the optimal dosage, patients could not obtain additional medication. There were significant improvements in pain, emotional functioning, and medication reliance. At the 12-month follow-up, 50% of the patients were opioid free and the remainder had reduced their use from 17 to 12 days/mo. There was no significant difference in outcomes for opioid and nonopioid users, although those who continued to take opioids appeared to function better overall. The authors suggested that long-acting opioids may provide both analgesia and reduction of cravings in this population. Jamison and colleagues108 conducted a 6-month-long randomized trial of opioid adherence strategies in 60 subjects with chronic non–cancer-related pain who were at high risk for opioid misuse but had no active substance use disorder. They found that an intervention consisting of monthly physician visits, urine toxicology screening every 3 months, and a monthly session with a psychologist conducting motivational interviewing for opioid adherence reduced opioid misuse from a 75% rate in the control group receiving usual care to 25% in the intervention group.

From these studies, as well as clinical reports, it is reasonable to conclude that chronic opioid therapy may be indicated in selected patients with concurrent chronic non–cancer-related pain and addictive disorder (or in those at risk for misuse but no active substance use disorder) when no other realistic treatment option is available. Long-term opioids may be considered in such cases if they provide subjective pain relief and improved level of function and do not result in adverse consequences, such as signs of loss of control over medication use or return to addictive drugs. The issue of ensuring that addiction is being adequately treated is often key to the management of these patients. A team approach consisting of a pain specialist, an addiction specialist, and the patient’s primary care physician in a highly structured program setting is strongly recommended. A team
physician should meet regularly with the patient to assess efficacy of the medication and monitor for any evidence of misuse or abuse of the prescribed medication. In addition, an exit strategy should be planned ahead and communicated appropriately with the patient and should include discontinuation of opioid therapy in case of lack of improvement in pain or function, failure to comply with the treatment plan, unexpected findings in urine drug screens, or documented misuse of the prescription in any form. Patients should clearly understand that if a decision is made to discontinue opioid therapy, this would not in any way affect their pain management treatment or support by the treating physician.

NON–OPIOID-BASED TREATMENT

A number of pharmacological and nonpharmacological interventions have proved useful for chronic pain and are effective in addition to or in lieu of opioids. It has been compellingly demonstrated over the course of several decades that there is a group of patients with chronic pain who are more comfortable and more functional without opioids. To date, we still lack accurate predictors of patients who will do well with opioids and are essentially limited to a therapeutic trial to ascertain patients who will show improved function, mood, and relief of pain and to assess side effects and aberrant behavior. It is likely that patients with addiction will be over-represented in the group who are better served without opioids because their risks are clearly increased. No randomized trials so far have directly evaluated the efficacy of behavioral therapy, psychiatric treatment, multidisciplinary rehabilitation, or functional restoration versus or in addition to chronic opioid therapy in patients with chronic pain.

INTRATHECAL DRUG DELIVERY

The appropriateness of intrathecal (IT) drug delivery in chronic pain patients with current or a past history of addiction remains a controversial topic. Although some may consider addiction an absolute contraindication to IT delivery, others would recommend it as an option, provided that the patient is treated appropriately for the addictive disorder. According to one recent consensus panel, selected patients with addiction may be reasonable candidates for IT opioid therapy since eliminating oral opioids and using only IT opioids shift the control of medication administration from the patient to the pump as prescribed by the physician. However, it is often quite difficult to eliminate the need for oral opioids to control pain in the treatment of cancer- or non–cancer-related chronic pain with an IT pump, and thus these risks of misuse and addiction are most often unchanged with IT therapy. The panel also recognized the potential risks and problems associated with IT opioid delivery in this population secondary to the higher incidence of associated personality problems since such patients can be demanding, manipulative, passive-aggressive, and generally noncompliant. Moreover, there is no assurance that these patients will not turn to other substances such as alcohol, benzodiazepines, or illicit drugs following resolution of the pain problem. There have been a few case reports of patients who attempted to penetrate their pump or catheter to gain access to the drug. Burton and coauthors reported a case of self-administration of phencyclidine, methamphetamine, and propoxyphene via an IT pump by an incarcerated patient. Thus, it is strongly recommended that if IT therapy is to be used, patients have to be monitored closely and treated appropriately for their addiction. Non–opioid-based IT therapy may also be a reasonable alternative for patients with serious abuse problems or an active addiction.

SPINAL CORD STIMULATION

Data on the outcomes of spinal cord stimulation (SCS) in patients with addiction and chronic pain are lacking, possibly because addiction is still considered an exclusion criterion for a trial of SCS by many physicians. Pain specialists are still unclear about the role of drug addiction and psychiatric comorbid conditions on SCS outcomes. Some would recommend treatment of the drug addiction before undergoing an SCS trial, whereas others have strongly related a history of drug addiction with poor outcomes regardless of current addiction status. Most authors, however, still consider an active alcohol or drug dependency that assumes an over-riding importance in the patient’s behavior or in whom there is obviously excessive drug-seeking behavior or uncontrolled escalation of prescribed or nonprescribed substances to be a contraindication to a trial of SCS. Such patients must first demonstrate an ability to conform to a reasonable medication regimen before implantation for SCS is attempted or else they are unlikely to do so afterward. However, patients may be reconsidered for SCS candidacy if they are able to demonstrate a minimum of 3 months of appropriate control of substance use.

SPECIALIZED PAIN SERVICES VERSUS PRIMARY CARE SETTING

Pain practitioners often find themselves in a difficult situation in which the current reimbursement system favors procedures and brief visits for medication management. However, this bias neglects a longitudinal management approach that integrates medical, physical, and psychological therapies, which is essential to address the biopsychosocial factors causing and perpetuating chronic pain. Thus, in this current practice environment, many practitioners tend to rely on opioids alone to help relieve their patients’ pain, although it may not be the most beneficial for them. The pain medicine and primary care community rehabilitation model emphasizes training primary care providers to use evidence-based clinical algorithms to manage different chronic pain conditions. Ideally, a multidisciplinary pain medicine team should be readily accessible to support primary care providers when algorithms are not effective in controlling pain and its consequences in a timely fashion. Referral to addiction specialists and rehabilitation facilities should also be made readily available if needed.

PHYSICIAN CONCERNS

As clinicians who are dedicated to the treatment of patients, the priority in the doctor-patient relationship is always focused on the well-being of the patient. However, the practice of medicine often requires a balance between physicians’ responsibilities to care for their patients and the appropriate concern of physicians to protect themselves from a medical-legal standpoint. Most often, these concerns are aligned; good patient care is also safe care, with the risks
well articulated to the patient. However, maintaining this balance may have an impact on access to care and how care is ultimately delivered. One could argue that treating pain in the context of addiction disorders provides an excellent example of the difficulties involved in striking this balance.

Pain physicians who prescribe opioids to patients with addiction disorders may be at elevated medical-legal risk if patients suffer significant negative consequences of their care. For instance, physicians are at risk for medical malpractice suits from patients who may claim to be victims of iatrogenic addiction as a result of a physician’s prescribing. Ultimately, protection of the physician is best achieved through meticulous and diligent documentation, diagnosis of a preexisting addictive disorder or a genetic predisposition for one, and a treatment plan accounting for these risks in the treatment of pain. Just as important is the responsibility of the clinician to document treatment response or lack thereof. In addition, clinicians who prescribe opioids on a regular basis should have access and the ability to seek consultation from an addiction specialist when needed.

As noted previously in this chapter, use of an opioid therapy agreement in both the acute and chronic settings is key not only for documentation purposes but also for establishing a clear agreement with the patient and the expectations regarding the guidelines and boundaries of opioid prescribing. Importantly, points in such a contract would be keeping all appointments, even those with other professionals (psychiatry, physical therapy, marriage counselor, and others). One would also want to see progress toward goals of improving function and life satisfaction. In addition, the agreement should include patient consent to the use of appropriate screening tools, such as random urine toxicology screens.

**KEY POINTS—cont’d**

- When taking opioids, careful monitoring is necessary.
- Physicians should identify any aberrant behavior early and respond appropriately to decrease the risk for subsequent addiction.
- Stringent measures of monitoring should be applied in such circumstances.
- Opioid therapy agreements are recommended but should be used with caution.
- Good communication with the patient during each step is crucial for success of treatment. Physicians must also have access to and know when to seek consultation with addiction specialists.

The primary indication for nerve blocks of the head and neck is for diagnostic and therapeutic purposes in cases of head and neck pain. Some of the more common indications are discussed in detail in this chapter, including the rationale for selecting regional nerve blocking techniques in the care and management of these patients.

**HEADACHES**

Differentiating the etiology for headaches is a vexing task, often requiring the skill and experience of multiple clinicians from diverse specialties. The pain practitioner and skilled regional block specialist are well suited to the task by virtue of their respective experiences in performing conduction blockade of the greater and lesser occipital nerves (occipital headache), the cervical medial branches of the facet joints (cervicogenic headache), the cervical epidural nerve block (nonspecific headache), and the atlanto-axial joint (suboccipital headache). Therefore, it is by use of the various modalities of regional block that a diagnostic/therapeutic block of the respective structures implicated in a given patient’s pain may be discernible. The anatomic method is a more scientific method of pursuing the source of a headache than that of solely relying on historical information presented by the patient.

**ATLANTO-AXIAL JOINT BLOCK**

The primary indication for performing atlanto-axial (A-A) nerve block is for the diagnostic and therapeutic evaluation of suboccipital pain that occasionally radiates into the temporomandibular joint (TMJ) area that is exacerbated by head rotation. Whiplash injuries and cervicogenic headaches are two of the more common indications for this block. The A-A joint (Figs. 52.1 and 52.2) lacks posterior articulations and therefore is neither a bona fide facet joint nor a true zygapophyseal joint. Also, there is no intervertebral disk between the atlas (C1) and the axis (C2), nor is there an intervertebral foramen at that level to accommodate an exiting nerve root. At the A-A joint, the head flexes, extends, and rotates in a horizontal plane, up to 60 degrees, giving the joint significant responsibility for both the stability and the mobility of the head and neck. The joint can be injured by seemingly trivial insults and trauma. The resulting pain syndrome can be significant, manifesting as dull, continual and achy pain in the posterior neck and suboccipital region. More severe injuries, such as those caused by motor vehicle accidents, might subject the joint to acceleration-deceleration type injuries, with sequelae exceeding pain and dysfunction. Indeed, paralysis and even death could result from ligamentous disruption, analogous to an odontoid fracture. The fibers of the respective spinal nerves C1 and particularly C2 contribute to the formation of the occipital nerves (greater and lesser), which are frequent targets for the practicing pain physician. An extremely important anatomic concept involves the relationship of the vertebral artery to the A-A joint; whereas the artery is medial to the atlanto-occipital (A-O) joint, it is found lateral to the A-A joint. Therefore, needles directed at the joint during nerve block need to be oriented slightly more medially, cognizant of the danger of aiming toward the interlaminar space, or even toward the foramen magnum.

**TECHNIQUE OF ATLANTO-AXIAL NERVE BLOCK (SEE FIGS. 52.3 AND 52.4)**

Blockade of the A-A joint requires fluoroscopic assistance to ascertain that the advancing needle does not encroach on the critical anatomic structures such as the vertebral artery and the spinal cord. Patients are placed prone, after obtaining the appropriate medical history, performing a targeted physical examination, and establishing that there are no bleeding problems or infectious issues related to the target for intended needle placement. Baseline vital signs are obtained and recorded. It is recommended that an intravenous access be established for prophylactic purposes. Bolsters are typically placed beneath the chest to elevate the shoulders off the procedure table, permitting the patient to flex the neck and rest the forehead on a neurosurgical donut or pillow. After performing a sterile skin preparation and draping, the fluoroscopic unit is oriented in an anterior-posterior direction to identify the atlas and the foramen magnum, implementing a moderate cranial tilt of the unit until all structures are clearly visualized. The A-A joint is located lateral and inferior to both the foramen magnum and the atlas (see Fig. 52.2). A local anesthetic skin wheal is made over the intended injection site using a small gauge, 1.5-inch needle. Next, an 18-gauge skin core is made using a sharp cutting needle to permit the passage of a blunt, 22-gauge, styletted Whitacre type subarachnoid needle. A curve is made at the distal tip of the needle to allow better steering once it has been advanced through the skin and subcutaneous tissues. The needle is advanced under continued fluoroscopic guidance, rotating the beam of the unit until the needle appears in tunnel or “gun barrel” view, which is represented as a dot advancing toward the posterolateral
aspect of the A-A joint. The needle should be directed slightly medially to avoid the vertebral artery, which is situated laterally, but not too medially, as this would potentially engage the spinal cord. Occasionally, but not always, a “popping” sensation will be appreciated as the needle traverses the joint and enters it from posterior to anterior (see Fig. 52.3). The fluoroscopic unit must then be rotated laterally (see Fig. 52.4) to confirm the needle placement at the appropriate depth between the atlas and axis. Once placement has been verified, gentle aspiration of the needle is undertaken to assess for the presence of cerebrospinal fluid (CSF) or blood. If none is present, a small (i.e., 1-mL) volume of radiocontrast media may be incrementally injected under real-time fluoroscopy. If the needle is situated within the confines of the joint, a bilateral concavity will be demonstrated, indicative of an intact joint capsule. If the joint capsule has been ruptured, then the dye may be seen as spreading into the peridural space, and care should be taken not to inject long-acting local anesthetic (bupivacaine, ropivacaine) through the needle. Rapid runoff of the dye may signify vascular injection and is to be guarded against, particularly if it is suspected that the needle may have entered the laterally situated vertebral artery. If this occurs, the needle should be redirected medially, re-aspiration of the needle in four quadrants undertaken, and re-injection of contrast material prior to considering injecting local anesthetics or adjuvants. Even without directly injecting into the vertebral artery (even miniscule volumes of dilute local anesthetics injected here can lead to grand mal seizures), ataxia following A-A block is not uncommon and is likely due to vascular uptake of local anesthetics in this extremely vascular region.
THIRD OCCIPITAL NERVE BLOCK

Diverse pain syndromes result from disorders of the cervical intervertebral disks, the facet joints (zygaphysial, or Z joints), or both. When confronted by individuals with headache and neck or shoulder pain, the clinician is compelled to seek a diagnosis based largely on history and physical examination. The physical examination is complicated by the finding of significant variability and overlap in the innervation patterns related to the sensory distribution of the cervical medial branch nerves (Fig. 52.5). The third occipital nerve has been implicated in chronic headache pain, primarily as attributed to cervicogenic headache. Syndromes related to dysfunction of the medial branches of the upper cervical spine have at times been misdiagnosed as being due to tension-type and other forms of headache. Patients, having been misdiagnosed as such, have ultimately failed to derive analgesic benefit from medication administration and other conservative treatment measures that were misguided.

The third occipital nerve (TON) is the superficial branch of the C3 dorsal ramus. It is the only medial branch that innervates the facet joint at C2-C3 (Figs. 52.6 through 52.8). Therefore, successful blockade of the TON, and the resultant block of the facet joint at C2-C3, has been associated with relief of headache pain in individuals suffering from “third occipital headache.”

ANATOMIC CONSIDERATIONS

The C2-C3 joint is the first joint of the cervical spine possessing a true joint capsule and synovium, and this level is the first wherein an intervertebral disk exists and wherein a foramen exists to accommodate the exiting C3 nerve root. In this regard, the C2-C3 joint is distinct from the atlanto-occipital (A-O) (C0-C1) and atlanto-axial (A-A) (C1-C2) joints superior to it. This level, then, represents a sort of transitional zone between the rotational joint of the neck (AA) and the lower cervical facet joints, which function not in neck and head rotation but in neck flexion and extension.

Facet joints contain free and encapsulated nerve endings. In addition, nerves in the zygaphysial joint (Z joint) contain substance P and calcitonin gene-related peptide (CGRP). The capsule of the Z joint contains low-threshold mechanoreceptors, mechanically sensitive nociceptors, and silent nociceptors. Each of these may respond to noxious stimulation, including moderate to severe levels of osteoarthritis, with the result being a nociceptive stimulation perceived as headache or neck pain.
The clinical anatomy of the cervical dorsal rami was described by Bogduk, following dissections of five adult cadavers. He pointed out that classic textbook descriptions of the cervical dorsal rami had been limited in scope and detail. While dissecting the medial branches, he was able to place wires superficially and parallel to the nerves and then perform radiographic analyses of the wires in relationship to the cervical vertebral skeleton. He noted that the semispinalis capitis muscle covers the cervical medial branches, whereas the lateral branches of C3-C7 lie superficial to the tendons of origin of that muscle. The TON penetrates the semispinalis capitis. The C3 dorsal ramus, a short nerve, was noted to arise from the C3 spinal nerve in the C2-C3 intervertebral foramen and then to curve dorsally through the intertransverse space. At this point, the C3 dorsal ramus was noted to divide into major branches: the two medial branches, the lateral branch, and a communicating branch. In three out of five of his specimens, the two medial branches of C3 were noted to arise from a common stem, and in the other two specimens they had their own respective origins. The third occipital nerve (TON) was the principal and constant medial branch of the C3 dorsal ramus. After arising from the C3 dorsal ramus, the TON was found to curve dorsally and medially around the superior articular pillar of the C3 vertebral body, crossing the C2-C3 Z joint either just below the joint itself or at the joint level. The TON runs transversely medially through the fibro-adipose tissue below the obliquus inferior and dorsal to the lamina of the C2 vertebra.

A branch of the TON supplies the semispinalis capitis, which lies superficial to it. A communicating branch to the greater occipital nerve (GON) is also given off. This branch arises just above the level of the C2 spinous process. The TON then passes dorsally and pierces the semispinalis capitis and the splenius capitis, turning rostrally to pierce the trapezius, which lies over it. The more medial terminal branch supplies the skin of the rostral neck and the occiput below the external occipital protuberance. More lateral branches travel toward the mastoid process, communicating with the cutaneous rami of the GON and lesser occipital nerves (LONs). Because of the transverse direction of the GON and the TON, these two nerves may be injured by parasagittal incisions made in the upper part of the neck.

The target branch for nerve block, the TON, wraps dorsally and medially around the middle of the waist of the articular pillar of C3 (center of the bony trapezoid). As it moves more medially, the TON invests the multifidus muscle. There is a communicating branch that typically arises from the C3 dorsal ramus, running rostromedially across the posterior part of the C2-C3 Z joint. The anatomic target for locating the nerve percutaneously, then, is to utilize lateral fluoroscopy to identify the waistline of the articular pillars of C2 and C3 and to advance a needle or radiofrequency cannula toward the Z joint at C2-C3. As Bogduk stated, the target is removed from any major arterial (vertebral artery) or other vascular structure, as well as from the exiting spinal nerve and spinal cord; it is therefore an appropriate target in terms of affording access to the medial branches as well as one that provides for an approach likely to minimize unwanted trespass into nontargeted tissues.

**THE THIRD OCCIPITAL NERVE AND HEADACHE PAIN**

Osteoarthritis of the C2-C3 Z joint and trauma related to motor vehicle accidents are causes of persistent occipital or suboccipital headache pain. As there is no clear-cut clinical evaluative technique or diagnostic tool for determining who is suffering from headache due to disease of this joint or from neck trauma (or that mediated by the TON), it is somewhat intuitive and logical that blockade of the TON should be performed in cases of persistent headache that are unresponsive to conventional medication management.

Bogduk and Marsland conducted fluoroscopically guided TON blocks in 10 consecutive patients presenting with occipital or suboccipital headache. They elected to place their needles at the lower half of the silhouette of the C2-C3 Z joint, recognizing the landmark on x-ray as a convexity arising upward from the concavity of the C3 articular pillar, lying horizontally opposite the level of the C2 spinous process and C2-C3 disk space (Figs. 52.9 through 52.11). All procedures were performed with patients in the prone position and with a bolster beneath the upper chest and shoulders to permit head flexion forward toward the procedure table. A solution of 0.5 mL of 0.5% bupivacaine was injected at three distinct sites: in the middle of the Z joint at C2-C3, at the lower end of the joint, and between the first two needle placements (for bilateral blocks the total volume was therefore 3 mL; 1.5 mL per side). Seventy percent of patients manifest total pain relief lasting the duration of the bupivacaine, following unilateral blocks. The 30% failures did not have positive responses to the bilateral blocks performed on their behalf. Bogduk stated that blockade of the medial.
branch nerves, particularly the TON, are easier for patients to tolerate than intraarticular injections because they are more easily performed and are associated with less pain during their performance than are the articular injections. Furthermore, it is apparent that local anesthetic injected into a joint may not actually stay within the joint space, potentially limiting any diagnostic information that might otherwise be derived from the procedure. Finally, markedly degenerated joints might not readily accommodate an advancing needle tip, rendering the choice of this articular approach potentially useless overall. If the ventral margin of the joint space is penetrated, there is also a distinct possibility that entrance into the epidural or subarachnoid spaces may occur, with potentially devastating consequences.

Although no one knows for certain how likely it is that pain in the occipital and suboccipital area emanates from the C2-C3 Z joint and although various studies show greatly disparate findings, several compelling attempts at determining the incidence (a measure of the risk of developing some new condition within a specified period of time) or prevalence (the total number of cases in the population, divided by the number of individuals in the population) need to be reviewed.

A study involved 24 consecutive patients presenting with undiagnosed neck pain who were evaluated using controlled diagnostic blocks incorporating low-volume local anesthetic injections. For individuals with occipital or suboccipital headache and neck pain, the lower half of the lateral margin of the C2-C3 Z joint was selected as the injection site. Complete pain relief was considered to occur if the patients, having received the bupivacaine blocks and then going home to perform their activities of daily living, noted at least 2 hours of total analgesia. Failure to derive pain relief resulted in patients undergoing additional cervical medial branch blocks at contiguous levels. Nineteen out of 24 patients had positive results, with 9 of these ultimately having pain isolated to the C2-C3 level. Therefore, in 47% of patients who had diagnostic block-proven cervical Z joint pain, the TON was the nerve responsible for mediating the pain. Although
this study has not been replicated, it is tempting to use the information as a general rule of thumb when approaching individuals with neck pain resulting from degenerative disease of the cervical spine and when planning nerve blocks based on the correlation of symptoms with joint pain maps.\(^5\)\(^6\) If it is known that in half of cases the level responsible for a given pain problem is at the C2-C3 joint, then it might save time, expense, and patient discomfort to rapidly move toward ruling in or ruling out that level, and the TON, at the outset as part of the diagnostic workup. However, as discussed later, these figures may be overbearing in terms of the actual prevalence of C2-C3-related pain. Although TON block may be performed easily and typically is without significant complications, side effects do occur commonly. Indeed, any patient presenting for this type of procedure must be duly appraised that successful blockade of the TON (or GON) will likely result in the temporary development of ataxia and some gait unsteadiness. For this reason, bilateral blocks at these levels should likely be staggered, or else the benefit-risk ratio must be significant enough that performing bilateral blocks is clearly warranted.

The subject of joint pain maps merits special mention, as noted previously (see Fig. 52.5). Multiple attempts have been made at delineating the specific cutaneous area of sensation, and hence pain, invested by each respective facet joint and medial branch.\(^5\)\(^9\) In the report by Fukui and associates,\(^8\) the site of Z joint intraarticular injection and electrical stimulation (selected cases) was chosen based on any focal paraspinous tenderness. They observed that with injections performed at C2-C3 (n = 14), symptoms were referable to the upper posterior cervical region (64%), the occipital region (50%), or the upper posterolateral cervical region (50%).\(^9\) Windsor and colleagues\(^8\) electrically stimulated the cervical medial branches, including the TON in 9 patients suffering from chronic neck pain. They used the lateral midpoint of the C2-C3 Z joint to indicate the location of the TON. Relatively reproducible referral patterns were identified for the TON nerve distribution as well as for the other medial branch nerves studied.\(^9\)

When reviewing these studies, however, considerable overlap in the areas served by each of the respective segments is noted, much more so than that observed with attempts at mapping spinal nerve dermatome distributions. This produces a diagnostic conundrum, as it is entirely conceivable when approaching cervical spine pain that even perfectly performed techniques, using standardized and accepted anatomic landmarks, may result in failures to derive antinociception with the resultant confusion on behalf of the patient and treating physician.

Because both the intervertebral disk and facet joint are fairly equivalently represented as sources of neck pain (approximately 40% each as sources of neck pain, according to two separate studies), a missed diagnosis might lead a pain physician in the wrong direction when seeking to provide pain relief to a given individual.\(^10\)\(^11\) Mapping studies may help to pinpoint discrete areas of pain referral sources that are then amenable to local anesthetic blockade or radiofrequency lesioning techniques. In one such study, joint maps were created by distending the respective joint capsules at segments from C2-C3 to C6-C7. This was done by sequential injections of contrast media, which could be subsequently identified using fluoroscopy. Each joint was noted to produce a characteristic, distinguishable pain pattern from which pain charts could be constructed (see Fig. 52.5).\(^9\) Although only four subjects were evaluated, that number is not too disparate from the original small group of subjects selected to develop the original dermatome charts in neurologically impaired individuals; such charts have been mostly unchallenged since the 1950s.\(^12\) In 10 subjects who received injections based on maps such as those derived and described earlier, 90% had complete concordance of the predicted level of pain and the positive response to the blocks.\(^7\) The C3-C4, C4-C5, and C5-C6 levels were most commonly affected, with only 10% (1 of 10) patients having pain that was documented to result from processes occurring at the C2-C3 (TON) level. These percentages are therefore less indicative of the possibility of the C2-C3 level being primarily involved in head and neck pain than they are of alternative levels lower in the cervical spine. However, a study by Barnsley and Bogduk demonstrated that, following cervical medial branch injections performed in 16 patients suffering from chronic neck pain, 33% (3 of 9) patients who had complete pain relief were patients for whom the TON was treated.\(^13\) It remains unclear how likely the TON is to be implicated in individuals suffering from chronic head and neck pain. The closest studies performed to identify the prevalence of TON-induced headache and neck pain may have been those performed by Lord and Barnsley and colleagues.\(^14\)\(^15\) In the first study, 100 consecutive patients underwent double-blind, controlled diagnostic blocks of the TON. On two separate occasions the nerve was blocked using either lidocaine or bupivacaine. The diagnosis of TON nerve involvement was only made if the double diagnostic blocks both relieved the symptoms, with the bupivacaine injection-induced pain relief outlasting that provided by the lidocaine. The prevalence of TON headache among whiplash patients was 27% and among those with dominant headache was 53%.\(^14\)

In the second study, 50 consecutive patients with chronic neck pain and whiplash injury underwent double-blind, controlled diagnostic medial branch blocks using either 0.5-mL lidocaine (2%) or bupivacaine (0.5%) in a random fashion. In 12 of 27 patients (44%), the source of symptoms was identified as being isolated primarily to the C2-C3 Z joint.\(^15\) These findings corroborated the impression that although there may be substantial overlap in cutaneous innervations of the central and peripheral nervous systems, these joint maps are essential tools in assessing the appropriate approach to a given pain process in any individual. They also demonstrated variability in determining the relative incidence and prevalence of C2-C3 Z joint pain, depending on technique of assessment and provocation maneuvers to assess the joint and the medial branch nerve (TON).

**RATIONALE FOR BLOCKING THE TON**

The TON block is useful in the diagnostic and therapeutic phases of treating cervicogenic headache. Evidence of efficacy for both local anesthetic blocks as well as for radiofrequency ablation of the cervical medial branches has accrued. However, only recently has the use of medial branch blocks and radiofrequency ablation techniques received scientific support in the literature. Indeed, two separate attempts at meta-analysis have shown somewhat disparate results. The first paper, published in 2001, suggested
that radiofrequency neurotomy used for treating pain from the cervical Z joints after flexion-extension injury was only supported by limited scientific data.\textsuperscript{16} However, a mere six total studies satisfied the authors’ criteria for inclusion, and so it is entirely possible that the data suffer lack of suitable cohort studies to make a true assessment of its validity. The second review performed in 2007 liberalized the inclusion criteria somewhat and found that the support for medial branch cervical block was moderate (level III) as was the support for cervical medial branch neurotomy.\textsuperscript{17} Here the authors relied on the criteria established by the Agency for Healthcare Research and Quality (AHRQ), which included some nonrandomized trials. They also incorporated studies from the Cochrane Musculoskeletal Review Group, which were randomized trials. One of the important points noted was that the evidence for performing cervical intra-articular facet joint injections was limited both for short-term as well as for long-term analgesia efficacy. This corroborates Dr. Bogduk’s earlier assertions that not only are medial branch techniques more likely to target the real source of pain associated with cervical degenerative facet conditions, but also that articular procedures have an inherently high failure rate because there is no guarantee that injected local anesthetic will remain in the confines of the joint.

The rationale for blocking the TON is twofold:

1. To provide a diagnostic evaluation of the C2-C3 facet joint as being the source of pain in the occipital and suboccipital area
2. To provide an indication as to whether or not neuroablative techniques applied over that nerve might be fruitful in treating pain on a long-term basis

We suggest performing double-diagnostic blocks using 0.5 mL of local anesthetic solutions, typically 0.5% ropivacaine plain, before undertaking neurotomy of the TON. Ropivacaine is used for two major reasons. It has intrinsic vasoconstrictor properties, and epinephrine does not have to be added to it. It also has a cardiovascular safety profile that is superior to that for bupivacaine. Unintentional injection into vascular structures, including the vertebral artery, is less likely to result in serious morbidity when ropivacaine is used, in contradistinction to bupivacaine. The rationale for using ropivacaine is to provide duration of analgesia that exceeds that provided by shorter-acting agents such as lidocaine or mepivacaine. In terms of assessing efficacy, it is likely that longer-acting local anesthetics may provide greater information than shorter-acting drugs, as the effect of the short-acting drugs may be so fleeting as to provide confusing or inexact clinical information.

Double-diagnostic blocks have been described for assessing the efficacy of cervical medial branch blocks.\textsuperscript{18} Barnsley and associates compared single to double-diagnostic blocks in 55 adult patients who had been having neck pain for longer than 3 months. They used 0.5 mL of either 0.5% bupivacaine or 2% lidocaine, randomly selected. The duration of analgesia was assessed in a double-blind fashion. They found that the false-positive rate (a test that shows evidence of a disease when it not present) of single blocks was 27\% (16/60).\textsuperscript{18} They also found that the most common positive levels were at C2-C3 and C3-C6.\textsuperscript{18} Lord and colleagues found that comparative blocks of the medial branches using lidocaine, bupivacaine, or normal saline in a randomized, double-blind, placebo-controlled fashion in 50 patients had a specificity (the statistical probability that an individual who does not have the particular disease being tested for will be correctly identified as negative, expressed as the proportion of true negative results to the total of true negative and false positive results) (TN/TN + FP) of 88\%, but only marginal sensitivity (the proportion of individuals in a population that is correctly identified when administered a test designed to detect a particular disease, calculated as the number of true positive results divided by the number of true positive and false negative results) (TP/TP + FN) (54\%).\textsuperscript{19} Hence, some 46\% of patients who are not placebo responders would incorrectly be labeled as placebo responders if diagnoses were based solely on comparative blocks.\textsuperscript{19}

Slipman and colleagues retrospectively reviewed 18 patients with chronic persistent daily headaches lasting a mean of 34 months following whiplash injury who underwent intraarticular C2-C3 facet joint injections.\textsuperscript{20} They noted that in 61\% of cases, headache frequency diminished from daily to less than three headaches per week. Although this work is retrospective, the results are nevertheless supportive for targeting the TON in chronic headache conditions refractory to conventional conservative management. Furthermore, because the injections were articular and not at the medial branch (TON), the information gleaned from this report may not be useful in determining candidacy for radiofrequency neurotomy.

**TECHNIQUE FOR TON BLOCK**

We perform C2-C3 medial branch (TON) procedures with the patient in the prone position using continual live fluoroscopic guidance throughout the injection phase (see Figs. 52.9 through 52.11).\textsuperscript{21} A bolster is placed beneath the shoulders and chest to elevate the thorax off of the table and to permit gentle head and neck flexion forward. An intravenous cannula is placed for purposes of administering resuscitative medications in the unlikely event that it is necessary to treat vasovagal syncope or for supportive medication administration in cases of unintentional vascular injection. Vital signs are monitored using standard American Society of Anesthesiologists (ASA) basic monitors including pulse oximetry and noninvasive blood pressure assessment. After performing a sterile skin preparation, scout films are obtained of the neck in an effort to identify the scalloped margins of the lateral vertebral bodies. Then, skin wheals are raised over the intended target(s) using a hypodermic needle and 1 to 3 mL of lidocaine solution with epinephrine, 1:200,000 (5 mcg/mL). Using short-beveled, 22-gauge, 2.5- to 3.5-inch needles, the targeted lateral scalloped margins of the vertebral bodies are advanced upon until bony contact is made. At this point the fluoroscopy unit is rotated laterally to assess the relationship of the advancing needle tip to the TON target, in the center of the C2-C3 Z joint (discussed previously). The needle tip must be repositioned posteriorly away from the C2-C3 intervertebral foramen as well as from the known location of the vertebral artery. If bone has not been contacted and 2 cm of the needle has been inserted into the skin, then a reassessment of the approach and direction is undertaken while still in the A-P fluoroscopy mode. Once the needle is appropriately seated on bone at the target site (Fig. 5.4), the A-P view is once again
undertaken to verify that the needle(s) is in the correct position vis-à-vis the lateral vertebral body margin.

Ultrasound-guided approaches are rapidly gaining popularity for all forms of interventional pain procedures, but in our experience they have not yet reached the level of sophistication to supplant fluoroscopy use for this particular procedure. At this point, aspiration tests are performed to verify the absence of blood or cerebrospinal fluid, and the patient is queried to ascertain that no paresthesias have been elicited. If there are none and vital signs remain stable and close to baseline values, 0.5 mL of 0.5% ropivacaine is injected. No glucocorticoid is added to the solution, as Manchikanti and associates, have demonstrated that there is little value, if any, of adding steroid to the blocks.22 Still, many clinicians continue to add a steroid in their practice. If the risk-benefit ratio favors using steroids in an individual suspected of having an inflammatory component to his or her pain, then there may be little harm in adding a nonparticulate steroid in judicious doses. After injection, the needle(s) is cleared and withdrawn, and a sterile dressing is applied over the injection site. The patient should be observed for at least 30 minutes, as it is common for patients to become ataxic or have unsteady gait following successfully performed procedures. Discharge instructions should be clear and precisely instruct patients to seek emergency medical care if they develop any delayed-onset side effects or complications from the procedure.

**RADIOFREQUENCY NEUROTOMY**

In selected patients, radiofrequency (RF) of the TON may be considered for long-term therapeutic benefit. In a study published in 1995, Lord and colleagues demonstrated the efficacy of performing radiofrequency ablation (RFA) of the TON in only 40% of patients (4 of 10), with only three having long-lasting pain relief.23 They used 10-cm needles with either 4-mm or 6-mm exposed tips. No stimulation test was performed to assure concordance of needle placement with the nerve; instead, the authors relied solely on fluoroscopic anatomic cannula placement. The mean duration of the C2-C3 neurotomy procedure was stated to have been 1.5 hours.23 The rather meager success rate was in sharp contrast to the 70% success that they noted for lower cervical medial branch procedures. The authors stated that radiofrequency of the cervical medial branches “carries a high rate of technical failure.”23 In 1996,24 Lord and associates noted that RFA of the cervical medial branches, performed in 24 patients with a median duration of pain of 34 months following motor vehicle accidents, provided a median duration of analgesia persisting 263 days. This contrasted sharply to the median analgesia of 8 days in a control group of patients. However, they excluded individuals with C2-C3 joint pain based on their rather dismal results from the previous study noted earlier. In a subsequent study published by the same group of investigators, complete pain relief was found in 71% of 28 patients following a single RF procedure, persisting a mean duration of 219 days. When failures were excluded from consideration, the mean duration extended out to 422 days (60 weeks).25 Again, excluded from study were individuals suffering from TON-mediated C2-C3 pain. In 2003, Govind and associates26 used three large-gauge electrodes to perform RFA procedures of the TON. Following controlled diagnostic blocks, 51 nerves in 40 patients were treated with RFA. Eighty-eight percent (43 of 49) achieved successful outcomes using this approach, with a median duration of 297 days (42 weeks). Side effects included slight ataxia, numbness, and temporary dysesthesias.26 Their improved success was attributed to use of three needles, as well as use of Ray electrodes instead of SMK electrodes (smaller), as well as the assurance that each of the three lesions was made at a distance no greater than one electrode width from an adjacent lesion.26

Cohen found that the only factor predicting the success of RFA, defined as at least 50% pain reduction lasting at least 6 months, was paraspinal tenderness.27 Although the authors stated that C2-C3 pain was included in this analysis, they never indicated how many individuals were thusly treated or what the success rate was for TON RFA.

**CERVICAL FACET BLOCK; MEDIAL BRANCH BLOCK**

(FIGS. 52.6 THROUGH 52.12)

The cervical facet joints and medial branches are commonly implicated in the etiology of cervicogenic headache. C2 and C3 blocks are undertaken to effectively disrupt neural

![Figure 52.12](https://example.com/figure5212.png) Lateral and posterior-anterior fluoroscopic images using cephalad tilt of the fluoroscopy unit, with patient in prone position demonstrating needles appropriately placed for blockade of C3, C4, C5 medial branch nerves, left sided. (Photos courtesy of Kenneth D. Candido, M.D.)
pathways giving rise to greater and lesser occipital nerve dysfunction. Blockade of the joints via the medial branches is typically undertaken for such headaches as well as for the treatment of nonspecific neck pain, degenerative arthropathies of the cervical spine, degenerative disk disease, cervical sprain, and trauma-related pain. Pain may be localized to the neck or may radiate in a capelike fashion from the neck over the shoulders, with extension to the suboccipital area and the supraclavicular area (see Fig. 52.5). The cervical facet joints are present from C2 to C3 caudally as the atlanto-occipital (A-O) and atlanto-axial (A-A) joints are not true zygapophysial joints, as described previously. From C2 to C3 caudally, the joints are lined by synovium and possess a true joint capsule, which is generously innervated and which may be a source of neck pain and headache pain in certain individuals. The joints themselves may be injured in acceleration-deceleration types of injuries or may be affected by chronic degenerative arthritic changes. Pain results from synovial joint inflammation caused by irritation from repetitive motion at an injured segment. The cervical facet joints, like the thoracic and lumbar facet joints, receive innervation from two adjacent spinal levels. The dorsal ramus from the level above the joint as well as from the level at the joint provides fibers that invest the joint. This forms the foundation for blocking both the affected level and superior levels to completely denervate the facet joint. Each dorsal ramus innervates two facet joints, and each facet joint receives its innervation from two separate nerves. The medial branch, which wraps around the waist of the articular pillars of the vertebral bodies (see Figs. 52.6 through 52.8), is the site for peripheral nerve block as well as for neuromodulation techniques of radiofrequency at the joint. These nerves are held against the bone by a fascial envelope and are anchored there by tendons of the semispinalis capitis. The medial branch is consistently found at this anatomic location between C4 and C7, making needle placement for these levels a relatively simple task to accomplish. For example, at the C4-C5 facet joint, the medial branches of C4 and C5 are blocked at their respective articular pillars to anesthetize the joint. At C2-C3, the joint receives innervation from the third occipital nerve (one of two median branches of the C3 dorsal ramus, as discussed previously), and also somewhat by the C2 dorsal ramus. The medial branch of the C2 dorsal ramus is the greater occipital nerve (discussed later). C2-C3 facet joint innervation is a complex anatomic scheme, and for practical purposes, our technique of blocking the third occipital nerve at the C3 articular process waist is sufficient for denervating or anesthetizing this joint.

TECHNIQUE OF BLOCKING THE MEDIAL BRANCHES FOR CERVICAL FACET JOINT PAIN (SEE FIGS. 52.9 THROUGH 52.11)

Our technique of blocking the medial branches requires the use of fluoroscopic guidance, although there are increasingly more advocates of performing an ultrasound-guided technique.28-30 We believe this is essential to minimize the likelihood of advancing our needles too far ventrally with the patient in the prone position. Advancing too far ventrally could cause injury or irritation to the exiting cervical spinal nerve roots or to the more ventrally situated vertebral artery. Also, if strict adherence to maintaining needle-to-bone contact is not maintained, it could be possible for advancing needles to stray too far medially toward the interlaminar or transforaminal spaces, or too far laterally with a resultant failure of accessing the medial branches, which are secured to the waists of the articular pillars by a fascial sheath and the semispinalis capitis tendons. Appropriately screened candidates (i.e., no coagulation problems, no infection at the intended insertion site, etc.) are placed in the prone position, with a bolster placed under the chest to permit flexion of the head on the neck. The forehead is supported using a ring neurosurgical donut or pillow, with unrestricted breathing and with minimal to no sedation utilized. Vital signs are monitored using standard ASA monitors, and an intravenous cannula is placed in a distal extremity for purposes of administering resuscitative medications or adjuvants, as indicated. A careful sterile skin prep and drape is performed using a generic antiseptic solution. The fluoroscope is oriented anterior to posterior with a moderate-steep cephalad orientation. This is an essential step that if not undertaken inhibits or impairs the ability to visualize the periarticular osseous structures because of the obstruction imposed by the thick mandible. Scout films are obtained using sterile needles placed over the skin of the intended needle entry sites, and local anesthetic skin wheals are raised using a 27-gauge, short (1.5-inch) needle with a short acting local anesthetic agent (i.e., lidocaine 1% without epinephrine), in doses of 2 to 3 mL per site. Next, a 22-gauge, 3.5-inch blunt (i.e., Whitacre type or equivalent) subarachnoid or block needle is advanced completely perpendicular to the skin toward the lateral-most edge of the vertebral body on the side selected. In this position, it may not be practical to gauge the exact site (i.e., C3 versus C4) where the needle is being directed. When 2 cm of needle have been introduced, it is essential to switch to a straight lateral view to observe the depth of needle advancement, as well as to ascertain which anatomic segment is being addressed. This is usually of little concern, as two levels (the level at the joint and the level cephalad to the joint) are being blocked to anesthetize a single level. So even if C4 was chosen, and the needle is seen as advancing toward the trapezoid body articular pillar at C3, the second needle may merely need to be placed caudad to the first to block both medial branches. Once the needle is seated at the appropriate depth, as seen on lateral fluoroscopy (see Fig. 52.9) and is seen not to be encroaching on either the visible neural foramens, or too far ventral, toward the anatomic site of the vertebral artery, the needle is checked to ascertain that the tip is touching bone. Using a curve tipped needle helps to realign the needle in cases where the depth appears appropriate, but the needle tip is laterally directed away from bone. In such cases, a mere twisting of the needle hub will usually suffice to turn and steer the tip toward, and subsequently against, the bone where the medial branches are situated in their respective fascial planes and are anchored by the semispinalis capitis tendons. When all needles are in the appropriate anatomic position for a given individual, they should be aligned like a picket fence. The lateral fluoroscopic image should demonstrate almost perfect parallel lines derived from the needles. An alternative technique is to place the patient prone and advance the needle from lateral to medial toward the bone under fluoroscopic guidance. This technique is clearly fraught with greater danger of striking the vertebral artery or an exiting cervical spinal nerve root than the technique described previously as a result of
the direction of the needle toward the central neuraxis. Additionally, and potentially more than a mere nuisance, the clinician who subsequently determines that the patient might derive benefit from a radiofrequency or a neurodestructive procedure of the cervical medial branches is then faced with the prospect of performing the procedure with the active tip of any RF needle making minimal and insignificant contact with the target area/nerve of interest. Contrast this with the approach described earlier, where the RF needle’s active tip will be hugging the bone through its entire length, making the likelihood of success inherently much greater. Additionally, there is less muscle in the pathway of the advancing needle using the lateral approach. This increases the likelihood that needles will not be firmly seated against the target and will be easily displaced once the second and possibly third or fourth needles are inserted at a given level.

Whichever technique is chosen, once the needles are situated, and once there has been no paresthesia or blood from the needle during aspiration, a small (typically 0.5 mL to 1 mL) volume of radiocontrast media may be injected merely to verify that no arterial cannulation has occurred. The incidence of intravascular injection following this procedure in the cervical spine is about 3.9%. If this injection proves negative for such a cannulation, the same volume of a short-acting (i.e., lidocaine, mepivacaine) local anesthetic with or without corticosteroid may be added. We prefer to use the nonparticulate steroid dexamethasone acetate for this purpose, in doses of 2 mg per medial branch (up to 12 mg total), because the particulate agents such as methylprednisolone acetate tend to flocculate or clump, with the potential for neurologic compromise if such a phenomenon occurs in an end artery. When assessing response to local anesthetic (LA) blocks, it may be prudent to query patients on more than one occasion to minimize a perception bias associated with single time frame, snapshot data capture. If RF procedures are anticipated to ameliorate recalcitrant symptoms, we typically perform double-diagnostic blocks as a prelude to RF, accepting an arbitrary 60% or better response prior to doing the actual RF. In the future, pulsed RF techniques may replace conventional RFA lesioning in the neck for the most part. These are performed by applying 42° to 45° C temperatures for 120 seconds to each nerve in question. Success rates of RFA in carefully selected patients may be found in up to 74% of patients for up to 20 months. If performed following cervical spine surgery in patients with ongoing neck pain, success may be found in 59.4% for up to 15 months. However, when data from eight cervical RFA studies were summarized in a systematic review, the average duration of analgesia was found to be more modest, at about 7 to 9 months. Even pulsed RF techniques of the cervical dorsal root ganglia may provide significant analgesia in patients with radicular pain, lasting up to 12 months. Using ultrasound guidance in the performance of the procedure has been associated with similar rates of success for RFA of the medial branches as that identified for fluoroscopic techniques.

**OCCIPITAL NERVE BLOCK (FIGS. 52.13 AND 52.14)**

The greater occipital nerve (GON) arises from the dorsal primary rami of C2, with occasional contributions from C3. The nerve penetrates the fascia inferior to the superior nuchal crest, where it runs alongside the occipital artery for a variable distance. The sensory area innervated by the nerve includes the medial portion of the posterior scalp, with radiation ventrally up to the vertex. The lesser occipital nerve (LON) arises from the ventral primary rami of C2 and C3 and passes superiorly and laterally from the occiput to the lateral edge of the sternocleidomastoid muscle. Here the nerve divides into cutaneous branches that innervate the lateral portion of the posterior scalp and the cephalad surface of the ear pinna. Along with the great auricular nerve, the GON and LON provide the majority of sensory afferent information for the occipital area and are responsible for transmitting information derived from C2-C3 facet joint derangements to the referral area described.

Occipital nerve block has become an increasingly popular method of managing headaches of diverse...
etiollogies, even though the scientific support for doing so is limited. GON blocks have been shown to be ineffective for chronic tension type headache when prilocaine and dexamethasone were used in a group of 15 patients.\textsuperscript{38} They have been used with various degrees of success for postconcussive headaches\textsuperscript{39} (80\% successful in their patients), atypical orofacial pain,\textsuperscript{40} and especially for migraine headaches, when they are often combined with trigger point injections\textsuperscript{41} or supraorbital nerve blocks,\textsuperscript{42} in both cases affording a very high degree of success for ameliorating pain and brush allodynia. A novel use of GON block has been in the successful treatment of patients with abnormal head movements who also suffered from tinnitus and dizziness associated with a previous history of trauma.\textsuperscript{43} Although oftentimes the diagnosis of headache due to occipital neuralgia is not too difficult to make,\textsuperscript{44} there are cases of refractory headache that require advanced evaluation techniques. Some suggest performing computed tomography (CT)-guided C2-C3 nerve blocks as a prelude to considering patients who may be candidates for percutaneous rhizotomy;\textsuperscript{45} in our experience, fluoroscopically guided techniques of C2-C3 nerve block have been extremely useful and have precluded the requirement to seek more advanced imaging for guidance (see Figs. 52.8 and 52.9).

**TECHNIQUE OF BLOCKING THE GREATER AND LESSER OCCIPITAL NERVES**

Occipital nerve blocks have been erroneously described by some to be merely a field block of local anesthetic and steroid layered somewhere in the posterior part of the occiput, without regard to anatomic landmarks or consequences of errantly placed medications. Indeed, there are cases of sudden unconsciousness reported following LON block, some resulting from occipital artery injection and at least one the result of unintentionally injecting local anesthetic into a previous bone defect from a craniotomy.\textsuperscript{36} Also, it is possible that unconsciousness might occur after GON block has been made too far inferiorly toward the foramen magnum. Additionally, if practitioners are not careful and discriminating in their choices of frequency of GON block, and use judicious doses of agents including corticosteroids, additional complications like the development of Cushing syndrome may result.\textsuperscript{47} Our technique of blockade of the occipital nerves is to perform the procedure with the patient in the sitting position, with the forehead forward, resting on either a Mayo stand, the edge of a padded table, or on a gurney. If possible, the occipital artery is palpated at the superior nuchal ridge. Using ultrasound guidance may help to identify the artery, which is often not robust or bounding and, subsequently, not always readily discernible as a distinct structure. As it is virtually impossible to completely disinfect the scalp injection site, we utilize alcohol wipes or a Betadine-soaked pledget to soak the area with disinfectant prior to inserting the needle, without expectations of complete asepsis. Next, we insert a fine-gauge (25-gauge, 1.5-inch) cutting needle immediately medial to the artery and advance it perpendicular to the skin until the needle tip touches periosteum. Once the occipital bone has been thusly contacted, the needle is retracted about 1 mm and is redirected slightly cephalad. After gently aspirating, 5 mL of local anesthetic (0.5\% bupivacaine or ropivacaine) with 4 mg of dexamethasone or 6 mg of betamethasone is injected in a fanlike manner, taking care not to direct the needle too far medially toward the foramen magnum. The lesser occipital nerve may be blocked, as can the greater auricular nerve, by removing the needle and placing it into the skin about 3 to 4 cm lateral to the entry point for GON block, while also directing it inferiorly instead of superiorly as for GON block. After gentle aspiration, 5 mL of the same combination of local anesthetic with or without corticosteroid as noted previously may be injected, again in a fanlike distribution, to block the nerve. After completing GON and LON blocks, it is important to gently massage the tissues of the scalp to assist in the spread of the agents while maintaining pressure over the injection site(s). This will minimize ecchymosis or hematoma formation from this highly vascular area. Often, an ice pack is applied for 20 to 30 minutes post-procedure to further minimize swelling and inhibit vascular absorption of the local anesthetic agents, particularly if bilaterally blocks have been performed.

**FACIAL PAIN**

**SUPRAORBITAL, INFRAORBITAL, MENTAL NERVE BLOCKS (FIGS. 52.15 AND 52.16)**

Peripheral branches of the trigeminal system may be readily accessible through percutaneous needle techniques. **Supraorbital nerve block** is useful in the treatment of painful conditions of the frontal nerve, a branch of cranial nerve V1. The nerve leaves the superior orbital fissure to enter the orbit, passing ventrally under the periosteum of the roof of
the orbit. The frontal nerve gives off two corollary branches: the supraorbital and the supratrochlear nerves. The supraorbital nerve is larger and more laterally situated than the supratrochlear nerve, and it supplies sensory fibers to the forehead, upper eyelid, and anterior scalp. The nerve is typically blocked by injecting a small volume of dilute local anesthetic, with or without corticosteroid, into the supraorbital foramen. A 22- to 25-gauge, 1.5-inch needle is typically employed for the block, which is readily accomplished once the foramen is palpated and after a sterile skin prep is performed. The goal of needle insertion is to avoid placing the needle tip through the foramen, which would assuredly elicit a paresthesia of the supraorbital nerve as it pins the nerve against the periosteum. It is more desirable to guide the needle toward the foramen, and, once periosteum is contacted, the needle should be slid slightly medially so that its tip is abutting the rim of the foramen. Following a negative aspiration, 3 to 4 mL of local anesthetic with 2 mg of dexamethasone or 6 mg of betamethasone may be incrementally injected. The needle should be flushed and withdrawn, and a dressing is applied over the injection site. Supraorbital nerve block has been successfully employed in the treatment of hemi-crania continua. Supratrochlear nerve block may be performed at a point slightly medial to the insertion site described earlier for supraorbital nerve block, using the same needle types and volumes and concentrations of local anesthetics and adjuvants. The indications, contraindications, complications, and side effects of this block are virtually identical to those aforementioned.

**Infraorbital nerve block** is used to block the peripheral contribution of the maxillary nerve, typically affected by conditions of chronic facial pain such as those resulting from complex regional pain syndrome and occasionally herpes zoster. The infraorbital nerve enters the orbit via the infraorbital fissure and passes along the floor of that structure in the infraorbital groove. It exits the skull through the infraorbital foramen, innervating the lower eyelid, lateral nose, and part of the superior lip. A branch of the nerve, the superior alveolar nerve, innervates the upper incisors, canine, and contiguous soft tissue.

Infraorbital block is performed with the patient in the supine position and with the head maintained in a neutral position. The infraorbital foramen is palpated, and a mark is placed over it using a marking pen. A sterile skin prep is performed, after which a fine-gauge (25- or 27-gauge), 1.5 inch needle is advanced into the foramen, while maintaining a slight medial direction of the advancing needle tip. This maneuver minimizes the pinning of the infraorbital nerve against bone and potentially traumatizing the nerve. Even taking such precautions, the nerve may be stimulated, resulting in a paresthesia to the teeth or lateral naris. After aspirating for the presence of blood, a small volume (3 mL) of local anesthetic, with or without a nonparticulate corticosteroid, is incrementally injected. After clearing the needle, it is withdrawn, and a small bandage is applied over the injection site. The patient should be observed for 20 minutes and examined for an expanding hematoma of the face, which, if present, is usually readily treated with pressure and occasionally with an ice pack.

**Inferior Alveolar (Mental) Nerve Block**

The inferior alveolar nerve is a distal branch of the mandibular nerve. The nerve exits the mental foramen at the level of the second molar tooth, having divided into an incisor branch and a mental branch. After exiting the foramen, the nerve sends a ramus superiorly, innervating the lower lip, inferior oral mucosa, and the chin (mental branch). This nerve block has been used in the treatment of mental neuralgia, facial herpes zoster, and cases of trigeminal neuralgia (TGN) of the V3, where the nerve is readily accessible for cryolesioning. As in the infraorbital nerve block technique, there is both an extraoral and an intraoral technique of mental nerve block. The intraoral technique is less painful for patients and provides a similar degree of successful block compared to the latter agent. When evaluated in 123 patients using a standardized alveolar nerve block method, the block provided analgesia/anesthesia to the first molar (92%), first premolar (55.3%), and canine (38.2%) teeth of the lower jaw. Additionally, levobupivacaine 0.5% with epinephrine 1:200,000 (5 µg/mL) was shown to be equipotent and equi-effective to the same concentration and dose of bupivacaine when used for inferior alveolar nerve block. Because of its inherent reduced systemic and cardiac toxicity, levobupivacaine may replace the latter agent for peripheral nerve blocks of the trigeminal system.

Infraorbital nerve block is performed with the patient in the supine position and the head maintained in a neutral position. After palpating the mental foramen and performing a sterile skin prep, a small (25- or 27-gauge), 1.5-inch needle is advanced toward the foramen using a slight medial direction, as noted earlier for infraorbital nerve block, to minimize the likelihood of pinning the exiting nerve against periosteum. A paresthesia may nevertheless be obtained while performing the needle insertion, and patients need...
to be appraised of this possibility. After a negative aspiration test, 3 mL of local anesthetic with or without a nonparticulate corticosteroid are incrementally injected. The needle is cleared and withdrawn, and a small bandage is applied over the injection site. The patient should be observed for approximately 20 minutes to guard against the development of a hematoma, which is typically amenable to compression or the application of an ice pack.

**TRIGEMINAL NERVE BLOCK AND GASSERIAN GANGLION BLOCK**

Gasserian ganglion block is an underutilized technique for managing chronic face pain resulting from trigeminal neuralgia (TGN) and for persistent pain resulting from conditions such as recalcitrant herpes zoster ophthalmicus and postherpetic neuralgia. It has also been utilized for diagnostic purposes to differentiate pain originating from somatic structures from those mediated by sympathetic mechanisms. By far the most common indication, however, remains pain caused by malignancy with invasion of neural structures of the head and face. In these cases, local anesthetic nerve blocks may be accomplished as prognostic blocks, prior to subjecting patients to alcohol or phenol blocks, or to radiofrequency (conventional or pulsed) or cryo-neurolysis of the gasserian ganglion. Some of the more common malignancies involving the respective structures innervated by the trigeminal nerve include tumors of the orbit, maxillary sinus, and mandible. At times, gasserian ganglion block may be undertaken in cases where neurosurgical management (i.e., Janetta’s procedure) is not feasible or practical. Occasional uses of the block and of neurodestruction of the ganglion include intractable cluster53-57 and migraine headache (reflecting the second author’s experience) and ocular pain due to glaucoma. Idiopathic TGN is due to vascular contact at the proximal portion of the preganglionic segment of the trigeminal nerve with preganglionic deformity and is observed in up to 97% of individuals so affected,58 with the remedy often being gasserian ganglion block. For individuals suffering from isolated dysfunction of either the maxillary (V2) or mandibular (V3) division of the trigeminal nerve, it is often more feasible to perform single nerve injections on these structures, as the success rate of performing blocks at the foramen rotundum (maxillary) and foramen ovale (mandibular) have been shown to be 84% and 92%, respectively, for chronic facial pain.59 When compared to peripheral nerve procedures, however, ganglion level procedures (radiofrequency thermocoagulation, balloon compression, glycerolysis) are more effective overall and should probably be attempted by skilled interventionalists if long-term success is sought.60 The median pain-free interval that may be expected after percutaneous retrogasserian glycerol injection is 32 months, although the complication rate (hypesthesias, dysesthesias, anesthesia dolorosa) may approach 50% or more using this technique.61 In another study using the same technique, the success rate, as defined by complete pain relief at 3.5 years, was 71.4%, with a 32% rate of mild hypesthesias, a 19% rate of paresthesias, and a 3% rate of dysesthesias.62 The choice of whether to perform percutaneous neurodestructive ganglion procedures using fluoroscopic guidance or CT scan guidance is operator dependent. The largest case series to date have included more than 2000 percutaneous ethanol or RFA blocks over a 13-year period using fluoroscopy with excellent success.63 On the other hand, the foramen ovale is often difficult to visualize using fluoroscopy alone. In recent times, CT-guided or CT-fluoroscopy-guided gasserian ganglion thermolysis procedures have become increasingly popular because of the ability to more readily identify osseous structures (Fig. 52.17).64 In the evolving practice of using CT scanning for head and neck nerve blocks, determinations are being made for the most appropriate skull-rotation angles in which the foramen ovale is best visualized, the relationship between the virtual puncture point and anatomic landmarks, and the distance between the virtual puncture point and the foramen.65

![Figure 52.17 CT-guided trigeminal ganglion block. The vertical, white arrow indicates the foramen ovale. The horizontal, black arrow indicates the needle through the foramen.](image)

**TECHNIQUE OF BLOCKING THE TRIGEMINAL NERVE VIA THE GASSERIAN GANGLION**

The gasserian ganglion resides in the middle cranial fossa.66-68 It is situated in a fold of dura mater that forms an invagination around the posterior two thirds of the ganglion. This region is referred to as Meckel’s cavity and contains cerebrospinal fluid. The ganglion is bound medially by the cavernous sinus and optic and trochlear nerves, superiorly by the superior orbital fissure. It further divides into the supraorbital, supratrochlear, and nasociliary nerves, which carry sensory information from the maxilla and overlying skin, the nasal cavity, palate, nasopharynx, and meninges of the anterior and middle cranial fossa. The mandibular division
The oculomotor, facial, and glossopharyngeal nerves. The autonomic nervous system via the ciliary, sphenopalatine, otic, and submaxillary ganglia. It also communicates with the facial muscles including the masseter, temporal, and medial and lateral pterygoids. The ganglion interfaces with the cranial muscles that innervate the muscles of mastication and other facial muscles.

All patients considered candidates for either diagnostic or therapeutic block, or for neurolysis procedures, need to be evaluated to rule out the presence of coagulation disorders or therapeutic block, or for neurolysis procedures, need to verify that no vascular structure has been entered and that the needle is still not in the subarachnoid space. If a diagnostic block is being performed, then 0.1 mL of 1% lidocaine without epinephrine, 0.2% ropivacaine, or 0.25% bupivacaine can be incrementally injected using a tuberculin syringe, to a total volume of about 0.5 mL, with continual intermittent aspiration. If neurolysis is desired, the same volume of 6.5% phenol in glycerin or absolute alcohol may be incrementally injected using a tuberculin syringe in the manner described previously for local anesthetic injection. For using hyperbaric phenol solutions, the patient should be placed in the sitting position with the chin aiming toward the chest prior to injecting the agent; this will help maximize the likelihood that the phenol will spread preferentially to V2 and V3 and avoid the ophthalmic division of the TGN. For absolute alcohol, the patient should be left in the supine position.

The same approach to gasserian ganglion block can be undertaken for radiofrequency (conventional or pulsed), cryolesioning, balloon compression, or even for placing stimulating electrode leads for subsequent attachment to an implanted pulse generator. For conventional radiofrequency lesioning, a 3- to 5-mm active-tip needle is placed. The target depth of the needle tip depends on the division of the trigeminal nerve that needs to be lesioned. The mandibular division is rostral and lateral, the maxillary division is intermediate, and the ophthalmic division is mostly cephalad and medial. Location of the needle tip on the appropriate division(s) is determined by the response to sensory and motor stimulation (50 Hz, 1 volt and 2 Hz, 2 volts, respectively) of the ganglion. Paresthesia should be perceived at less than 0.3 volt, with little to no muscle contraction of the masseter muscle at 0.6 to 1 volt. If no contraction is observed, then the tip of the needle is on the ophthalmic or maxillary divisions. Once the patient senses paresthesia in the painful area, inject 0.5 mL of 0.25% bupivacaine or 0.2% ropivacaine with steroid. Wait 30 to 60 seconds and begin lesioning at 60°C for 90 seconds. If the patient cannot tolerate the lesioning, stop and wait an additional 30 minutes before repeat implantation.

Figure 52.18 Lateral fluoroscopic image of a 22-gauge, curved, blunt block needle through the foramen ovale.
seconds, then try again or add another 0.5 mL of local anesthetic prior to resuming lesioning. If more than one branch of the trigeminal nerve is affected, perform several lesions of the ganglion. Reposition the needle and repeat the stimulation test to get paresthesia in the desired site. For lesioning of the ophthalmic division, assess the corneal reflex during and after each lesion. Lesioning is typically started at temperatures of 55° to 65° C to preserve this reflex. One or two lesions are recommended. If the corneal reflex diminishes, lesioning should be stopped. Pulsed radiofrequency is not a temperature-dependent technique. It is a nondestructive method of providing long-term pain relief. After proper positioning of the needle tip, perform two to four pulsed radiofrequency cycles for 120 seconds each at 45 to 60 volts. The temperature of the needle tip rarely exceeds 42° C, thus local anesthetic is not required. If significant masseter contraction is noted during pulsing, inject 1 to 2 mL of local anesthetic to diminish this effect, or hold the patient's mouth closed with your hand while the cycles complete.

MAXILLARY AND MANDIBULAR NERVE BLOCKS

The trigeminal nerve branches may also be blocked using a coronoid approach. The benefit of accessing the V2 and V3 nerves using this approach is the facility in doing so, the ease of reproducibility, and the possibility, albeit not recommended, of doing the procedure absent the requirement for radiologic guidance. The coronoid approach is a useful technique of accessing V2 as it leaves the foramen rotundum. From a technical ease standpoint, coronoid trigeminal block far surpasses the classical technique of gasserian ganglion block, so it is probably our technique of choice in all situations where a V1 block is not essential for diagnosis or management of facial pain (as noted by the first author).

With the patient in the supine position, the head is turned to the side opposite of the intended block. The coronoid notch is easily identified by asking patients to open and close their mouths with palpation anterior and inferior to the external auditory meatus. Once the landmarks are identified, the patient is asked to maintain the mouth in a neutral position, while a 22-gauge, 3.5-inch Whitacre or other blunt-tipped block needle is advanced perpendicular to the skin of the side of the face, just below the zygomatic arch directly in the center of the coronoid arch. Once the lateral pterygoid plate is contacted (at about 4 to 5 cm from the skin), the needle is withdrawn about 22 mm. Withdrawing the needle slightly as such improves the likelihood of successfully blocking the mandibular nerve (V3) in addition to V2. A total of 5 to 10 mL of local anesthetic, with or without corticosteroid, is used for diagnostic/therapeutic block, whereas the same volume of alcohol may be carefully injected using the same approach if neurolysis is desired. The mandibular (V3) branch may be separately blocked here, or it may be blocked in tandem with V2 as described previously. If the nerve is to be blocked as noted previously for the V2 block, the simplest and likeliest chance for success is via the coronoid approach. If one desires to block the nerve separately, then, once the needle contacts the lateral pterygoid plate, it should be redirected posteriorly and inferiorly until it passes the inferior aspect of the plate. At a point corresponding to approximately 1 cm deeper than the contact point of the lateral pterygoid plate, there will typically be a V3 paresthesia elicited. A usual dose of local anesthetic, or of neurolytic agent, is 3 to 5 mL using continual intermittent aspiration tests because of the high degree of vascularity in the area. Because the mandibular nerve (V3) has motor branches, it is not inconceivable that a well-performed local anesthetic or neurolytic procedure might result in paresis or weakness of the muscles of mastication and also some facial asymmetry resulting from muscle weakness. This may be more than a nuisance and should be clearly described during the informed consent process with the patient.

Mandibular and maxillary nerve blocks are typically used for ameliorating pain related to TGN, but indications for surgical analgesia, including using mandibular block as an adjunct for cervical plexus block (CPB) for carotid endarterectomy surgery, have been described. Although most clinicians continue to use fluoroscopic guidance in most instances of mandibular nerve block, the technique of CT-guided block has been described and may be a suitable alternative if this modality is considered necessary to delineate the relevant anatomy. Continuous catheter techniques of mandibular block have also been described both for cancer pain management and for analgesia after mandibular fracture repair. Neural complications after mandibular nerve injury are not uncommon and involve the lingual nerve more commonly than the inferior alveolar nerve, oftentimes lasting much longer than other common peripheral nerve injuries such as neuropraxias. These injuries may represent neurotoxicity as a central etiology, according to one recent review undertaken in 52 patients who had received these blocks. Otherwise, intravascular injection, hematoma, dizziness, and ataxia occur with some frequency after these procedures and should be discussed with patients during the informed consent process.

For maxillary nerve block using the coronoid approach, it is important to not advance the block needle more than 0.25 cm once the pterygoid plate has been contacted in order to minimize the chance of causing neural injury. And as for mandibular nerve block described earlier, a CT-guided technique and a continuous catheter technique of maxillary nerve block have both been described, the former to increase the likelihood of success and the latter to extend the duration of analgesia in a group of patients undergoing radical maxillary sinusotomy.

GLOSSOPHARYNGEAL NERVE BLOCK AND RADIOFREQUENCY

The glossopharyngeal nerve (GPN) (cranial nerve IX) is infrequently implicated in painful conditions of the face and neck. Nevertheless, because of the lack of familiarity of many pain practitioners with the anatomy and implications of glossopharyngeal nerve dysfunction, it is an important entity to consider in cases of recalcitrant pain particularly of the tongue, mouth, and pharynx. GPN block may be suitable for conditions such as glossopharyngeal neuralgia and pain from malignancy. The nerve may be affected by tumors of the tongue, hypopharynx, and palate and tonsils. The block is also used during the anatomic evaluation method of differential nerve block. The GPN is a mixed cranial nerve carrying both motor and sensory fibers. The nerve is attached by three or four filaments to the medulla oblongata in a groove between the olive and inferior peduncle.
Motor fibers, from cells of the nucleus ambiguus, innervate the stylopharyngeus muscle, while the sensory branches, from cells of the superior and petrous ganglia, innervate the tongue (the posterior third), palatine tonsil, fauces, and mucous membranes of the mouth and pharynx. A branch of the GPN, the carotid sinus nerve, is important in the regulation of blood pressure, pulse, and respiration, as this branch innervates the carotid body and carotid sinus. Sympathetic efferent fibers from the nucleus ambiguus are both preganglionic motor fibers and preganglionic secretory fibers of the sympathetic system. Parasympathetic fibers pass to the otic ganglion, and postganglionic fibers innervate the parotid gland. In conjunction with the vagus and spinal accessory nerves (cranial nerves X and XI), the GPN exits the jugular foramen near the internal jugular vein. All three cranial nerves as well as the hypoglossal nerve (cranial nerve XII) lie between the internal jugular vein and the internal carotid artery. The styloid process of the temporal bone is a major landmark for successfully blocking the GPN. GPN block is performed with the patient in the supine position and the head turned slightly opposite to the affected side.

Our practice includes the use of fluoroscopic imaging to help delineate and define the ipsilateral mastoid and the ipsilateral angle of the mandible, as the styloid process is typically found equidistant between those two respective structures. Fluoroscopy also permits real-time imaging of the pattern of injection of contrast media, so that in cases where the needle tip has penetrated either the carotid or jugular systems, this activity should be observable and intra-vascular injection subsequently preventable. Once baseline scout films have been obtained, intravenous access assured, and baseline vital signs documented, the skin overlying the styloid process should be prepped and draped in sterile fashion. A small skin wheal may be made over the styloid process using a 25-gauge 1.5-inch needle and 1% plain lidocaine, 3 to 4 mL. Next, a 22-gauge, 1.5- to 2-inch blunt tipped block needle may be advanced perpendicular to the skin toward the process, aiming for its posterior aspect. The usual depth of contact of the styloid varies from about 1.5 cm to 4 cm. Once the needle tip has slipped posteriorly off of the process, 1 mL of iodinated contrast media should be incrementally injected under live continuous fluoroscopy (Fig. 52.19). Then, barring any intravascular spread, a short-acting (lidocaine, mepivacaine) and dilute (1% concentration) local anesthetic with epinephrine 1:200,000 (5 µg/mL) in a volume of 5 to 8 mL should be incrementally injected in divided doses. If indicated, a modest dose of nonparticulate corticosteroid (dexamethasone, betamethasone) may be added to the injectate. Patients need to be monitored for a minimum of 30 minutes following the block to verify that there has been no systemic response to the injected local anesthetic solution. Even taking these precautions and using fluoroscopic guidance does not completely eliminate the possibility of local anesthetic spillover onto the vagus nerve (with resultant ipsilateral vocal cord paralysis, or bradycardia, asystole, reflex tachycardia, and syncope) or onto the spinal accessory nerve (weakness of the trapezius muscle).

There is also an intraoral approach that can be utilized when there is an anatomic distortion externally by previous surgery or tumor. The patient is placed in a supine position with the mouth wide open and the tongue is retracted downward and medially using a tongue depressor or a laryngoscope blade. The nerve will be located at the inferior portion of the tonsillar pillar and is accessed via the palatoglossal fold. Once the fold is identified, a topical local anesthetic spray or pledget with 1 mL of saline with epinephrine is applied for hemostasis. A 22- or 25-gauge needle with a slight distal bend (25 degrees) is advanced to depth no more than 0.5 cm into the mucosa. After negative aspiration, 2 mL to 3 mL of local anesthetic (0.2% ropivacaine) with or without steroid is injected. With the intraoral approach, there is a potential of vessel trauma and neurotoxicity but much less than might occur with the extraoral approach.

**SPHENOPALATINE GANGLION BLOCK AND RADIOFREQUENCY**

The sphenopalatine ganglion (SPG) block is useful for treating acute migraine headaches, acute and chronic cluster headache, post-traumatic headache, and facial neuralgias including Sluder’s, Vail’s, and Gardner’s syndromes. Some have suggested that SPG block using 4% viscous lidocaine is not superior to placebo in the analgesic management of patients suffering from myofascial pain of the head. Others have found that RF of the SPG relieved the symptoms of episodic cluster headache in 60.7% of 56 patients and in 30% of 10 patients with chronic cluster headache. An infrapyramydgal approach was used, and complications were transient in all cases. The ganglion resides in the pterygopalatine fossa. The fossa is bordered anteriorly by the maxillary sinus, posteriorly by the medial pterygoid plate, medially by the palatine bone, and superiorly by the sphenoid sinus. The pterygomaxillary fissure allows passage of a needle into the fossa, whereas the pterygopalatine foramen is located medial to the ganglion and is just posterior to the middle turbinate. The fossa is approximately 1 cm wide and 2 cm high and resembles a V-shaped vase on a lateral fluoroscopic image. The SPG is covered by a 1- to 1.5-mm thick layer of connective tissue and mucous membrane and is approximately 5 mm in
size and triangular in shape. A large venous plexus overlies the fossa. Foramen rotundum and the pterygoid canal are located on the superolateral and inferomedial aspect of the fossa, respectively. The maxillary artery resides in the fossa. The ganglion is “suspended” from the maxillary nerve by the pterygopalatine nerves and is medial to the maxillary nerve. Posteriorly the ganglion is connected to the vidian nerve, which is formed by the deep petrosal (sympathetic from the upper thoracic spinal cord) and greater petrosal (parasympathetic from the superior salivatory nucleus) nerves. The ganglion has efferent branches and forms the superior posterior lateral nasal and pharyngeal nerves. Caudally, the greater and lesser palatine nerves exit the ganglion. Sensory fibers arise from the maxillary nerve, pass through the SPG, and innervate the upper teeth, nasal membranes, soft palate, and some parts of the pharynx. A small number of motor nerves are believed to travel with the sensory trunks.

There are several techniques to block the SPG, one of which is to block the ganglion using the topical application approach. With the patient in the supine position and the head maximally extended, as in the sniffing position, the practitioner applies 3 mL of 4% viscous lidocaine absorbed onto cotton-tipped pledgets. The pledgets are advanced slowly and deliberately, to minimize the chance of causing epistaxis, in a direction that is directly perpendicular to the floor. The path taken with the pledgets is along the superior border of the middle turbinate of each nostril until the tip contacts the mucosa overlying the SPG. The pledgets are left in place for 30 minutes while the patient’s vital signs are monitored, and then they are removed and discarded. Side effects are typically related to iatrogenic epistaxis, as local anesthetic toxicity is exceedingly rare using this approach.

Another technique is the infrrazygomatic approach to SPG blockade, which can be technically challenging. It can be performed without fluoroscopy, but fluoroscopic guidance is highly recommended, as this will anecdotally improve the success of the block and the speed at which it is performed, and will decrease potential complications. Noninvasive monitors should be used to record vital signs. Place the patient in the supine position. Sterilely prep and drape the appropriate side of the face. Obtain a lateral fluoroscopic image. Palpate the mandibular notch and anesthetize the skin. If the notch is not palpable, identify the notch on a lateral fluoroscopic view. Identify the pterygopalatine fossa (which appears as a “V”) on the lateral image and superimpose the right and left fossae. This is accomplished by manipulating the C arm or the head. The block can be performed with a 3.5-inch, 22-gauge, short-bevel needle with the distal tip bent at a 30-degree angle or with a curved, blunt, 10-cm, 20- or 22-gauge needle. The technique described reflects the use of a blunt needle. Anesthetize the skin and insert a 1.25-inch, 16-gauge angiocatheter through the skin and advance until it is just medial to the ramus of the mandible. This can be checked on an A-P image. Pass the block needle through the angiocatheter and advance it medially, anterior, and slightly cephalad. Obtain a lateral image to check the direction of the needle. Your target is the midportion of the pterygopalatine fossa (Fig. 52.20). Get an A-P view and advance the needle toward the middle turbinate, stopping when the tip is adjacent to the palatine bone (Fig. 52.21). If resistance is encountered at any point, withdraw and redirect the needle. Given the small size of the fossa, frequent A-P and lateral images are may be required to redirect the needle. Once in the fossa, inject 0.5 to 1 mL of nonionic, water-soluble contrast and observe for intravascular spread or intranasal placement of the needle. Once correct placement has been confirmed, inject 1 to 2 cc of local anesthetic, with or without steroids.

After a successful diagnostic block, two therapeutic choices are available: conventional radiofrequency lesioning (RFTC) and pulsed radiofrequency (PRF). An insulated RF needle with a 3- to 5-mm tip is placed using the infrrazygomatic approach. Once in place, sensory stimulation is performed at 50 Hz up to 1 volt. If the tip of the needle is adjacent to the SPG, the patient should perceive a paresthesia at the root of
the nose at less than 0.3 volt. If the paresthesia is felt in the hard palate, the needle should be redirected cephalad and medial. A paresthesia in the upper teeth indicates stimulation of the maxillary nerve, and the needle should be more caudal and medial. Motor stimulation is not necessary. After appropriate sensory stimulation, RFTC can be performed at 67° C for 90 seconds times two cycles. Before lesioning, 2 to 3 mL of local anesthetic should be injected. To avoid inadvertent lesioning of other nerves around the SPG, a 3-mm active tip is a better choice. For pulsed RF, the size of the active tip is not as important as the electromagnetic field is projected from the tip of the needle and not from the shaft. With pulsed RF, two to four 120-second cycles are performed at 45 volts. Local anesthetic is not required for pulsed RF. The choice of whether to do a conventional or a pulsed RF lesion after a successful block is up to the discretion of the pain practitioner. Bradycardia (“Konen” reflex) has been noted during both conventional and pulsed RF lesioning and can be prevented with pretreatment with atropine or glycopyrrolate.

Facial, head, and neck pain remains a diagnostic and therapeutic challenge for many pain practitioners. Knowledge of relevant anatomy is crucial to avoid complications and to increase the success of the therapeutic procedure. Appropriate patient selection, monitoring, proper injection technique, and knowledge of the pharmacokinetics and pharmacodynamics of the agents used are mandatory. The possible drug-drug interactions, increasing use of anticoagulant agents by individuals at high risk, and anatomic variation found in clinical practice serve to confound the picture even further. With proper education and training, pain management interventionalists can add these techniques to their everyday skills and open an avenue to patients suffering from these maladies.

One of the most daunting challenges in contemporary pain medicine is that presented by the patient complaining of head or neck pain. The complexities of the anatomy and the overlapping zones of innervation of somatic and sympathetic nerve pathways and ganglia leads commonly to implementation of incomplete treatment strategies and resultant partial remedies. The astute pain practitioner is well served to approach the chronic head and neck pain sufferer using an algorithmic approach that relies on a comprehensive appreciation of anatomy, physiology, and pharmacology but that progresses in an orderly fashion from simpler to more complex. For example, in the chronic headache patient who complains of symptoms in the posterior head and cervical spine following a motor vehicle accident, and following a comprehensive diagnostic workup, simpler attempts at analgesia using occipital nerve blocks should precede attempts at cervical medial branch neurotomy. Similarly, for someone complaining of supraorbital type pain, a supraorbital or supratrochlear nerve block should be considered before doing a CT scan-guided V-1 nerve block at the foramen ovale. A modicum of conservatism, coupled with a multimodal systematic evaluation and implementation approach, is the most prudent way of dealing with these difficult cases.

### KEY POINTS

- Detailed knowledge of the anatomy of the facial structures will improve the success of trigeminal ganglion, sphenopalatine ganglion, and glossopharyngeal nerve blocks.
- Expected side effects (e.g., numbness in the distribution of the targeted nerve) versus complications of trigeminal ganglion rhizotomy should be fully explained to and comprehended by the patient before proceeding.
- The use of pulsed radiofrequency for trigeminal-mediated pain syndromes should be considered prior to using thermal radiofrequency after a successful diagnostic block.
- The practitioner should be prepared to treat bradycardia, which is commonly seen with trigeminal and sphenopalatine ganglion procedures.
- Given the complexity of the facial pain syndromes, the sphenopalatine ganglion block should be considered for diagnostic and therapeutic purposes.

REFERENCES

Regional anesthetic approaches to the brachial plexus are a mainstay of surgical anesthesia practice and play an increasingly important role in postoperative analgesia. Well-designed outcome studies have confirmed the benefits of regional anesthesia in patients undergoing upper extremity surgery. When compared with traditional opioid-based postoperative analgesia for outpatient shoulder, arm, or hand surgery, single-injection regional anesthesia techniques provide superior analgesia, reduce opioid-related side effects, improve patient satisfaction, and reduce the number of unplanned admissions. Although these benefits are generally limited to the day of surgery, they nevertheless represent a valuable alternative to general anesthetic and postoperative opioid techniques. Furthermore, limited comparative studies have shown that an interscalene or suprascapular block provides better analgesia than does an intra-articular injection or infusion of local anesthetic and without any risk for chondrolysis. Continuous perineural catheter techniques provide superior analgesia for total shoulder arthroplasty and various ambulatory shoulder surgeries. Similar to single-injection techniques, the prolonged analgesia afforded by continuous perineural catheters is associated with fewer opioid-related side effects and higher patient satisfaction. What remains unclear is whether these techniques substantially improve economic outcomes such as faster rehabilitation or return to work. This chapter offers a brief review of brachial plexus anatomy and pertinent pharmacology, with a primary focus on the techniques and complications of upper extremity blocks.

**BRACHIAL PLEXUS ANATOMY**

The brachial plexus is composed of the ventral primary rami of cervical nerves C5 to C8 and thoracic nerve T1, with occasional contributions from C4 and T2 (Fig. 53.1). Understanding the complex interdigitations that define the brachial plexus is important for two reasons. First, brachial plexus approaches are directed toward its various anatomic divisions. For example, the interscalene approach is directed toward the level of the distal roots and proximal trunks, whereas the infracavicular approach is directed toward the level of the cords. This anatomic subarchitecture, in turn, determines the expected motor response to peripheral nerve stimulation and the distribution of anesthetic resulting from the particular approach. Second, supplemental procedures are often necessary to anesthetize nerves that are distinct from the brachial plexus or are intermediary branches. For example, the intercostobrachial nerve is primarily derived from T2, which is not part of the brachial plexus and must therefore be blocked separately if anesthesia of the medial aspect of the upper part of the arm is desired. Therefore, basic knowledge of brachial plexus anatomy is crucial for understanding the advantages and limitations of the various approaches to upper extremity regional anesthesia.

The functional neuroanatomy of the upper extremity is critically important for determining selection of the block and assessment. Motor function is generally well correlated with an observed motor response after electrical stimulation of a specific terminal nerve; for example, distal stimulation of the radial nerve consistently elicits wrist and finger extension. In contrast, as one moves proximally along the brachial plexus, stimulation yields muscle movements of a mixed nature. As an example of this concept, electrical stimulation of the superior trunk during the interscalene approach results in mixed muscle stimulation that produces shoulder elevation (Table 53.1).

Sensory innervation of the upper extremity is inconsistent and widely overlapping (Fig. 53.2). Certain areas of the arm, such as the distal palmar aspect of the forearm, have overlapping sensory innervation from the medial and lateral antebrachial cutaneous nerves, plus occasional contributions from the median nerve. A practical implication of this neuroanatomic overlap is that most areas of the upper extremity require anesthesia of two or more terminal nerves, which supports the effectiveness of plexus-based regional anesthesia over multiple selective nerve blocks at the elbow or wrist. Furthermore, overlapping cutaneous sensory fields and motor function can be problematic for assessing anesthesia, which is best accomplished by testing end functions that can be attributed only to a single nerve. The “four P’s” is an example of such a tool (Table 53.2).

**PHARMACOLOGIC CONSIDERATIONS**

Selection of a local anesthetic for brachial plexus anesthesia is based on the expected duration of surgery and the optimal duration of postoperative analgesia. When considering block duration, anesthesiologists should be cognizant of the expected degree of postoperative pain. For mildly painful procedures, some patients may interpret prolonged arm numbness as bothersome, whereas dense analgesia may mask early signs of impaired circulation in crush injuries or surgeries with potential for the development of compartment syndrome. Thus, selection of a local anesthetic for an upper extremity block is best individualized to achieve specific therapeutic goals.

Potency studies of long-acting local anesthetics applied to the brachial plexus suggest that 0.5% bupivacaine is
Figure 53.1 Anatomic architecture of the brachial plexus. The illustration shows the various portions of the brachial plexus. Note how different approaches to upper extremity regional anesthesia result in different distributions of anesthetic. (©American Society of Regional Anesthesia and Pain Medicine and Jennifer Gentry. equipotent to 0.75% ropivacaine.\textsuperscript{13,14} This equivalence is important because a tendency to use more ropivacaine to attain the same effect as bupivacaine will probably negate the lower cardiotoxicity properties of ropivacaine. When considering the total mass (dose) of a local anesthetic, decisions are best skewed toward using a lower volume, concentration, and dose. Although it may appear counterintuitive, the work of Vester-Andersen and colleagues,\textsuperscript{15-17} along with other confirmatory investigations,\textsuperscript{18-20} clearly demonstrates that block onset, quality, and duration are not improved by using larger volumes or concentrations of local anesthetic. Indeed, doing so risks local anesthetic

Figure 53.2  Cutaneous innervation of the upper extremity. In practice, cutaneous sensory zones are not distinct but, instead, are widely overlapping. concentration-dependent neurotoxicity and dose-dependent systemic toxicity. Therefore, traditional local anesthetic volumes for an upper extremity plexus block are generally between 20 and 40 mL, depending on the approach chosen, and concentrations to produce surgical anesthesia should be 1.5% or less for lidocaine or mepivacaine, 0.75% or less for ropivacaine, and 0.5% or less for bupivacaine. Conversely, if one seeks only postoperative analgesia, ultrasound guidance facilitates the use of much lower volumes of local anesthetic for an interscalene block. However, further evidence suggests that ultrasound-guided regional anesthesia (UGRA) with low-volume blocks may indeed result in a shorter duration of analgesia.

Four local anesthetic additives have proven value when applied to the brachial plexus. Epinephrine, 2.5 µg/mL (1:400,000), prolongs the duration, acts as a marker of local anesthetic in approximately 50% of cases, so an intermediate-acting local anesthetic is clinically significant, but they do not reliably prolong the duration of long-acting local anesthetics. Clonidine, 0.5 µg/kg, prolongs anesthesia and analgesia by 50% without systemic side effects such as hypotension or sedation. Clonidine does not improve block quality during continuous perineural catheter techniques. The effect of epinephrine and clonidine on intermediate-acting local anesthetics is clinically significant, but they do not reliably prolong the duration of long-acting local anesthetics. Buprenorphine, 0.3 mg, also prolongs anesthesia and analgesia, but at the expense of nausea and vomiting. Dexa-methasone can also prolong intermediate-acting agents to a degree similar to epinephrine, but the optimal dose and any potential long-term effects of dexamethasone remain uncertain. The beneficial effects of these additives, as well as their potential neurotoxicity, alone and in combination, are currently still under investigation. Other opioids, neostigmine, calcium channel blockers, hyaluronidase, and tramadol either do not improve local anesthetic blocks or have unresolved neurotoxicity issues.

Alkalization of intermediate-acting local anesthetics facilitates faster onset of the block during epidural anesthesia but does not have the same effect at the brachial plexus. Onset is not hastened by adding sodium bicarbonate to plain local anesthetic or to local anesthetic freshly mixed with epinephrine. Indeed, animal models have shown that alkalization of local anesthetic reduces block intensity and duration.

### BLOCK TECHNIQUES FOR MAJOR APPROACHES TO THE BRACHIAL PLEXUS

A number of techniques involving various nerve localization modalities may be used for successful brachial plexus blocks, but only a sample can reasonably be presented in one chapter. When using ultrasound, target nerves can theoretically be imaged in short or long axis; target imaging is then combined with the needle guidance technique, in plane or out of plane, to fully describe the approach, for instance, short axis in plane or short axis out of plane. Since long-axis imaging for nerve blocks is limited to lower extremity techniques to date and in-plane needle guidance permits visualization of the tip of the needle, this chapter will cover only short-axis in-plane techniques using ultrasound.

### CONTINUOUS PERIPHERAL CATHETERS

Prolonged analgesia of the upper extremity can be accomplished with continuous perineural catheter techniques. Surgeries expected to cause prolonged, moderate to severe pain are appropriate for catheter placement. Such surgeries include total shoulder arthroplasty, rotator cuff repair, and major reconstructive operations on the elbow, wrist, or hand. Accumulated evidence suggests that perineural catheters can be managed efficiently in the ambulatory setting with a high degree of patient acceptance. Key to successful management is establishing clear lines of contact with the physician and patient. Even major surgeries such as total shoulder arthroplasty can be managed on an outpatient basis when perineural catheters are used to control pain and facilitate rehabilitation. Recent data indicate that ultrasound guidance can decrease the time needed to successfully place upper extremity perineural catheters in comparison to traditional nerve stimulation techniques.

For infraclavicular perineural catheter insertion, ultrasound may reduce the incidence of unintentional vascular puncture when compared with nerve stimulation techniques. Limited data suggest that patient-controlled perineural analgesia techniques are superior to continuous infusion techniques. However, in the ambulatory setting, perineural infusion regimens that combine patient-controlled boluses with a continuous infusion rate are preferred.

### INTERSCALENE BLOCK

#### INDICATIONS

For an interscalene block, the brachial plexus is approached at the level of its distal roots/proximal trunks. The most consistent local anesthetic distribution resulting from this approach involves the shoulder and upper part of the arm (Fig. 53.3). The inferior trunk (C8, T1) is unaffected by local anesthetic in approximately 50% of cases, so an interscalene block is not recommended for surgeries involving the medial aspect of the upper part of the arm, the forearm, and the hand. Ultrasound-guided approaches are also likely to spare the lower trunk distribution, although some investigators describe targeting these nerves.
**TECHNIQUES**

**Traditional Techniques**

The brachial plexus traverses the interscalene groove, which is bordered by the anterior and middle scalene muscles. In the classic Winnie technique, the patient’s head is turned 30 degrees to the contralateral side, and then a 50-mm or shorter needle is inserted into the interscalene groove at the level of the sixth cervical vertebra. The needle is oriented perpendicular to all planes of the skin and then advanced with a slightly caudad angulation, which lessens the risk of entering the intervertebral foramen and encountering spinal nerves or the vertebral artery (Fig. 53.4). The end point for advancement of the needle is either paresthesia or an evoked motor response (from peripheral nerve stimulation) in the arm or anterior aspect of the shoulder. Movement of the posterior portion of the shoulder indicates that the needle is too posterior and is stimulating the dorsal scapular nerve (C5), whereas a diaphragmatic motor response indicates placement of the needle too far anterior with resultant stimulation of the phrenic nerve. Once paresthesia or a motor response at approximately 0.5 mA is obtained, a 1-mL local anesthetic test dose is injected to rule out intravascular injection, followed by incremental injection of 20 to 30 mL of local anesthetic.

Borgeat and colleagues modified lateral interscalene approach has reportedly facilitated perineural catheter placement by reducing the angle that a catheter must take as it exits the block needle and enters the perineural area. Because the lateral approach directs the needle away from the vertebral column, this approach theoretically reduces the risk for injection of the vertebral artery or contact of the needle with the spinal cord or perispinal neural elements.

**Ultrasound-Guided Technique**

With the patient positioned as just mentioned, a high-frequency linear-array transducer should be placed at the level of the cricoid cartilage along the posterior border of the sternocleidomastoid (SCM) muscle (Fig. 53.5). After identifying the SCM, the scalene muscles are reliably located deep to the SCM fascia posterior to the internal jugular vein and carotid artery. If the fascial plane between the anterior and middle scalene muscles (interscalene groove) is not easily visualized, slide the transducer caudad toward the clavicle while keeping the scalene muscles in the center of the screen.
until the interscalene groove widens to reveal the brachial plexus. Following infiltration of the skin and subcutaneous tissue with local anesthetic posterior to the transducer, advance the block needle in an anteromedial trajectory in plane through the middle scalene muscle and into the interscalene groove.51,52 Proceed with incremental injection of local anesthetic solution as described previously. In this region, successful interscalene blocks with injectate volumes of less than 5 mL have been reported.21,53 For perineural catheter insertion, placing the patient in the lateral decubitus position with the operative side up may facilitate this posterior approach when using ultrasound guidance.52,54

SUPRACLAVICULAR BLOCK

INDICATIONS

The supraclavicular approach aims to encounter the brachial plexus at the juncture of the distal trunks and divisions as the brachial plexus courses under the clavicle and across the superior surface of the first rib (Fig. 53.6). This area represents the most compact architecture of the brachial plexus, which has been postulated (but never proved) to explain the propensity of supraclavicular blocks for rapid onset and nearly complete anesthesia of the upper extremity. This block is indicated for any surgery on the arm (see Fig. 53.1), although shoulder surgery may require supplemental blockade of the supraclavicular nerve (C3-4) to ensure anesthesia of the cape area around the shoulder. A supraclavicular block is successful in approximately 95% of patients, including those who are obese.55

TECHNIQUES

Traditional Techniques

A variety of techniques have been described for performing a supraclavicular block.56-58 With the patient in the supine position, the plumb bob technique places the needle just above the clavicle at the lateral border of the SCM muscle. The original description by Brown and associates56 involved directing the needle straight downward, similar to a brick
mason’s plumb bob. If a motor response or paresthesia is not elicited, the needle is incrementally fanned 20 degrees cephalad and then 20 degrees caudad in the parasagittal plane until the desired motor response is obtained. In a modification of this technique, the initial needle pass is made 45 degrees cephalad, followed by incremental caudad angulation until a suitable paresthesia or motor response is obtained. The logic of this modification is that it reduces the risk for contact with the lung copula in tall individuals.59 If during the course of a supraclavicular block the needle encounters the subclavian artery, the needle should be redirected posteriorly and laterally to identify the brachial plexus. Injecting 20 to 30 mL of local anesthetic after a single paresthesia or motor response into the arm or shoulder at less than 0.5 to 0.9 mA60 completes the block procedure.

Ultrasound-Guided Technique

Using the same surface anatomic landmarks as presented for the traditional techniques, a high-frequency linear-array transducer is placed with its midpoint centered posterior to the clavicle and along the posterior border of the SCM (Fig. 53.7). The subclavian artery is the most important sonographic anatomic landmark and helps localize the divisions of the brachial plexus, which is reliably superficial and
posterior to the artery. With the transducer in this position, tilt the plane of the ultrasound beam more laterally to visualize the subclavian artery over the first rib. At this location the divisions of the inferior trunk, composed of C8 and T1, should be visualized in the “corner pocket” posterior to the subclavian artery and superficial to the first rib.61,62 The subclavian artery and brachial plexus at this level are still within the interscalene groove. After infiltration of the skin and subcutaneous tissue with local anesthetic posterior to the transducer, advance the block needle in an anteromedial trajectory in plane through the middle scalene muscle and into the interscalene groove.58,61 Ultrasound-guided supraclavicular perineural catheter insertion has been described with this approach, although there may be an analgesic advantage to using the infraclavicular technique for the postoperative management of patients undergoing distal upper extremity surgery.63 Alternatively, when using ultrasound guidance, the block needle may be directed in a posterolateral direction.64

Inject the local anesthetic solution incrementally and visually confirm spread of the injectate in the vicinity of the target nerves. Unlike an interscalene block, an ultrasound-guided supraclavicular block requires a volume of injectate similar to that used with the traditional techniques.65,66

**INFRACLAVICULAR BLOCK**

**INDICATIONS**

The infraclavicular block, which is indicated for surgery on the arm distal to the shoulder, approaches the brachial plexus at the level of the cords (Fig. 53.8). This block anesthetizes the axillary and musculocutaneous nerves more reliably than does the axillary approach.67,68 Infraclavicular block techniques have the advantage of not requiring a specific arm position during placement, which is useful for patients with limited arm motion because of pain, casts, or dressings.69 The infraclavicular approach is frequently used for continuous perineural catheter placement because the catheters reliably remain in place during use. There have been reports of successful use of continuous infraclavicular perineural infusion for the treatment of complex regional pain syndrome of the upper extremity70 and for upper extremity limb salvage.71
Part 6 — Nerve Block Techniques

Traditional Techniques

Similar to the supraclavicular approach, several techniques have been described for an infraclavicular block; none are inherently superior. The coracoid approach begins with identification of the lateral aspect of the coracoid process in a supine patient. From this point, an entry point 2 cm caudal and 2 cm medial is marked (Fig. 53.9). A stimulating needle is directed posteriorly, perpendicular to all planes. Stimulation of the various cords can be ascertained by their resulting motor response—"at the cords, the pinkie towards." Stimulation of the posterior cord causes the little finger to move posteriorly, stimulation of the medial cord results in medial movement, and stimulation of the lateral cord results in lateral movement. The posterior cord occupies the middle position and is the deepest of the three cords. Block success is maximized when two cords are identified and subsequently bathed with local anesthetic; identification and subsequent injection around the posterior cord are the most important determinants of block success. A total of 30 to 40 mL of local anesthetic is sufficient for an infraclavicular block.

Ultrasound-Guided Technique

With the arm abducted 90 degrees and the coracoid process used as a surface landmark, the transducer is oriented in the parasagittal plane with its midpoint slightly medial and caudal to the coracoid process (Fig. 53.10). Although a small-footprint, lower-frequency curvilinear transducer may have advantages because of this region’s limited space and the expected steep angle of the block needle, a high-frequency linear transducer may also be used in most nonobese patients. The optimal short-axis ultrasound image should demonstrate the axillary artery and the brachial plexus cords to be located immediately deep to the pectoralis minor muscle and its accompanying clavipectoral fascia. It is helpful to visualize the axillary artery as being in the center of a clock face, with the brachial plexus cords arranged around the artery in a parasagittal topographic arrangement. The exact position of the cords relative to the artery is variable, but the posterior cord is always located between the lateral and medial cords. Deep to the pectoralis minor muscle and clavipectoral fascia, the axillary artery is visualized cephalad to the axillary vein, where it is surrounded by the three brachial plexus cords. After infiltration of the skin and subcutaneous tissue with local anesthetic cephalad to the transducer, advance the block needle in a caudad direction through the pectoralis muscle toward the axillary artery. Local anesthetic may be deposited separately around each cord or via a single injection incrementally posterior to the axillary artery with comparable block efficacy. Similar to a supraclavicular block, injectate volume when using ultrasound guidance for an infraclavicular block does not seem to differ significantly from that used with traditional techniques. For distal upper extremity postoperative analgesia, many ultrasound-guided infraclavicular perineural catheter insertion techniques have been described. Continuous infraclavicular perineural infusions have been shown to provide postoperative analgesia that is superior to that achieved with supraclavicular perineural infusions after distal upper extremity surgery. A combination of continuous infusion and patient-controlled boluses optimizes analgesia when compared with either a basal-only or a bolus-only dosing regimen.
### AXILLARY BLOCK

#### INDICATIONS

The axillary block anesthetizes the brachial plexus at the level of the four terminal nerves: the radial, ulnar, median, and musculocutaneous nerves (Fig. 53.11). It is indicated for surgeries distal to and including the elbow (see Fig. 53.1). With the exception of very proximal approaches high in the axilla, the axillary block is not as ideally suited for continuous catheter techniques as are the infraclavicular approach and approaches above the clavicle.

#### TECHNIQUES

**Traditional Techniques**

The patient lies supine with the arm abducted approximately 90 degrees and externally rotated such that the dorsum of the hand lies flat while supported by one or two pillows. Classic descriptions of the axillary neurovascular bundle place the radial nerve nearly posterior to and slightly inferior to the artery, the ulnar nerve more superficial but also inferior to the artery, the median nerve superficial and superior to the artery, and the musculocutaneous nerve superior to the artery and residing deeper within the fascial plane between the coracobrachialis and biceps muscles or within the belly of the coracobrachialis muscle (Fig. 53.12). However, anatomic variation is frequently present, especially with regard to nerve position relative to the axillary artery. These inherent variations may partially explain why the various techniques for axillary block have similar success rates. The transarterial technique generally achieves higher success rates with two 10- to 20-mL local anesthetic injections anterior and posterior to the axillary artery. Success rates are similar with the paresthesia and peripheral nerve stimulation techniques. Either technique’s success is enhanced by identifying and subsequently injecting local anesthetic near three or four terminal nerves rather than using a single injection. Four injections may increase performance time without appreciably affecting success rates. The motor responses expected for each nerve are listed in Table 53.1. Further technical refinement suggests that success is most dependent on identifying and

![Axillary Block](image)

**Figure 53.11** Axillary block. The upper left inset illustrates the expected distribution of anesthetic with an axillary block. The musculocutaneous nerve (MC) is superior to the axillary artery and typically within the fascial plane between the coracobrachialis and biceps muscles. Note how the other three terminal nerves are arranged around the axillary artery. As shown in the upper right inset (which is rotated 90 degrees clockwise from its normal patient-oriented view), the terminal manifests considerable positional overlap (median nerve = green, ulnar nerve = blue, radial nerve = orange). The medial cord frequently lies between the axillary artery and vein. (©American Society of Regional Anesthesia and Pain Medicine and Jennifer Gentry. Used with permission. All rights reserved.)
subsequently injecting local anesthetic near the radial and median nerves and least dependent on injection around the ulnar nerve. Clinical trials suggest that traditional axillary block techniques should require less than 40 mL of local anesthetic. Because the musculocutaneous nerve diverges from the plexus at the level of the axilla, it may remain unanesthetized during transarterial or single-injection techniques. If not localized by ultrasound or nerve stimulation, the musculocutaneous nerve is easily blocked by infiltrating 5 mL of local anesthetic into the belly of the coracobrachialis muscle. The perivascular infiltration technique uses a continuously moving needle to fan 10 to 15 mL of local anesthetic next to the superior border of the axillary artery in three progressively outward needle passes and then repeats the process along the inferior aspect of the artery. Because of this outwardly fanning technique, the musculocutaneous nerve is usually anesthetized.

**Ultrasound-Guided Technique**

With the arm abducted 90 degrees at the shoulder, the midpoint of a high-frequency linear-array transducer is placed over the axillary artery pulse in the proximal part of the axilla. Such placement and orientation will provide a short-axis view of the axillary artery, the terminal nerves, and the surrounding perineural musculature (conjoint tendon and biceps and coracobrachialis muscles) (Fig. 53.13). The artery and other blood vessels may be clearly identified with the aid of color flow Doppler. The locations of the terminal branch nerves relative to the artery, especially the musculocutaneous nerve, are highly variable, and ultrasound-guided axillary blocks may still result in nerve sparing. Therefore, it may be advantageous to identify the individual peripheral nerves more distally and trace them back toward the axilla. After visualizing the axillary artery and target nerves and following injection of local anesthetic lateral to the transducer, the block needle is advanced in a medial direction toward the axillary artery and local anesthetic is injected so that each target nerve is surrounded. With an ultrasound-guided multiple-injection technique, the volumes of local anesthetic required may be drastically reduced as compared with the traditional techniques. However, recent prospective randomized controlled studies indicate that when using traditional volumes of local anesthetic (35 to 40 mL), an ultrasound-guided double-injection (with one injection specifically targeting the musculocutaneous nerve) perivascular approach results in success comparable to that achieved with an ultrasound-guided quadruple-injection perineural technique but with fewer needle passes.

**ACCESSORY BLOCKS**

**SUPERFICIAL CERVICAL PLEXUS BLOCK (SUPRACLAVICULAR NERVE BLOCK)**

**INDICATIONS**

Nerves that arise separately from the brachial plexus or are inconsistently anesthetized with a brachial plexus block innervate selected upper extremity sensory fields. Also known as the superficial cervical plexus block, blockade of the supraclavicular nerve (C3-4) is a useful adjunct to a suprascapular brachial plexus block when surgery is performed around the cape of the shoulder (Fig. 53.14). Traditional techniques for the interscalene block typically anesthetize the suprascapular nerve. However, a lower-volume ultrasound-guided interscalene block or the suprascapular approach may be associated with insufficient anesthesia of this nerve.

**TECHNIQUES**

The suprascapular nerve is anesthetized by injecting a subcutaneous wheal of local anesthetic along the posterior border of the SCM muscle from the clavicle to the mastoid. Several milliliters of local anesthetic can also be infiltrated into the midpoint of the SCM muscle, which the nerve traverses before branching into three components.

**SUPRASCAPULAR NERVE BLOCK**

**INDICATIONS**

The suprascapular nerve (C5-6) branches from the superior trunk of the brachial plexus to supply the posterior
The suprascapular nerve and artery can usually be visualized using a coronal plane over the suprascapular fossa. Once contact is made, 10 mL of local anesthetic is injected suprascapular and spinoglenoid notches (Fig. 53.16). Directed toward the scapular spine. This approach, rather than posterior to anterior, avoids entry into the suprascapular fossa between the bicipital groove (between the biceps and triceps muscles) and lay directly superficial to the conjoint tendon (of the teres major and latissimus dorsi muscles). The musculocutaneous nerve (Musc. n.) typically lies either within the body of the coracobrachialis muscle or less commonly in between the fascial plane of the coracobrachialis and biceps muscles.

two thirds of the shoulder joint and the acromioclavicular joint. Blocking this nerve prolongs analgesia after shoulder arthroscopy performed under general anesthesia but adds no value to an interscalene block for open, anterior shoulder surgery. A suprascapular block with local anesthetic and steroid also provides prolonged relief of acute painful conditions and the chronic degenerative shoulder conditions commonly encountered in pain medicine practice. The block can also be used for diagnostic purposes.

TECHNIQUES
A suprascapular nerve block is accomplished by depositing local anesthetic near the suprascapular notch. Drawing a line along the scapular spine and bisecting it with a second line drawn parallel to the vertebral spine outlines the surface landmarks. The resultant upper outer quadrant is then entered with a needle traveling cephalad to caudad and face landmarks. The resultant upper outer quadrant is then entered with a needle traveling cephalad to caudad and face landmarks. The resultant upper outer quadrant is then entered with a needle traveling cephalad to caudad and face landmarks. The resultant upper outer quadrant is then entered with a needle traveling cephalad to caudad and face landmarks.

An ultrasound-guided approach involves placing the transducer in a coronal plane over the suprascapular fossa. The suprascapular nerve and artery can usually be visualized along the floor of the suprascapular fossa between the suprascapular and spinoglenoid notches (Fig. 53.16).

SELECTIVE NERVE BLOCKS AT THE TERMINAL BRANCHES
There are few indications for selective nerve blocks of the upper extremity because innervation of the forearm and hand is typified by extensive crossover of the cutaneous sensory distribution; therefore, single-nerve blockade is rarely adequate. Selective blocks at the elbow or wrist as a sole anesthetic are also problematic if prolonged use of a pneumatic tourniquet is required. One indication for a selective block is use of a median nerve block at the wrist for carpal tunnel release, although supplemental local anesthesia may still be required.

Ultrasound may be used to identify the distal peripheral nerves of the upper extremity, and ultrasound-guided blocks of these nerves in the forearm may be performed. The use of ultrasound-guided pulsed radiofrequency ablation of the median nerve has been reported for recurrent carpal tunnel syndrome following surgical intervention.

COMPLICATIONS OF UPPER EXTREMITY BLOCK

NERVE INJURY
Permanent nerve injury after an upper extremity block is extremely rare and probably occurs in 0 to 16 per 10,000 patients (95% confidence interval [CI]). Nerve dysfunction, particularly persistent paresthesia or numbness, is relatively common (up to 19%) immediately after surgery, but the vast majority of these symptoms resolve within 4 weeks. Warning signs that an injury may be particularly worrisome include complete absence of nerve function immediately after surgery (probably indicative of nerve transection or ischemia), motor deficit, worsening symptoms over time, or failure to show early signs of resolution. Particularly in these cases, early neurologic consultation is recommended to rule out reversible causes, establish bilateral baseline function, and coordinate further diagnostic workup and rehabilitation.

Whether brachial plexus blocks should be attempted in anesthetized or heavily sedated patients is controversial. Especially with interscalene blocks, a series of case reports clearly point to the risk for intramedullary injection with devastating consequences. As the approach moves away from the neck, the risk for spinal cord injury probably lessens, but the chance of unrecognized intraneural (specifically, infraneural) injection remains poorly quantified. Some peripheral nerve injuries have occurred in nonanesthetized patients without a preceding warning such as pain on injection or severe paresthesia, whereas other patients have noted these warnings and have still sustained injury. Yet another subset of patients has experienced pain on injection but no subsequent injury. Until our understanding of peripheral nerve injury and premonitory symptoms becomes clearer, the American Society of Regional Anesthesia (ASRA) recommends that patients be given every opportunity to recognize potential injury by not routinely placing brachial plexus blocks in anesthetized patients.

Clinicians must recognize that neither peripheral nerve stimulation nor ultrasound guidance consistently protects against nerve injury. Peripheral nerve stimulation is neither sensitive nor specific for detecting subepineurial needle placement. Indeed, with the supraclavicular approach, stimulation thresholds between 0.2 and 0.5 mA may indicate either extraneural or subepineurial needle placement. There is no evidence that UGRA reduces the incidence of neural injury, and there are reports of injury despite its use.
Whether a brachial plexus block is contraindicated in patients with preexisting nerve injury is unclear. Patients who underwent ulnar nerve transposition were no more likely to sustain a postoperative exacerbation or new symptoms regardless of whether they received general anesthesia or a brachial plexus block. In contrast to these reassuring data, postoperative dysfunction has developed in patients with preexisting nerve dysfunction, even of a subclinical nature.

**INTRAVASCULAR INJECTION**

Brachial plexus blocks have a relatively low risk for delayed local anesthetic systemic toxicity (LAST) when compared with epidural or intercostal blocks, but there are no reliable data on which to base the maximum recommended doses of local anesthetic. Furthermore, the risk for seizure secondary to intravascular injection is five times higher with peripheral nerve blocks than with epidural blocks. This risk is particularly relevant to brachial plexus regional anesthesia because of the proximity of the vertebral, carotid, and subclavian (via retrograde flow) arteries to direct injection during placement of an interscalene or supraclavicular block. Because upper extremity regional anesthesia typically uses volumes of local anesthetic that are capable of inducing severe systemic toxicity, it is recommended that practitioners be familiar with and have readily available the ASRA checklist for managing LAST.

**UNINTENDED DESTINATIONS OF LOCAL ANESTHETICS**

Because the neck contains so many vital structures, it is common for local anesthetics intended for the brachial plexus to affect other structures. Most serious is when local anesthetic is unintentionally placed near the neuraxis and causes epidural or spinal anesthesia during attempted interscalene anesthesia. The C6 foramen is only 23 mm from the skin in the average patient, so it is easy to conceive how excessively deep needle placement could result in this complication. Neuraxial injection of local anesthetic is manifested by the rapid (total spinal anesthesia) or delayed (massive epidural anesthesia) appearance of a bilateral upper and lower extremity block, which is often associated with hypotension, bradycardia, and apnea. This complication must be diagnosed and treated rapidly with airway control, volume
expansion, and early provision of exogenous epinephrine to counteract blockade of the cardioaccelerator fibers and absent vascular tone.\textsuperscript{10} An ultrasound-guided interscalene block and the modified lateral interscalene block use a more superficial approach to the brachial plexus. Though not proved in randomized trials, these approaches are theoretically less likely to result in neuraxial deposition of local anesthetic than the classic Winnie approach is.

Local anesthetics intended for the brachial plexus during blocks above the clavicle and infraclavicular blocks can also spread to the cervical sympathetic chain, where they cause Horner’s syndrome. Another unintended effect is anesthesia of the recurrent laryngeal nerve, which results in hoarseness or difficulty swallowing. Both these nuisance side effects resolve in unison with resolution of the anesthetic block.\textsuperscript{10}

**HEMIDIAPHRAGMATIC PARESIS**

Impairment of diaphragmatic function is common during above-the-clavicle approaches. Hemidiaphragmatic paresis (HDP) occurs in all patients who undergo an interscalene block via the traditional techniques, and about one in four of these patients will have a 25\% to 32\% reduction in spirometric measures of pulmonary function.\textsuperscript{129} Ultrasound-guided interscalene blocks that use low volumes of local anesthetic (5 to 10 mL) result in a reduced incidence and severity of HDP, but the side effect still occurs unpredictably.\textsuperscript{10,21,130,131} The incidence of HDP is less (95\% CI = 14\% to 86\%) in patients undergoing a supraclavicular block. Although healthy volunteers experienced no diminution in pulmonary function during the supraclavicular approach, this may not hold true for patients with underlying pulmonary disease.\textsuperscript{99} A low-volume supraclavicular block performed under ultrasound guidance reduces the incidence of HDP to almost 0.\textsuperscript{132} Nevertheless, it is recommended that any patient unable to withstand a 25\% or greater reduction in pulmonary function not be given an

---

**Figure 53.15** Suprascapular nerve block. A line is drawn along the scapular spine and then bisected by a second line parallel to the vertebral spine. The entry point is 2 to 3 cm into the upper outer quadrant. The needle is directed from the top to avoid entry deep into the suprascapular notch, which could pose a risk for pneumothorax. (Adapted from Rathmell JP, Neal JM, Viscomi CM. Regional Anesthesia. The Requisites in Anesthesiology. Philadelphia: Elsevier Mosby; 2004:69.)

**Figure 53.16** Ultrasound-guided suprascapular nerve block. A, The suprascapular nerve resides between the suprascapular notch and the spinoglenoid notch on the floor of the scapular fossa. The arrowhead indicates the suprascapular nerve and the arrow indicates the artery. Available at www.usra.ca.)
above-the-clavicle brachial plexus block, even when using ultrasound guidance. The incidence of HDP is lower with infraclavicular approaches and may be specific to the approach. For instance, in 26% of patients given a vertical infraclavicular block, reduced or paradoxical hemidiaphragmatic function developed along with an approximate 50% diminution in spirometric values. Conversely, no ventilatory dysfunction was observed with the more distal coracoid approach. HDP during continuous perineural infusion appears to lessen over time. In a study of patient-controlled perineural interscalene catheter analgesia with 0.2% ropivacaine, diaphragmatic function and spirometric values were no different from those observed in patients randomized to receive opioid patient-controlled analgesia.

PNEUMOTHORAX

The incidence of pneumothorax associated with a supraclavicular block has probably decreased with the advent of techniques such as the plumb bob and ultrasound-guided approaches, which avoid needle contact with the pleural dome. Nevertheless, there remains a small (<1%) but poorly defined risk for pneumothorax with the supraclavicular and inter-SCM approaches. Even though extremely rare, pneumothorax has been reported with the interscalene and coracoid infraclavicular approaches. There are reports of pneumothorax despite the use of ultrasound guidance. Clinicians should recognize that the symptoms of pneumothorax are typically delayed 6 to 12 hours after initial needle puncture and are more likely to consist of pleuritic chest pain than dyspnea.

PERIPHERAL NERVE BLOCKS FOR CHRONIC PAIN MANAGEMENT

Peripheral nerve blocks are usually performed for diagnostic, prognostic, and therapeutic reasons in chronic pain management. A block may help in confirming the etiology and pathway of the patient’s pain, for example, a suprascapular nerve block for relief of frozen shoulder. Prognostically, it may predict the efficacy of more definitive procedures, such as pulsed radiofrequency ablation of the nerve. Interestingly, the duration of pain relief may outlast the duration of nerve blockade by 50% or longer.

In a review of the published literature by Vlassakov and colleagues, single-injection peripheral nerve blocks with local anesthetic alone at certain locations resulted in pain relief durations of longer than 1 week. In fact, some patients experienced relief for 1 to 3 weeks, 7 to 13 months, and 2 to 4 years. In pain practice, a series of blocks are usually performed every 1 to 3 weeks. It is common for the pain physician to add steroid to the local anesthetic solution (4 mg dexamethasone or 40 mg methylprednisolone/triamcinolone per 30 mL local anesthetic) to reduce inflammation in the nerve. Topical application of steroid on a peripheral nerve has also been shown to suppress nociceptive impulses by blocking the motor and sensory fibers. The lasting effect of local anesthetic blocks has been attributed to “interruption of the vicious cycle of pain.” Another explanation is elimination of maintenance of central sensitization in neuropathic pain conditions (most neuralgias have a neuropathic pain component). It is difficult to prove these theories despite the frequency with which the pain physician sees these responses. Even if the relief lasts only for the duration of the block, such numbness facilitates other therapeutic modalities such as physical therapy in patients with complex regional pain syndrome or myofascial pain syndrome. Nerve blocks are therefore an important component of the multidisciplinary treatment of chronic pain.

SUMMARY

Upper extremity regional anesthesia is a valuable part of the anesthesiologist’s armamentarium, particularly since it provides superior analgesia and improved early outcome measures after ambulatory surgery. This chapter has described common techniques for achieving neural blockade at various approaches along the brachial plexus via a variety of traditional and ultrasound-guided techniques. It has also reviewed the basic anatomy of the brachial plexus and drug selection, plus the more common and serious complications of these useful blocks.

KEY POINTS

- Upper extremity regional anesthetic techniques can improve analgesia in the immediate postoperative period, reduce opioid-related side effects, improve patient satisfaction, and reduce unplanned hospital admissions. Single-injection brachial plexus blockade does not affect outcome measures beyond the first 24 hours.
- The functional anatomy of the upper extremity is variable. Relying on a single cutaneous distribution to plan which nerve requires blockade or to assess the adequacy of anesthesia is unreliable.
- The primary determinant in selecting a local anesthetic for an upper extremity block is anesthetic or analgesic duration. Epinephrine, clonidine, dexamethasone, and buprenorphine extend the duration of intermediate-acting local anesthetics, but not long-acting ones.
- As one proceeds distally along the brachial plexus when using traditional techniques, multiple-injection techniques improve block success. Ultrasound-guided blocks tend to involve multiple injections. There is no evidence that any regional anesthetic technique—paresthesia, peripheral nerve stimulation, perivascular, ultrasone, or transarterial—is inherently more effective or safer than another.
- Shoulder surgery is best accomplished with an interscalene block; arm or hand surgery is amenable to an infraclavicular block; and arm surgery, including the elbow and areas distal, is a classic indication for an axillary block. A supraclavicular block is most likely to anesthetize the entire upper extremity, although it will occasionally not anesthetize the supraclavicular or ulnar nerves.
KEY POINTS—cont’d

• Accessory blocks are valuable for surgeries that involve a cutaneous sensory distribution outside the brachial plexus. A supraclavicular (superficial cervical plexus) nerve block anesthetizes the cape distribution around the shoulder, and a suprascapular block adds value to general anesthesia for shoulder arthroscopy or for pain management indications.

• Continuous perineural catheter techniques provide analgesia superior to that achieved with placebo or opioid techniques. Data are as yet insufficient to show meaningful improvement in other outcomes such as rehabilitation or earlier return to work.

• Permanent anesthesia-related nerve injury after a brachial plexus block is distinctly rare. Particularly when using the interscalene approach, it is recommended that placing these blocks in anesthetized or heavily sedated patients be avoided.

• Local anesthetic systemic toxicity is relatively common with brachial plexus regional anesthesia, at least in part because of unintentional injection into arteries that directly supply the brain.

• Anesthesiologists must be vigilant for the rare complication of neuraxial anesthesia during the course of an interscalene brachial plexus block. Signs and symptoms of high spinal or massive epidural anesthesia require prompt airway control and aggressive treatment of hypotension and bradycardia with potent α-adrenergic agonists such as epinephrine.

• Above-the-clavicle blocks are not recommended in patients who are unable to withstand a 25% to 30% reduction in pulmonary function.

• Selected upper extremity blocks have a diagnostic, therapeutic, and prognostic role in chronic pain management.

INTRODUCTION
Lower extremity blocks (LEBs) are common techniques for surgical anesthesia and postoperative analgesia. They are being used more frequently in the setting of outpatient surgery worldwide because of their favorable recovery and side effect profile when compared with general and neuraxial anesthesia.1-3 LEBs may decrease the incidence of postoperative pain syndromes, including chronic postamputation phantom limb pain.4,5 In addition to surgical applications, LEBs have also been reported to be beneficial in patients with complex regional pain syndrome, chronic cancer pain, peripheral vascular diseases (ischemia, Reynaud’s disease, peripheral embolism), intractable phantom limb pain, and spasticity.6-9 Continuous LEBs with perineural catheters can also provide analgesia for an extended period.6,10 Moreover, neurolysis of lower extremity peripheral nerves can also be performed with techniques analogous to peripheral nerve blockade.11,12

Ultrasound-guided techniques are becoming more prevalent methods of performing LEBs in many centers. Several reports have suggested that ultrasound guidance results in more precise needle and catheter placement during LEBs than do blocks performed with nerve stimulator or landmark techniques only or with both.13

This chapter provides an overview of the relevant anatomy of the lower extremity, technical aspects of performing LEBs, and common indications for their use in clinical practice.

ANATOMY
Innervation of the lower extremity is derived from both the lumbar plexus and the sacral plexus, sometimes referred as the lumbosacral plexus.

LUMBAR PLEXUS
The lumbar plexus is made up of the L1 through L5 spinal nerve roots. As the L2, L3, and L4 roots of the lumbar plexus depart from their spinal nerves and emerge from the intervertebral foramen, they enter the posterior third of the psoas muscle.14 Once in the muscle, these roots then become organized into anterior and posterior divisions. The divisions reunite to form the iliohypogastric, ilioinguinal, genitofemoral, lateral femoral cutaneous, femoral, and obturator nerves.15 (Fig. 54.1). The most significant nerves in the lower extremity are the femoral, lateral femoral cutaneous, and obturator nerves.

The femoral nerve is formed by the posterior divisions of L2-4. The nerve descends from the plexus lateral to the psoas muscle. The femoral nerve innervates the rectus femoris, vastus medialis, vastus intermedius, and vastus lateralis muscles. It also provides cutaneous sensory innervation to much of the anterior and medial aspects of the thigh, as well as the medial part of the leg distal to the knee (Fig. 54.2).

The lateral femoral cutaneous nerve is formed from the L2 and L3 nerve roots and, as its name indicates, is a cutaneous, sensory nerve. It provides sensation to the lateral aspect of the thigh (see Fig. 54.2).

The obturator nerve (L2-4) provides sensory innervation to a variable portion of the leg proximal to the knee, as well as motor innervation to the adductor muscles (see Fig. 54.2).

The iliohypogastric and ilioinguinal nerves are primarily sensory nerves that arise from L1 and supply innervation to the skin of the suprapubic and inguinal regions.

The genitofemoral nerve arises from the L1 and L2 roots and supplies motor innervation to the cremasteric muscle and additional sensory innervation to the inguinal area.

SACRAL PLEXUS
The sacral plexus is formed from the L4-S3 nerve roots (Fig. 54.3). It is shaped like a triangle pointing toward the sciatic notch, with its base spanning across the anterior sacral foramina. The roots of the sacral plexus lie on the anterior surface of the lateral sacrum and form the sciatic nerve on the ventral surface of the piriformis muscle.16 The sacral plexus gives rise to one major nerve and six collateral nerve branches. The sciatic nerve exits the pelvis through the greater sciatic notch and then descends between the greater trochanter of the femur and the ischial tuberosity. It runs along the posterior part of the thigh to the lower third of the femur, where it diverges into two divisions: the tibial and common peroneal. The sciatic nerve provides motor and sensory innervation to the hamstring muscles and the entire leg below the knee with the exception of the cutaneous region medially, which is innervated by the saphenous nerve (see Fig. 54.2). The posterior cutaneous nerve of the thigh exits the pelvis with the sciatic nerve but then diverges posteriorly to become a cutaneous nerve that is the major sensory nerve from the sacral plexus within the thigh.17

LUMBAR PLEXUS BLOCK

CLINICAL APPLICATIONS

A lumbar plexus block (LPB) can provide anesthesia or analgesia to the anterolateral and medial aspects of the thigh, the knee, and the medial portion of the leg below the knee. Common indications include anesthesia and analgesia following total hip arthroplasty, total knee arthroplasty, and anterior cruciate ligament reconstruction, as well as for treatment of chronic hip pain.18-23

NERVE STIMULATOR– AND SURFACE-BASED TECHNIQUES

An LPB is a deep block and the needle traverses several layers of structures, including (from posterior to anterior) the posterior lumbar fascia, paraspinal muscle, anterior lumbar fascia, quadratus lumborum muscle, and psoas muscle.17

Nerve stimulation is probably the most commonly used method to localize the lumbar plexus during blockade. To perform the block, the patient is placed in the lateral decubitus position with the operative side up (Fig. 54.4). The foot on the side to be blocked is positioned over the dependent leg so that the motor response of the quadriceps muscle can easily be seen. The two surface anatomic landmarks for determining the insertion point for the needle are the iliac crest and the midline spinous processes.

The top of the iliac crest correlates with the L3-4 interspace in most patients.24 The point 3 to 3.5 cm lateral to the intersection of the iliac crest and the midline spinous processes marks the needle insertion site (see Fig. 54.4). After setting the nerve stimulator to an initial current of 1.5 mA (0.1 msec, 2 Hz) and skin preparation, a 4-inch insulated needle is advanced in a posterior-to-anterior manner. As the needle is advanced, local contractions of the paravertebral muscles are commonly elicited and indicate that placement of the needle is too shallow. The needle is advanced further until the transverse process is encountered. Contact with the transverse process is not routinely sought, but when present, it provides a consistent landmark. After contact with the transverse process, the needle is redirected cephalad or caudad and advanced approximately 2 cm beyond the transverse process. Starting from the level of the skin, the lumbar plexus is located between 6.1 and 10.1 cm in men and 5.7 and 9.3 cm in women.25

Once a quadriceps muscle–evoked response is obtained between 0.5 and 1.0 mA, 20 to 35 mL of local anesthetic is injected slowly, with frequent aspiration between injection aliquots. Unintentional deep placement of the needle carries a risk for injury to internal organs, such as renal hematoma.26 Epidural spread of local anesthetic has been reported to occur in as many as 16% to 27% of blocks.17 Limiting the force of injection decreases the risk for epidural spread.27

ULTRASOUND-GUIDED TECHNIQUES

Because of the deep location of the plexus, ultrasound-guided LPBs have not become as rapidly adopted as ultrasound-guided blocks of more peripheral sites. To obtain adequate views, a low-frequency (4 to 8 MHz) curvilinear probe is used. Perhaps the most common approach is an ultrasound-assisted technique in which the scanning is performed in the parasagittal axis. After preparation of the skin and transducer, the transverse processes are identified first on the parasagittal axis (Fig. 54.5). Starting from the sacrum, the L5 transverse process is identified. Continuing the scan cephalad will allow visualization of the other transverse processes in ascending order.28 Once the transverse process of L3 is identified, the needle is inserted until contact with the transverse process and then “walked off” until contractions of the quadriceps muscle are elicited. The rest...
of the injection procedure is similar to the nerve stimulator–
guided technique.

More recently, a transverse oblique technique has been
suggested in which the stimulating needle is directed into
the posteromedial aspect of the psoas muscle.\textsuperscript{29} With this
technique the roots of the lumbar plexus may be seen exiting
through the intervertebral foramens (Fig. 54.6).\textsuperscript{30-32} The
needle is advanced in plane, and its position is routinely
monitored by nerve stimulation.

**LATERAL FEMORAL CUTANEOUS NERVE BLOCK**

**CLINICAL APPLICATIONS**

Blockade of lateral femoral cutaneous nerve (LFCN) is indi-
cated for anesthesia or analgesia of the anterolateral aspect
of the thigh, as well as for the diagnosis and treatment of
meralgia paresthetica.\textsuperscript{45-47}

**ANATOMY**

The LFCN is typically blocked 1 to 2 cm medial and infe-
rior to the anterior superior iliac spine (ASIS). At this location
the nerve lies beneath the fascia iliaca, just lateral to
the sartorius muscle and medial to the tensor fasciae latae
muscle (TFLM).

**NERVE STIMULATOR– AND SURFACE-BASED
TECHNIQUES**

Surface-based techniques yield variable success rates
because of the anatomic variability of the LFCN.\textsuperscript{48} Electric-

cal nerve stimulation can be used to elicit paresthesia in the
sensory distribution of the nerve to increase the chance of
success. With either technique, the needle is inserted 1 to
2 cm medial and inferior to the ASIS and advanced until loss
of resistance is felt as the needle penetrates the fascia iliaca.\textsuperscript{49}

When the technique is aided by nerve stimulation, current
intensity is set to 1.0 to 2.0 mA with a pulse duration of
1.0 msec for greater sensitivity.

**ULTRASOUND-GUIDED TECHNIQUE**

After preparation of the skin and transducer, a high-
frequency linear probe is placed inferior to the ASIS, parallel
to the inguinal ligament, to identify the sartorius and TFLM
first.\textsuperscript{50} The LFCN is visualized as a small oval hypoechoic
structure beneath the fascia iliaca, just lateral to the sarto-
rious muscle, and medial to the TFLM (Fig. 54.7). A 2-inch,
22-gauge needle is used to approach the nerve, typically in
an in-plane technique, and 5 to 10 mL of the local anesthetic
of choice is injected.
PART 6 — NERVE BLOCK TECHNIQUES

COMPLICATIONS
Because no large vascular structures or other organs are nearby, an LFCN block is associated with a low risk for complications.

FEMORAL NERVE BLOCK

CLINICAL APPLICATIONS
A femoral block is one of the most commonly used peripheral nerve block techniques in clinical practice. It is often used for anesthesia or postoperative analgesia (or both) in patients undergoing surgery on the anterior aspect of the thigh and the knee, quadriceps tendon repair, and femoral surgery. A continuous femoral nerve block has become a mainstay analgesic technique in patients after knee arthroplasty. It has also been reported to be used for palliative care, and in such cases an indwelling catheter can be left in situ for up to several weeks.

ANATOMY
The femoral nerve arises from the L2-4 roots of the lumbar plexus. The nerve travels through the psoas muscle and ends on the anterior surface of the iliopsoas as it passes under the inguinal ligament. At this level the nerve lies beneath the fascia iliaca and lateral to the femoral artery (Fig. 54.8). A femoral nerve block provides sensory anesthesia to the anterior aspect of the thigh, the knee, and the medial portion of the calf and ankle.

TECHNIQUE
Nerve Stimulator- and Surface-Based Techniques
After skin preparation, the needle is introduced in a sagittal, slightly cephalad plane immediately lateral to the femoral artery at the femoral crease to obtain a femoral nerve response (quadriceps twitch). If a sartorius muscle twitch is obtained first (twitch of the medial aspect of the thigh with no patellar movement), the needle is advanced deeper and more lateral to ensure that the needle is positioned closer to the main trunk of the femoral nerve. A recent report suggests that injection of local anesthetic after obtaining a sartorius motor response results in a successful femoral nerve block. However, a sartorius response can also take place when a sartorius branch is stimulated remotely from the main trunk of the femoral nerve, particularly in patients with less than ideal anatomy (e.g., obese). Once a quadriceps muscle twitch at a current of 0.2 to 0.5 mA is elicited, 10 to 15 mL of local anesthetic is injected to accomplish the block.

Ultrasound-Guided Techniques
A high-frequency linear transducer (8 to 14 MHz) is used in most patients. After preparation of the skin and transducer,
the transducer is placed parallel to the inguinal crease to identify the femoral artery and vein. The nerve is imaged just lateral to the femoral artery on the surface of the iliacus muscle, underneath iliacus fascia (Fig. 54.9). A 4-inch needle block needle can be inserted in an in-plane or out-of-plane fashion, the former being favored by many clinicians. The needle is advanced underneath the iliacus fascia to allow spread of the local anesthetic around the femoral nerve. When adequate needle-nerve imaging is present, it is not necessary to elicit a motor response. However, when a motor response is elicited, the current is reduced to ensure that the response is not present below 0.2 mA because a motor response to a very low current intensity may indicate intraneural placement of the needle. Injection underneath the fascia iliaca (perineural) should not result in significant resistance to the injection. A monitoring algorithm combining nerve stimulation with ultrasound guidance for a femoral nerve block, as well as most other peripheral major nerve blocks, is outlined in Figure 54.10.

**CONTINUOUS FEMORAL NERVE BLOCK**

A continuous femoral nerve block is similar to the single-shot technique except that a larger-gauge needle is used to allow insertion of the catheter. Once the tip of the needle is deemed to be in the correct position, the catheter is inserted through the needle approximately 3 cm beyond the tip. After an initial bolus of local anesthetic, a continuous infusion is started at a rate of 5 mL/hr, typically with a patient-controlled bolus of 5 mL/hr. Ultrasound imaging can be used to confirm proper spread of local anesthetic underneath the fascia iliaca in the vicinity of the femoral nerve.

A continuous femoral nerve block is used to provide postoperative analgesia after knee surgery, and catheters may be left in situ for several days. Perineural infusion for up to several weeks has also been reported to be useful in palliative care.

**THREE-IN-ONE BLOCK**

A 3-in-1 block refers to a modification of the standard femoral block in which a larger volume of local anesthetic is
injected, with pressure being held distal to the needle injection site. Although this technique is still used in clinical practice, several studies have failed to document reliable spread of the local anesthetic.56 Usually, the obturator nerve is not blocked with this technique. Technically, a 3-in-1 block is essentially the same as a large-volume femoral block or fascia iliaca block.

COMPLICATIONS

Complications of a femoral nerve block include injury to the nerve itself, vascular injury, and loss of muscle strength. The incidence of transient adverse neurologic symptoms associated with a continuous block is 0.4% to 0.5% with femoral catheters.51,57 The rate of vascular puncture during placement of a femoral nerve block has been reported to be as high as 5.6%, but this rate may be decreased with the use of ultrasound.58 Femoral neuropathy secondary to compression of the femoral nerve by a retroperitoneal hematoma has also been documented.57 Quadriiceps weakness in patients with femoral nerve blocks may lead to falls, which can cause significant morbidity. The frequency of falls in these patients may have been underreported.59,60

The incidence of bacterial colonization associated with continuous femoral nerve blocks was evaluated in 208 patients.58 Fifty-seven percent were found to have positive bacterial colonization of the catheter 48 hours postoperatively. Three patients had transient symptoms of bacteremia that resolved with removal of the catheter, but there was no report of long-term infectious complications.61 Two case reports of a psoas abscess requiring drainage and intravenous antibiotic therapy after a continuous femoral nerve block have been described,62,63 but there are no case reports of infection after a femoral nerve block performed with a single injection.

FASCIA ILIACA BLOCK

A fascia iliaca block is an alternative approach to a femoral nerve block in which local anesthetic is injected underneath the fascia iliaca at a distance from the femoral nerve. The rationale is that because the femoral nerve and LFCN both lie deep to the iliacus fascia, a sufficient volume of local anesthetic deposited beneath the fascia iliaca will spread underneath the fascia and reach these nerves. Ultrasound has been shown to improve the success rate of a fascia iliaca block over the landmark-only approach.64 Functionally, the technique is similar to a femoral block except that the large volume of local anesthetic used has a greater chance of also blocking the LFCN in addition to the femoral nerve.

SURFACE ANATOMY–BASED TECHNIQUE

The traditional landmark-based technique involves placement of the needle at the lateral third of the distance from the ASIS and the pubic tubercle by using a “double-pop” technique as the needle passes through the fascia lata and fascia iliaca. Block success can be sporadic because false “pops” can occur.

ULTRASOUND-GUIDED TECHNIQUE

With the patient in the supine position, a high-frequency linear probe is placed on the femoral crease and the fascia iliaca is identified. The probe is then moved to the medial border of the sartorius muscle (Fig. 54.11). At this position a 4-inch 22-gauge needle is inserted in an in-plane approach, the fascia is pierced, and the local anesthetic is placed below the fascia iliaca, above the iliopsoas muscle (see Fig. 54.11). If infiltration is observed within the muscle, the needle should be withdrawn slightly. Proper injection will result in separation of the fascia iliaca from the muscle in a medial-to-lateral direction.

SAPHENOUS NERVE BLOCK

Techniques for saphenous nerve blockade include the perifemoral, trans-sartorial, below-the-knee field block, and above-the-medial-malleolus approaches.65 The perifemoral approach may be associated with weakness of the quadriceps muscles. The trans-sartorial approach may be most effective in blocking the saphenous nerve. However, use of the landmark-based technique for the trans-sartorial approach may result in inconsistent results because deposition of local anesthetic into the trans-sartorial canal cannot be monitored with ultrasound.

ULTRASOUND-GUIDED SAPHENOUS NERVE BLOCK

Several different approaches to ultrasound-guided saphenous nerve block have been described.66 Most techniques
involve placement of the transducer proximal to the knee joint. Typically, the sartorius muscle is visualized in relation to the vastus medialis and gracilis muscles, and local anesthetic is injected anterolateral to the femoral artery. Five to 10 mL of local anesthetic is injected. An advantage of the subsartorial technique is that blockade of the motor branches for the entire quadriceps muscle may be avoided.

**SCIATIC NERVE BLOCK**

**CLINICAL APPLICATIONS**

The primary indications for sciatic nerve blockade are for foot and ankle surgery. A sciatic nerve block can also be combined with a femoral nerve block to provide analgesia after knee surgery, amputation, or tibial osteotomy. Along with a lumbar plexus block or a femoral block, a sciatic block can also provide anesthesia of the entire lower extremity.67,68

A continuous sciatic nerve block has been used for analgesia and sympatholysis in patients with severe ischemia-induced pain.69 A single or continuous femoral block may also be used with a sciatic nerve block for chronic pain and treatment of pressure ulcers, which need multiple surgeries and have a high recurrence rate.70,71 Sciatic nerve injections with alcohol neuroablation were helpful in the treatment of a patient with knee and hip flexor spasticity and related right trochanteric and ischial pressure ulcers.70

If blockade of the posterior femoral cutaneous nerve of the thigh is desired (such as for surgical anesthesia for above-knee amputation), a block of the sciatic nerve at the subgluteal level or above is indicated. However, the frequency of posterior femoral cutaneous nerve block with different approaches to blockade of the sciatic nerve has not been well established by clinical trials.17

**ANATOMY**

The sciatic nerve is the largest nerve of the sacral plexus, and it innervates almost the entire leg below the knee. The sciatic nerve passes from the pelvis through the sacrosacral foramen between the ischial tuberosity and greater trochanter of the femur. It lies anterior to the gluteus maximus muscle and runs with the sciatic artery. It courses down the posterior aspect of the thigh to the popliteal fossa, where it diverges into the tibial nerve (TN) and the common peroneal nerve (CPN) (Fig. 54.12). Sensation to the posterior aspect of the thigh is provided by the posterior femoral cutaneous nerve, which also originates from the sacral plexus, follows a similar course as the sciatic nerve in the thigh, but is not formally part of the sciatic nerve (see Fig. 54.2).

**TECHNIQUE**

There are several approaches to block the sciatic nerve. The level at which it should be blocked depends on the surgical site.

**Nerve Stimulator- and Surface-Based Techniques**

**Transgluteal Approach.** This approach is based on the geometric relationship of the posterior superior iliac spine (PSIS) and greater trochanter to the sciatic nerve with the patient in a modified Sims position. Winnie modified the original description by adding another landmark, the sacral hiatus, to account more precisely for the variability in body habitus.72,73

A line is drawn from the PSIS to the greater trochanter. A second line is drawn perpendicular to the midpoint of the first line drawn and extended 4 cm. This point is the site of needle insertion (Fig. 54.13). After skin preparation, the needle is introduced perpendicular to all planes until the appropriate motor response below the knee (dorsiflexion or plantar flexion) is elicited. Once a twitch is obtained, 10 to 20 mL of local anesthetic is injected to accomplish the blockade. Regardless of the technique, the motor response and local anesthetic dose are similar.

**Anterior Approach.** A line is drawn over the femoral crease. The femoral artery is palpated, and a second line is drawn perpendicular to the first line originating at the femoral pulse. The line is extended 2 to 4 cm from the femoral crease. The greater trochanter is palpated and a line is extended from its tuberosity medially across the anterior surface of the thigh, parallel to the inguinal ligament. The point of intersection of this line and the perpendicular line from the inguinal crease marks the entry site for the needle.74

After skin preparation, a 6-inch needle is inserted perpendicular to the skin. Once bone is contacted, the needle is withdrawn and redirected medially to pass 5 cm beyond the femur, where it should be resting slightly posterior and medial to the femur to elicit a motor response in the calf or foot. Slight internal rotation of the leg can greatly facilitate

---

**Figure 54.12** Schematic representation of the branches and course of the sciatic nerve. (From Hadzic A, ed. Hadzic’s Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia. 2nd ed. New York: McGraw-Hill: 2012. Used by permission.)
finding the sciatic nerve because it swings the lesser trochanter away from the path of the needle.75

Ultrasound-Guided Techniques

Depending on the level at which the sciatic block is performed, either a low-frequency transducer (transgluteal approach) or a high-frequency transducer (subgluteal approach) can be used. We limit description in this section to the subgluteal technique because it is probably the most common method. However, once the reader is familiarized with the ultrasound anatomy of the sciatic nerve at the subgluteal location, the block can be accomplished at any desired level.

Subgluteal Approach

The patient is placed in a modified Sims position and the ischial bone is located. The sciatic nerve is lateral to the ischial bone and medial to the greater trochanter. It lies anterior to the gluteus maximus muscle (Fig. 54.14A).

A 5-MHz low-frequency curvilinear probe is used. The transducer is placed in a transverse plane. The sciatic nerve is seen as a hyperechoic structure between the greater trochanter and ischial tuberosity, laterally and medially, respectively (Fig. 54.14B). In addition, it also lies in the plane with the fascia of the surrounding muscles; this appears as a hyperechoic line extending from the nerve in the same plane. A 4-inch nerve-stimulating needle is used in either an in-plane or out-of-plane approach. If a combined nerve stimulator– and ultrasound-guided technique is used, the appropriate evoked motor response should be observed. Once satisfactory ultrasound images and nerve stimulation are obtained, 20 to 30 mL of local anesthetic can be injected.

POPLITEAL BLOCK

Popliteal approaches to a sciatic nerve block are performed from the lateral or posterior aspect of the leg. The lateral approach offers the benefit of maintaining the patient in the supine position, and the posterior approach offers the benefit of easily identifiable landmarks and ease of performance. The level in the thigh at which the sciatic nerve branches into the TN and CPN varies greatly; to block both components, a more proximal needle insertion site should be chosen. Alternatively, an injection can be made between the TN and the CPN in the common epineurial sheath. With an ultrasound-guided technique, the block can be performed in either position by using the same end point— injection of local anesthetic within the epineurial sheath to encircle the sciatic nerve and its two divisions.

TECHNIQUE

Nerve Stimulator– and Surface-Based Techniques

Lateral Approach. The landmarks for the lateral approach to a popliteal block are 7 cm above the popliteal fossa crease, the posterolateral border of the vastus lateralis muscle, and the superior lateral border of the biceps femoris muscle (Fig. 54.15). After skin preparation, the needle insertion site is 7 cm cephalad to the popliteal fossa crease, between
the two muscles. The needle is inserted perpendicular to the skin and advanced until it touches the femur. The depth is marked and the needle is withdrawn to the skin and advanced at a 30-degree angle posterior to the angle that produced contact with the femur initially. The needle is advanced 2 cm past the skin-femoral distance to reach the sciatic nerve. A double-injection technique with a slightly caudal needle orientation that requires stimulation of both the TN and CPN components of the sciatic nerve has also been described.

**Posterior Approach.** Originally, the needle insertion site for a sciatic nerve block was described to be at a level 5 cm above the popliteal fossa (classic approach). However, the sciatic nerve diverges into the CPN and TN more proximally in the thigh (7 to 12 cm). The tendons of the biceps femoris (laterally) and the semitendinosus and semimembranosus muscles (medially) provide consistent landmarks for identifying the needle insertion site.

Once the popliteal crease and the tendons of the hamstring muscles are identified and after skin preparation, the needle insertion site is labeled 7 cm proximal to the popliteal crease at the midpoint between the two tendons. Twitches of the foot or toes should be visible with a current of between 0.2 and 0.5 mA, and 20 to 30 mL of local anesthetic is injected incrementally. Inversion is associated with the highest success rate since this evoked motor response implies stimulation of both the TN and CPN.

**Ultrasound-Guided Techniques**

A high-frequency linear transducer (8 to 12 MHz) is used for most patients. The transducer should be placed at the level of the popliteal crease and the popliteal artery located at this level. The sciatic nerve can then be located as a hypeerechoic round or oval structure lateral and superficial to the artery. Frequently, the TN is identified first. The TN is traced to where it joins the CPN. The sciatic nerve is reimaged both distally to observe its divergence into the CPN and TN components and proximally to see the nerves form a single sciatic nerve. This is to confirm that what is seen is indeed the sciatic nerve rather than muscles or their tendons. Once adequate views are observed, the nerve should be blocked before or at its division. The nerve can be approached in either an in-plane or out-of-plane technique (Fig. 54.17). The injection is made between the TN and CPN.

**COMPLICATIONS**

The incidence of transient adverse neurologic symptoms associated with a continuous block is 0% to 1.0% for sciatic catheters. Persistent paresthesia after use of a popliteal sciatic catheter and pressure ulcers have been described in some patients receiving peripheral nerve blocks because of lack of sensation in the foot. The risk for pressure ulcers can be decreased by padding the pressure points and improved teaching of the nursing staff caring for these patients.

Footdrop is a complication of total knee surgery and is usually surgically induced. To avoid confusion with regard to its cause, a selective TN block instead of a sciatic nerve block has been recommended. Such individual block of the TN, in conjunction with a femoral nerve block, has been shown to be as effective as a sciatic nerve block at the popliteal fossa (and femoral nerve block) in terms of postoperative pain control. Preservation of peroneal nerve integrity (i.e., no footdrop after the nerve block and before surgery) allows easy determination of the cause of the footdrop.
ANKLE BLOCK

All terminal nerves to the foot are branches of the sciatic nerve (deep peroneal, superficial peroneal, posterior tibial, sural) except the saphenous nerve, a branch of the femoral nerve. Because of variations in the distribution of sensory innervation provided by each nerve, some have recommended blocking all five nerves for any procedure on the foot. An ankle block is typically used for surgery on the distal end of the foot. For more proximal or extensive surgery involving the calcaneus or ankle joint (or both), a popliteal block may result in a longer duration of analgesia and better patient satisfaction. These are all important considerations when deciding between ankle and popliteal blocks.

CLINICAL APPLICATIONS

An ankle block is useful for a wide variety of procedures on the feet and toes. Some examples of common procedures include midfoot and toe amputations, toe deformities, forefoot reconstruction, arthroplasty, metatarsal osteotomy, bunionectomy, hallux valgus, neuromas, cysts, tumors, fractures, soft tissue injury, gouty arthritis, and incision, drainage, and débridement procedures.

TECHNIQUE

Surface-Based Techniques

Deep Peroneal Nerve. The needle insertion site is immediately lateral to the dorsalis pedis artery, lateral to the tendon of the extensor hallucis longus muscle. After skin preparation the needle is advanced through the skin until bone is contacted. The needle is then withdrawn back 1 to 2 mm, and 2 to 3 mL of local anesthetic is injected. A fan technique is then used in which the needle is redirected 30 degrees medially and laterally, and additional injections of 2 to 3 mL of local anesthetic are made in both directions (Fig. 54.18).

Posterior Tibial Nerve. The TN is anesthetized by injecting local anesthetic just behind the medial malleolus, followed by a fan technique similar to that described for the deep peroneal nerve (Fig. 54.19).

Superficial Peroneal, Sural, and Saphenous Nerves. The superficial peroneal and sural nerves are superficial cutaneous extensions of the sciatic nerve, and the saphenous nerve is a superficial cutaneous extension of the femoral nerve. Blockade of all three nerves is accomplished by using a simple circumferential injection of local anesthetic subcutaneously at the level of the medial and lateral malleoli (Fig. 54.20).

Ultrasound-Guided Techniques

Ultrasound guidance can be used to perform the two deep blocks of the ankle, the posterior tibial and deep peroneal...
nerves. To avoid compressing the artery, the lighter ultrasound probe should be used.

**Posterior Tibial Nerve.** A high-frequency transducer is placed in a transverse view, just above the medial malleolus. At this position the pulsatile posterior tibial artery can be observed, and the TN is the hyperechoic oval structure just posterior to the artery (Fig. 54.21). The nerve can be approached in an in-plane or out-of-plane technique.\(^{95,96}\)

**Deep Peroneal Nerve.** The transducer is positioned on the dorsum of the foot at the intermalleolar line in a transverse view. The dorsalis pedis artery should be seen at this level. The nerve can be viewed as a hypoechoic structure just lateral to the dorsalis pedis artery.\(^{97}\) Two to 3 mL of local anesthetic can be injected on either side of the nerve. If the nerve cannot be viewed, 2 to 3 mL of local anesthetic can be injected on either side of the artery (Fig. 54.22).

**CONCLUSION**

LEBs are safe, reliable methods of anesthesia and analgesia and good alternatives for patients who may not tolerate general anesthesia or large doses of opioids. LEBs can also be very useful in austere environments.\(^ {98}\) The introduction of ultrasound guidance has allowed more widespread use of LEBs in the modern practice of anesthesia and pain medicine.

Truncal Blocks

Similar to peripheral nerve blocks of the upper or lower limb, truncal blocks provide excellent postoperative pain relief, avoid the risk for major complications associated with central nerve blockade such as epidural hematoma or abscess, and can be used as a sole anesthetic technique for some types of surgery. However, their use in daily practice has remained limited until recently. Because of the many advantages that they offer, truncal blocks should have a place in the armamentarium of every anesthesiologist involved in the management of postoperative analgesia, particularly in the outpatient setting. In this chapter, the following truncal blocks are discussed: paravertebral, intercostal, ilioinguinal, iliohypogastric, genitofemoral, transverse abdominal plane, and rectus sheath blocks.

**PARAVERTEBRAL NERVE BLOCKADE**

The renewed interest in paravertebral nerve blockade is related to many factors: the involvement of anesthesiologists in postoperative pain control, the development of ambulatory surgery, and the need to apply simpler and more reliable techniques to reduce postoperative stay in the intensive care unit. Paravertebral blockade consists of injecting local anesthetic close to the vertebra at the level where the spinal nerves exit the intervertebral foramina. Such injection induces an ipsilateral somatic and sympathetic blockade that extends, most of the time, longitudinally above and below the injected vertebral level. It is indicated for acute as well as unilateral chronic pain syndromes. Such blockade is associated with no major cardiovascular or respiratory effects.

**ANATOMY**

The paravertebral space is triangular shaped. It is limited by the superior costotransverse ligament posteriorly, by the parietal pleura anterolaterally, and by the head and neck of the adjacent ribs superiorly and inferiorly. It is in continuity with the epidural space through the intervertebral foramina, with the intercostal space, and with the contralateral paravertebral space anteriorly. It contains the dorsal and ventral rami and the sympathetic chain. Hence, injection of local anesthetic into the area results in unilateral sensory, motor, and sympathetic blockade (Fig. 55.1).

In the paravertebral space, the endothoracic fascia is firmly applied to the ribs and fuses medially on the vertebral body. It thus divides the paravertebral space into two compartments: the extrapleural space anteriorly and the subendothoracic space posteriorly. Naja and coworkers claim that longitudinal spread of local anesthetic is better when the injection is performed ventral to the endothoracic fascia whereas a dorsal injection results in localized spread. However, another author has questioned the significance of the endothoracic fascia.

Whether local anesthetic injected into the low paravertebral thoracic segments spreads to the lumbar levels remains controversial. Some authors question the anatomic barrier created by the psoas muscle. Others stress that local anesthetic can spread through the posterior insertion of the diaphragm when the solution is injected deeper to the endothoracic fascia or along the lateral border of the psoas muscle.

**TECHNIQUE**

As for any regional technique, standard monitoring includes electrocardiography, pulse oximetry, and noninvasive blood pressure monitoring.

**POSITIONING**

The sitting position is usually preferred since it facilitates palpation of the landmarks. The lateral decubitus position is an alternative.

**APPROACHES**

Several approaches have been suggested for locating the paravertebral space.

**Blind Approach**

Once the transverse process is contacted (usually at a maximum distance of 4 to 5 cm from the skin), the needle is withdrawn to subcutaneous tissue, reoriented caudally (but sometimes cephalad when caudal insertion is impossible because of contact with bone), and advanced 1 to 1.5 cm deeper to the transverse process.

**Loss-of-Resistance Approach**

Loss of resistance (a syringe filled with saline, air, or both is connected to the needle) is felt once the paravertebral space is entered. This approach may be associated with the blind approach.

**Nerve Stimulator Approach**

Clinical studies have shown that use of a peripheral nerve stimulator may improve the position of the needle with respect to the nerve. Effective intravenous sedation and local anesthetic infiltration of the puncture sites are mandatory. Indeed, needle insertion through the different muscular structures and bone contact are painful.

**Single Injection Technique.** The needle entry site is located 2.5 to 3 cm lateral to the cephalad border of each spinous

---

745
process ipsilateral to the side to be operated on (Fig. 55.2). The needle, attached via extension tubing to a syringe, is advanced anteriorly in the parasagittal plane until it contacts the transverse process. It is then withdrawn and reoriented caudally so that it can be walked off the caudad edge of the transverse process. The needle is then advanced anteriorly approximately 1 to 1.5 cm deeper to the transverse process. Note that Naja and colleagues have shown that the distance from the skin to the paravertebral space is greater at the upper and lower thoracic levels than at the midthoracic levels (T4-8). Their median needle insertion depth was 55 mm. They also determined that body mass index influences the depth at the upper and lower thoracic levels but not at the midthoracic ones. After negative aspiration, 4 to 5 mL of a long-acting local anesthetic (e.g., 0.5% ropivacaine or levobupivacaine) is injected at each level, with the total volume not to exceed 0.3 mL/kg. The onset of sensory loss and surgical anesthesia typically occurs 10 minutes and 20 to 30 minutes, respectively, after injection.

Some studies suggest that a single-injection technique is as effective as a multiple-injection one (average of five dermatomes blocked) as long as the total volume of 0.3 mL/kg is used. These results were confirmed in a thermographic study by Cheema and coworkers. However, it seems preferable to use a “multiple-injection” technique when extensive spread of local anesthetic is required because of the risk for bilateral or epidural spread associated with a single large-volume injection.

**Catheter Technique.** Once the paravertebral space has been identified, the catheter is threaded 2 to 3 cm through the needle. A bolus dose of 20 mL of long-acting local anesthetic is injected for surgery (an average of six to eight segments are blocked), followed by continuous infusion of a dilute solution (e.g., 0.125% levobupivacaine or 0.2% ropivacaine) at a rate of 5 to 10 mL/hr. The catheter technique has the advantage of providing surgical anesthesia and prolonged postoperative analgesia. Bilateral paravertebral block catheters have been shown to be effective after bilateral thoracotomy in children, after major abdominal vascular surgery, and in outpatient bilateral reduction mammaplasty.

**Ultrasound Approach**

Initially, ultrasound was used to visualize landmarks such as the transverse process and to measure the distance from the skin before inserting the needle. Pusch and coauthors reported good correlation between the depth of needle insertion, from the skin to the transverse process, and such distance when measured by the ultrasound machine. Presently, anesthesiologists are using ultrasound guidance to perform paravertebral blocks because it allows reliable identification of critical anatomic structures such as the pleura.
Being able to preview the paravertebral anatomy and determine the depth of the transverse process and pleura helps in reducing the incidence of pleural puncture. Moreover, ultrasound guidance allows visualization of the spread of local anesthetic.

The thoracic paravertebral space can be scanned in two different anatomic planes:

• Transverse scan (Fig. 55.3). Performed with a high-frequency probe, a transverse scan allows identification of the apex of the paravertebral space as a triangular hypoechoic area limited by the hyperechoic parietal pleura anteriorly and the internal intercostal membrane posteriorly.

• Sagittal paramedian scan (Fig. 55.4). This scan allows identification of the transverse processes, the intertransverse and costotransverse ligaments, and the hyperechoic pleura.

Under ultrasound guidance, the needle approach can be either in plane or out of plane. Thus, four different techniques to approach the thoracic paravertebral space are described.

• Transverse scan with an “in-plane” approach.13-15 The transverse process is identified as an acoustic shadow hiding the visibility of the paravertebral space. The block needle is inserted in the plane of the ultrasound beam in a lateral-to-medial direction. Note that as the needle is advanced medially in the direction of the intervertebral foramen, there is a risk for central spread of local anesthetic or catheter placement. Moreover, such an approach seems to be less comfortable for the patient because the needle path is long and a 100-mm needle is usually required to reach the paravertebral space.

• Transverse scan with an “out-of-plane” approach.16 When compared with the previous one, this approach has the advantage of significantly reducing the distance between the skin and the paravertebral space, thus making it more comfortable for the patient. In addition, because the direction of the needle remains in the paramedian plane, the risk for central spread of the local anesthetic solution should be lower than with the previous approach.

• Sagittal scan with an “out-of-plane” approach.17 Once the pleura has been carefully identified between two adjacent transverse processes, the needle is advanced until it crosses the costotransverse ligament. Two to 3 mL of local anesthetic is injected into the paravertebral space. Such injection displaces the parietal pleura anteriorly. This approach appears to be the easiest one for the single-shot technique because the path of the needle is very short (3 to 4 cm) and the pleura is easily visible.

• Sagittal scan with an “in-plane” approach.18 With this approach it is often difficult to visualize the complete path of the needle because the angle of needle insertion is very steep. Nevertheless, it is the authors’ preferred approach for catheter insertion.

With all these approaches, hydrolocation with very small amounts of either local anesthetic or saline during needle insertion is helpful to accurately check the location of the needle tip. As soon as the paravertebral space is entered and injected, the parietal pleura is displaced anteriorly by the injected solution.

**EQUIPMENT**

An 8- to 10-cm needle is required to perform this block. It can be a 22-gauge spinal, a 19-gauge Tuohy epidural, or an insulated stimulating needle.

**PUNCTURE SITE**

The puncture site is determined by the type of surgery. At the thoracic level, breast surgery requires blockade of the T1-6 dermatomes, whereas thoracotomy requires lower dermatomal blockade (T4-10). At the lumbar level, an extensive block (T10-L2) is required.

**DRUGS AND ADDITIVES**

A bolus dose of 2 mg/kg of ropivacaine can be used safely as demonstrated in a recent pharmacokinetic study.19 The authors recommended the addition of epinephrine (1:200,000) to ropivacaine to decrease $C_{\text{max}}$ and delay $T_{\text{max}}$ and the rapid absorption phase. The measured venous plasma ropivacaine concentration (2.83 ± 1.31 µg/mL) did
not exceed the toxic threshold when a continuous infusion rate of 0.1 mL/kg/hr of a 0.5% solution was used.

INDICATIONS

A paravertebral block is associated with excellent analgesia after many types of chest surgery and a reduction in the incidence and severity of chronic pain syndromes (Box 55.1).

MAJOR BREAST SURGERY

In addition to postoperative pain, a high incidence of nausea and vomiting has been reported after general anesthesia during the first 24 hours following breast cancer surgery. Paravertebral blockade results in effective anesthesia for operative procedures on the breast and axilla, reduces postoperative nausea and vomiting, and provides prolonged postoperative analgesia, thereby minimizing narcotic requirements. When compared with the standard analgesic regimen, which usually requires an overnight hospital stay, a paravertebral block allows discharge of the patient on the same day, for a total cost savings of up to 22%.²¹

When performed as a multiple-injection technique, paravertebral blockade has been shown to be effective for breast surgery. Moreover, the unilateral sympathetic blockade that it induces improves oxygenation of the flap tissue after breast reconstruction with the latissimus dorsi,²² thus potentially improving healing of the flap.

Breast surgery may result in a "postmastectomy pain syndrome." Its incidence varies between 20% and 50%.²³,²⁴ Risk factors include the severity of postoperative pain, anxiety, and young age. Interestingly, preincisional paravertebral blockade has been shown to reduce the prevalence of motion-related and chronic pain 1 year after such surgery.²⁵,²⁶ It should be kept in mind that because of potential complications such as pneumothorax or epidural spread, the risk-benefit ratio does not favor its use for minor breast surgery. Moreover, the relatively low pain scores and the very low incidence of postoperative nausea and vomiting after minor breast surgery do not warrant the use of a paravertebral block in these situations.²⁷

THORACIC SURGERY

Although thoracic epidural analgesia is still considered the “gold standard” for postoperative analgesia after thoracic surgery, continuous paravertebral analgesia has been shown to be as effective as epidural analgesia.²⁸ Such efficacy occurs whether the catheter is inserted blindly by the anesthesiologist or under direct vision by the surgeon before wound closure. Moreover, a paravertebral catheter avoids the potential risks observed with epidural analgesia, including epidural hematoma, infection, and spinal cord injury. Chronic pain after thoracotomy occurs in 20% to 50% of patients.²⁹ The occurrence of this syndrome is significantly reduced when early and effective postoperative pain treatment (e.g., epidural analgesia, paravertebral block) is provided.³⁰

CARDIAC SURGERY

A unilateral continuous paravertebral block has been shown to be effective in managing pain after major unilateral thoracic surgery, such as minimally invasive coronary artery bypass surgery.³¹

INGUINAL HERNIA REPAIR³²,³³

The effectiveness of a paravertebral block in providing adequate and long-lasting postoperative relief of pain after herniorrhaphy is well documented in the literature. In this setting, a paravertebral block should be performed between the T10 and L2 levels. In pediatric surgery, a paravertebral block with a mixture of 2% lidocaine, epinephrine, and clonidine provided better postoperative analgesia during the first 48 hours than did standard general anesthesia. In adults, Hadzic and associates³² showed that a paravertebral block (T9-L1) using 20 mL of 0.75% ropivacaine was more effective than the combination of general anesthesia and wound infiltration. This was supported by more patients bypassing the postanesthesia care unit, less need for supplemental analgesics, and earlier discharge home.

MULTIPLE RIB FRACTURES

A paravertebral block provides effective pain relief after multiple rib fractures.³⁴ It can be performed either as a single shot (bolus of 15 to 20 mL of a long-acting local anesthetic) or as a continuous technique. It has been shown to improve both ventilatory and arterial blood gas parameters.

NEURALGIA AND PLEURITIC PAIN

Paravertebral blocks have been used to treat chronic pain after thoracotomy or mastectomy.³⁵

CONTRAINDICATIONS

Contraindications to paravertebral blockade include infection (local, empyema), allergy to local anesthetics, major chest deformity, previous ipsilateral thoracic surgery, and coagulation abnormalities.

FAILURE RATE

A paravertebral block is an easy technique to learn. Even in inexperienced hands, it rapidly provides a high success rate. Indeed, it has been shown that the success rate is significantly improved after a cutoff of 15 blind paravertebral blocks. The failure rate with the blind technique varies between 6% and 15%, depending on the experience of the operator.³⁶ Recently, ultrasound assistance has made this block much easier and more popular than in the past.

**Box 55.1 Indications for Paravertebral Blockade**

- Major breast surgery
- Thoracic surgery
- Laparoscopic cholecystectomy
- Inguinal hernia repair
- Renal surgery
- Percutaneous transhepatic biliary drainage
- Labor pain, first stage
- Rib fractures
- Intercostal neuralgia
- Pleuritic pain
- Coronary syndromes

---

22. Breast reconstruction with the latissimus dorsi, thus potentially improving healing of the flap.
23. The incidence varies between 20% and 50%.
24. Moreover, the unilateral sympathetic blockade vertebral blockade has been shown to be effective for breast surgery.
25. It should be kept in mind that because of potential complications such as pneumothorax or epidural spread.
26. Although thoracic epidural analgesia is still considered the “gold standard” for postoperative analgesia after thoracic surgery.
27. Continuous paravertebral analgesia has been shown to be as effective as epidural analgesia.
28. Such efficacy occurs whether the catheter is inserted blindly.
29. The occurrence of this syndrome is significantly reduced when early and effective postoperative pain treatment is provided.
30. A paravertebral block has been shown to be effective in managing pain after major unilateral thoracic surgery, such as minimally invasive coronary artery bypass surgery.
31. The effectiveness of a paravertebral block in providing adequate and long-lasting postoperative relief of pain after herniorrhaphy is well documented.
32. In this setting, a paravertebral block should be performed between the T10 and L2 levels.
33. In pediatric surgery, a paravertebral block with a mixture of 2% lidocaine, epinephrine, and clonidine provided better postoperative analgesia.
34. It can be performed either as a single shot (bolus of 15 to 20 mL of a long-acting local anesthetic).
35. Paravertebral blocks have been used to treat chronic pain after thoracotomy or mastectomy.
36. Recently, ultrasound assistance has made this block much easier and more popular than in the past.
COMPLICATIONS

The incidence of complications after paravertebral blocks varies between 2% and 5% (Box 55.2). The incidence of hypotension requiring a low dose of vasopressors (e.g., ephedrine) is 4%. The hypotension may be due to either sympathetic blockade (unilateral or bilateral) or a vagovagal event during the procedure. Horner’s syndrome is due to cephalad spread of the local anesthetic after a high thoracic paravertebral block. With regard to epidural spread, dye injection studies have shown the incidence of unilateral epidural spread to be up to 70% when using the blind approach. However, its clinical effects are negligible because of the small amount of local anesthetic injected.

INTERCOSTAL NERVE BLOCKADE

ANATOMY

The intercostal nerves are the anterior divisions of the thoracic spinal nerve from T1 to T11. They are distributed mainly to the thoracic pleura and abdominal peritoneum. The first two nerves supply fibers to the upper limb in addition to their thoracic branches, the next four are limited in their distribution to the parietal pleura of the thorax, and the lower five supply the parietal pleura of the thorax and abdomen. The 7th intercostal nerve terminates at the xiphoid process, the 10th intercostal nerve terminates at the umbilicus, and the 12th (subcostal) thoracic nerve is distributed to the abdominal wall and the groin.

TECHNIQUE AND DRUGS

An intercostal block (ICB) is usually performed at the level of the posterior axillary line (Fig. 55.5). The needle is inserted until it contacts the rib. It is then partially withdrawn, reoriented caudally, and advanced less than 0.5 cm deeper than the bone contact. Use of a stimulating needle connected to a peripheral nerve stimulator may be helpful. Elicitation of intercostal muscle contractions indicates adequate needle location. It is preferable to block the two proximal and two distal adjacent nerves from the selected level to cover all the areas affected by the surgical incision.

During thoracotomy, the block may be performed by the surgeon under direct vision either at the beginning or at the end of the operation before skin closure.

ULTRASOUND-GUIDED TECHNIQUE

With direct visualization of the ribs and pleura (Fig. 55.6), ultrasound guidance allows the anesthesiologist to perform an ICB proximal to the scapula, where the intercostal nerve can be blocked before its division to ensure adequate anesthesia of the pleura. In addition, ultrasound guidance allows visualization of injection of the local anesthetic into the intercostal space, thereby enabling the provider to adjust the trajectory and depth of the needle to ensure adequate spread of anesthetic and avoid pleural puncture. The patient is positioned prone, and the spina processes of the thoracic vertebrae are identified by palpation. The chest wall is best imaged in a parasagittal plane. The intercostal space is visualized with a high-frequency linear probe. The ribs appear as an oval structure with a bright surface (periosteum). A dark shadow is seen deep to the rib secondary to echo shadowing. The pleura and lungs are visualized deep to the intercostal space between the echo shadows. The needle target is the internal intercostal muscle.

After subcutaneous infiltration of local anesthetic, a 22-gauge needle is inserted either in plane or out of plane
toward the plane just deep to the internal intercostal muscle. Then, 3 mL of a long-acting local anesthetic with epinephrine is injected into the intercostal space.

With continuous techniques, the infusion rate is 5 to 7 mL/hr for an average-sized adult. Many studies have shown that $C_{\text{max}}$ occurs rapidly within 3 to 20 minutes after the block. Administration of 16 mL of either 0.5% plain bupivacaine or 1.5% lidocaine with epinephrine results in an acceptable range of local anesthetic plasma concentrations (1.44 ± 0.2 µg/mL for bupivacaine and 2.78 ± 0.2 µg/mL for lidocaine).

**INDICATIONS**

Indications for ICB include relief of postoperative pain after breast surgery, thoracotomy, video-assisted thoracic surgery, and coronary artery bypass surgery. It has been used for the relief of pain after rib fractures and with chronic pain syndromes involving the chest.

For minor breast surgery, multiple ICBs (T3-6) result in a significantly better quality and duration of postoperative analgesia than afforded by general anesthesia alone. Many studies have confirmed the effectiveness of ICB in relieving pain after thoracic surgery. It has been noted that when performed at five levels, ICB results in effective analgesia during the first 6 hours after thoracotomy, similar to thoracic epidural analgesia. In contrast, intrapleural analgesia was ineffective in providing adequate pain relief.

Video-assisted thoracic surgery is less invasive than open thoracotomy but is still followed by postoperative pain and impairment of lung function. Bilateral ICB of the second, third, and fourth intercostal nerves, under direct vision during surgery, has been shown to be safe and effective in reducing postoperative pain and analgesic requirements. However, another study was unable to show any difference between ICB, intrapleural analgesia, and opioid analgesia.

The efficacy of ICB in relieving pain and improving ventilatory parameters after multiple rib fractures has clearly been demonstrated. For minimally invasive coronary bypass surgery, it has been shown that when compared with opioid analgesia, ICB (four levels, 5 mL of 0.1% ropivacaine per level) provides better pain relief in the early postoperative period and allows earlier patient discharge to the intermediate care ward.

**CONTRAINDICATIONS AND COMPLICATIONS**

Contraindications to ICB include local infection and contralateral pneumothorax. Its major complication is pneumothorax, the incidence of which is estimated to be 1.4% for each intercostal nerve blocked.

**ILIOPHYSIOGASTRIC AND ILIOINGUINAL NERVE BLOCKADES**

**ANATOMY**

The ilioinguinal (II) and iliohypogastric (IH) nerves originate from the T12 and L1 nerve roots of the lumbar plexus. Both nerves pass through the fascia lumborum at the lateral border of the quadratus lumborum muscle and then extend to the area between the obliquus internus abdominis and transversus abdominis muscles. The IH nerve is located superior and medial to the II nerve. In the area of the anterior superior iliac spine, it bifurcates into the lateral and medial cutaneous rami as its two terminal branches. The lateral cutaneous ramus passes through the obliquus internus abdominis and externus abdominis muscles and provides sensory innervation to the skin in the region of the anterior aspect of the buttock. The medial cutaneous ramus passes through both the obliquus internus abdominis muscle and the aponeurosis of the obliquus externus abdominis muscle and supplies the skin of the abdominal wall region above the symphysis. The II nerve supplies the skin region of the superomedial aspect of the thigh, as well as the anterior region of the scrotum in males or the mons pubis and labia majora in females.

The genitofemoral (GF) nerve is mainly a sensory nerve. It is formed from L1-2 in the substance of the psoas major muscle. At the L3-4 level, it emerges on the ventral surface of the muscle along its medial border. It runs downward on the muscular surface and divides into genital and femoral branches above the inguinal ligament. The genital branch enters the inguinal canal through the deep inguinal ring. It supplies motor fibers to the cremasteric muscle and sensory fibers to the skin over the scrotum in men and the mons pubis and labia majora in women. The femoral branch accompanies the external iliac artery and, below the inguinal ligament, remains enveloped by the femoral vascular sheath lateral to the femoral artery. It supplies the skin over the femoral triangle.

**INDICATIONS**

**ILIOPHYSIOGASTRIC AND ILIOINGUINAL NERVE BLOCKS**

In conjunction with GF nerve blockade, these blocks are indicated as anesthetic and analgesic techniques for inguinal herniorrhaphy, orchidopexy, and hydrocelectomy. Combined IH and II nerve blocks significantly reduce pain scores and supplemental analgesia after discharge following inguinal herniorrhaphy. When compared with spinal anesthesia, these blocks are associated with a shorter time to discharge home, lower pain scores at discharge, higher satisfaction scores at 24-hour follow-up, and lower cost. These blocks have been suggested as an alternative anesthetic technique for repair of strangulated hernias in high-risk patients who are not suitable candidates for general or neuraxial anesthesia. In children, the effectiveness of the blocks appear to be similar to that of caudal blocks.

The amount of postoperative intravenous morphine needed during the first 24 hours after cesarean section was significantly reduced by bilateral II nerve blocks. However, no difference in the incidence of opioid-related adverse effects was noted.

II nerve blocks have been recommended in patients with persistent pain and paresthesia after inguinal herniorrhaphy, appendectomy, cesarean section, and hysterectomy. Successful pain relief after a diagnostic II nerve block may indicate II nerve entrapment.

**GENITOFEMORAL NERVE BLOCK**

In conjunction with II and IH nerve blocks, a GF block is indicated for inguinal herniorrhaphy, orchidopexy, and
hydrocelectomy. However, when compared with combined II and IH nerve blocks during inguinal herniorrhaphy, its benefit is limited to pain related to traction on the hernia sac, and it has no additional postoperative analgesic effect.

In addition to a femoral nerve block, it is an effective anesthetic and analgesic technique for stripping of the long saphenous vein.54

CONTRAINDICATIONS AND DRUGS
Local infection and previous II, IH, or GF nerve injury are the only contraindications.

Bupivacaine has been the most commonly used local anesthetic. However, it is more rapidly absorbed from the injection site and thus results in higher plasma concentrations than ropivacaine does.55 At the present time, 0.5% ropivacaine or levobupivacaine appears to be the more appropriate local anesthetic solution to perform the blocks. Both drugs combine rapid onset of anesthesia and prolonged (i.e., up to 12 hours) postoperative analgesia.56 The addition of clonidine57 offers no advantage over plain local anesthetic solution.

TECHNIQUE
ILIOINGUINAL AND ILIOHYPOGASTRIC NERVE BLOCKADE

Classic Approach
The patient lies supine. The landmarks are the umbilicus, the ipsilateral anterior superior iliac spine, and the pubic tubercle (Fig. 55.7). A line is drawn between the anterior superior iliac spine and the umbilicus, and another line is drawn between the anterior superior iliac spine and the pubic tubercle; both lines are divided into three equal segments. On each line, the site of puncture is located at the junction of the lateral and middle thirds. At both puncture sites, a short-beveled needle is inserted at a 50- to 70-degree angle to the skin in an anteroposterior and caudal direction. It is advanced until loss of resistance is felt, which occurs as the aponeurosis of the external oblique muscle is pierced. After negative aspiration, 5 mL of local anesthetic is injected. The needle is then advanced deeper to pierce the internal oblique muscle aponeurosis, and a similar amount of local anesthetic is administered.

Ultrasound-guided Technique
The classic approach can be inaccurate. A failure rate as high as 20% to 30% has been reported. The safety and effectiveness of these blocks can be greatly improved by direct visualization with ultrasonography.58,59 The ultrasound examination should be performed with a high-frequency linear probe (Fig. 55.8). The II nerve is best visualized immediately medial to the anterior superior iliac spine. It is located at a mean distance of 6 mm from this bony landmark. The IH nerve is close (<1 cm) to the II nerve, and both nerves are located close to the peritoneum. With an out-of-plane approach, the needle is inserted between the obliquus internus abdominis and transversus abdominis muscles. The volume of local anesthetic required to anesthetize both nerves is 0.075 mL/kg in children and 0.2 mL/kg in adults,59 doses much smaller than those recommended with the “blind” technique. The ultrasound-guided technique resulted in a 96% success rate58,59 and significantly reduced the risk for complications such as intestinal puncture.

GENITOFEMORAL NERVE BLOCKADE
With the patient in the supine position, the following landmarks are identified: the pubic tubercle, inguinal ligament, inguinal crease, and femoral artery. The femoral branch of the nerve is blocked by inserting the needle at the lateral border of the femoral artery in the inguinal crease. A fan-like infiltration of the subcutaneous tissue with 10 to 15 mL of local anesthetic solution is performed in a medial, caudal, and cephalad direction. The genital branch of the nerve is blocked by infiltration of 10 mL of local anesthetic just lateral to the pubic tubercle, below the inguinal ligament.
PART 6 — NERVE BLOCK TECHNIQUES

COMPLICATIONS

Transient femoral nerve palsy, pelvic hematoma, and small bowel or colonic puncture have been described mainly with the blind techniques. These complications can be avoided when an ultrasound-guided technique is performed. However, additional large-scale studies are required to confirm the safety of such techniques.

RECTUS SHEATH BLOCKADE

ANATOMY

The umbilical area is innervated by the 10th right and left intercostal nerves. Each nerve passes between the transverse abdominal and internal oblique muscles. It runs between the sheath and the posterior wall of the rectus abdominis muscle and ends as the anterior cutaneous branch supplying the skin of the umbilical area. The rectus abdominis muscles extend between the xiphoid and the pubic tubercle. The nerves are enclosed in the rectus sheath, which is formed by the aponeurosis of the external and internal oblique and the transverse muscles.

INDICATIONS, CONTRAINDICATIONS, AND DRUGS

The limited area of anesthesia and analgesia that rectus sheath blockade provides (midline to the linea semilunaris) makes it inadequate as the sole technique for surgery. It is generally used in combination with general anesthesia for surgery around the umbilicus (umbilical hernia) and for upper abdominal midline incisions. More recently, it has been used for midline incisions above and below the umbilicus and for postoperative analgesia as part of an enhanced postoperative recovery technique consisting of the use of indwelling local anesthetic catheters. Because of crossover innervation, bilateral blocks need to be performed in all patients. However, unilateral injections may be performed as part of management of chronic pain syndromes in adults and children.

A rectus sheath block is indicated as an analgesic technique after umbilical or epigastric hernia repair. It has been noted to decrease pain after laparoscopy and midline laparotomy. Local infection is a specific contraindication.

Bupivacaine has been the most commonly used local anesthetic. Less cardiotoxic drugs such as 0.5% ropivacaine or levobupivacaine are effective alternatives, particularly when high doses are used.

TECHNIQUE

CLASSIC APPROACH

The aim of the block is to inject the local anesthetic solution between the muscle and the posterior aspect of the rectus sheath. The needle is inserted 0.5 cm medial to the linea semilunaris in a perpendicular plane, just above or below the umbilicus (Fig. 55.9). The anterior rectus sheath is identified by moving the needle in a back-and-forth motion until a “pop” is felt. The rectus sheath and the belly of the muscle are entered. The needle is then advanced further up to the posterior aspect of the rectus sheath. After a negative aspiration test for blood, 10 to 15 mL of local anesthetic is injected on each side.

ULTRASOUND GUIDED TECHNIQUE

An ultrasound-guided technique has recently been described and appears to be beneficial, especially in children, in whom the depth of the posterior rectus sheath is unpredictable. It provides a high success rate with few complications. Dolan and colleagues reported that the incidence of accidental intraperitoneal injection of local anesthetic during a blind rectus sheath block is as high as 20.9%, as opposed to 0% with an ultrasound-guided approach.

COMPLICATIONS

Intravascular injection is a potential complication. A case of retroperitoneal hematoma has recently been reported.
TRANSVERSE ABDOMINAL PLANE BLOCK

This technique allows placement of local anesthetic in the abdominal neurovascular plane at the level of the lumbar triangle. The inferior lumbar triangle of Petit is a triangular area located at the posteroinferior part of the lower abdominal wall. It is limited anteriorly by the posterior border of the external oblique muscle and posteriorly by the lateral border of the latissimus dorsi muscle, with the internal oblique and transversus abdominis muscles as the floor. Deep to the transversus abdominis muscle is the parietal peritoneum. It separates the floor of the triangle from the peritoneal cavity. The transverse abdominal plane block was first described in 2001 by Rafi as an abdominal field block performed with the use of superficial landmarks and a loss-of-resistance technique.

INDICATIONS

This block has been used as postoperative analgesia for most abdominal surgical procedures, bilaterally for midline surgery or unilaterally for unilateral surgery. A catheter technique has recently been advocated for prolonged postoperative analgesia after cesarean section, colectomy, open prostatectomy, or abdominal hysterectomy.

TECHNIQUE

BLIND TECHNIQUE

The triangle of Petit is identified by palpation. While standing opposite the operated site, the crest of the ileum is identified at the midaxillary line. The finger is moved posteriorly and a gap is felt in the musculature of the lateral abdominal wall. A 22- or 24-gauge, 50-mm blunt needle is inserted perpendicular to the skin, approximately 1 to 2 cm above the iliac crest, toward the apex of the triangle. Two distinct pops (loss of resistance) are felt. After negative aspiration, 15 to 20 mL of local anesthetic is injected.

ULTRASOUND-GUIDED TECHNIQUE

Ultrasound allows direct visualization of the external oblique, internal oblique, and transverse abdominal muscles, thus allowing accurate placement of the local anesthetic solution within the relevant plane (i.e., between the internal oblique and transverse abdominal muscles). Two ultrasound approaches have been described.

Midaxillary Approach

A high-frequency linear probe (small adults and children) or a low-frequency curvilinear probe (large adults, obesity) is placed transversely on the abdomen at the midline just below the umbilicus. The rectus abdominis muscle is then identified. Moving the probe laterally, the three abdominal muscles (external and internal obliques and transverse abdominal) are identified in a superficial-to-deep direction (Fig. 55.11). The probe is positioned posterior to the midaxillary line midway between the rib cage and the iliac crest, a point where the three muscle layers can easily be delineated. Using either an in-plane or an out-of-plane approach, a 22-gauge, 50- to 100-mm needle is inserted. The tip of the needle is placed between the internal oblique and transverse abdominal muscles, and its position is confirmed by hydrolocation. Fifteen to 20 mL of the local anesthetic solution is injected; separation of the two muscular layers confirms correct placement of the tip of the needle.

Subcostal Approach

The probe is placed transversely in the midline just below the sternum and moved laterally along the lower border of the ribs. The rectus muscle and then the three abdominal muscles (external and internal obliques and transverse abdominal) are identified. A 50- to 100-mm needle is inserted in a medial-to-lateral direction in an in-plane approach. This technique is specifically used for upper abdominal and subcostal incisions.

Figure 55.11 Sonographic anatomy for a transversus abdominis plane block (arrow).

KEY POINTS

- A paravertebral block provides excellent pain relief after thoracotomy and major breast surgery. A continuous catheter technique could be used in this setting. The incidence of side effects and complications remain low when compared with thoracic epidural analgesia.
- Intercostal blocks are effective in relieving pain after unilateral thoracic or abdominal surgery. However, the need to block multiple intercostal nerves limits their wider use in clinical practice.
- Minor blocks such as ilioinguinal, iliohypogastric, and rectus sheath blocks are very helpful in managing postoperative pain after ambulatory procedures, such as inguinal or umbilical hernia repair. These blocks have a low incidence of complications and side effects.
- A transversus abdominis plane block is considered an effective alternative to epidural analgesia after major abdominal surgery. It is easy to perform under ultrasound guidance, is very effective, and has a better safety profile than epidural analgesia does.

CERVICAL SYMPATHETIC (STELLATE GANGLION) BLOCK

Stellate ganglion block (SGB) was originally introduced by René Leriche for the treatment of angina pectoris. Findley and Patzer eventually modified the technique, which has remained largely unchanged since then and was named the anterior approach.1 This method is the most popular technique in North America. In addition, lateral, superolateral, and posterior approaches were introduced in the first half of the 20th century.1 All techniques are based on bony landmarks, such as the transverse process of C6, the spinous process of C7, and the first rib. Eventually, these techniques were empirically validated with fluoroscopy and computed tomography (CT) and later with ultrasonography.

CLINICALLY RELEVANT ANATOMY

The stellate ganglion, also known as the cervicothoracic ganglion, represents a fusion of the inferior cervical and first thoracic ganglia of the sympathetic trunk. It can be found in about 80% of the population. The anatomy and position of the stellate ganglion have been investigated by dissection, magnetic resonance imaging (MRI), and CT.2-6 It is usually situated at the lateral border of the longus colli muscle (LCM) anterior to the neck of the first rib (Fig. 56.1). It lies posterior to the vertebral vessels and is separated from the cervical pleura by the suprapleural membrane inferiorly. The stellate ganglion measures 1 to 2.5 cm in length, is about 1 cm wide and 0.5 cm thick, and may be fusiform, triangular, or globular in shape.5

INDICATIONS

SGB is commonly used for the diagnosis and management of sympathetically mediated pain and vascular insufficiency of the upper extremity. In addition, more esoteric indications that have been advocated include the treatment of a variety of medical conditions, such as phantom pain, post-herpetic neuralgia, cancer pain, cardiac arrhythmias, orofacial pain, and vascular headache.7 Recently, cervical sympathetic blockade has been suggested as an effective method for prevention and treatment of cerebral vasospasm, hot facial flushes, and post-traumatic stress disorder.8-10

EVIDENCE FOR STELLATE GANGLION BLOCK

Clinical effectiveness of SGB can be defined as undetermined. The majority of publications are case reports and case series. Neurolytic SGB is currently rarely practiced because the evidence is anecdotal. Malmqvist and colleagues assessed 54 SGBs performed blindly with bupivacaine. Their criteria for effective sympathetic blockade included Horner’s syndrome in combination with increased skin temperature, increased skin blood flow, and a completely abolished skin resistance response on both the radial and ulnar sides of the blocked hand. Only 15 of 54 blocks met four of the five criteria for an effective block.11 Another study examined the efficacy of SGB in patients with complex regional pain syndrome (CRPS) type 1. Pain relief and improved skin perfusion were observed in 40% of patients who had CRPS symptoms for 12 or fewer weeks, but no improvement occurred in the group with more protracted disease (35.8 ± 27 weeks).12 Two small pilot studies suggested that SGB can provide relief from hot flushes and sleep dysfunction with few or no side effects in survivors of breast cancer and post-traumatic stress disorder.9,10

AVAILABLE TECHNIQUES

Although a C7 approach to the stellate ganglion has been described,13 SGB is still routinely performed at the C6 level by using the following anatomic landmarks: prominent anterior tubercle of the transverse process (Chassaignac’s tubercle) and cricoid cartilage, both of which facilitate identification of the level and finally the location of the carotid artery.2 Given that only traversing sympathetic fibers or middle cervical ganglia can be found at the C6 level,15 the procedure should more accurately be called a cervical sympathetic block. The middle cervical ganglion or traversing sympathetic fibers are located anterolateral to the belly of the LCM.15 Conceivably, such a “convenient” location makes it easy to access the sympathetic chain for either diagnostic or therapeutic blockade.

Cervical sympathetic block is traditionally performed as a “blind” injection via the anterior approach. It is accomplished...
by positioning the patient supine with the head rotated to the opposite side. Following palpation of the anterior tubercle of the C6 transverse process (Chassaignac’s tubercle), the carotid artery is gently retracted laterally. The needle is then inserted paratracheally until it contacts bone, presumably the lateral part of the vertebral body (Fig. 56.2). The needle is then withdrawn 1 to 5 mm, and the medication is injected. This maneuver was presumed to be sufficient to position the needle outside the LCM, where the sympathetic ganglion is likely to be situated.

Fluoroscopic guidance reduces the overall risks associated with the “blind” technique. It has the advantage of identifying the bony anatomy, although the anatomic position of the cervical sympathetic trunk (CST) is confined to the soft tissues (LCM, thyroid, and esophagus) rather than to the cervical vertebrae. Injection of a contrast dye helps to confirm the procedural accuracy, although it may show aberrant and inconsistent spread. Such injection will, however, significantly decrease, if not eliminate the risk for intravascular injection. Typically, fluoroscopically guided SGB is performed similar to the blind technique just described. A coaxial anteroposterior view is used to direct the block needle toward the anterior base of either the C6 or C7 transverse process. Alternatively, the injection can be

---

Figure 56.1 The peripheral autonomic nervous system. (From Bonica JJ. *The Management of Pain*. Philadelphia: Lea & Febiger; 1953.)
performed via an oblique fluoroscopic view (Fig. 56.3). Most likely, neither “blind” nor fluoroscopically guided injection can ensure reliable results. Since the ultimate thickness of the LCM remains unknown, the contrast dye and subsequently the local anesthetic are injected into the muscle and then reach the sympathetic trunk by overflow or diffusion.

Several clinical and cadaver trials have been conducted in an attempt to elucidate the pattern of spread when solutions are injected at the C6 level. The results of these studies have been conflicting, probably because of differences in study design: cadavers or live subjects, low or high volume of injectant, and CT or fluoroscopy control. The results of one cadaver study suggested that deposition of a solution only into the prevertebral “interlaminar space” provides reliable spread to the stellate ganglion. The cervical prevertebral fascia is attached to the base of the skull and extends over the prevertebral muscles (longus capitis, rectus capitis, and longus colli) to the T4 vertebra, just beyond the LCM. This positioning of the fascia forms a plane along which the injected fluid can flow.

Although some anatomic and imaging studies indicate a subfascial position, textbooks allocate the path of the CST to the suprafascial plane. Two recently published studies have hopefully resolved this issue. The first used cadaver dissection and human MRI and showed a subfascial position of the stellate ganglion. This study found the thickness of the LCM to be highly variable, which may lead to negative block results. The second study was designed as a step-by-step methodology to validate a new ultrasound-guided approach (below); a subfascial position of the sympathetic trunk was detected by three-dimensional ultrasonography and confirmed by cadaver dissection. In addition, this study measured the thickness of the LCM at the C6 level and proved that the muscle is 2 to 10 times thicker than was previously suggested in the regional anesthesia literature. Accordingly, routine injection by the traditional method would have resulted in an intramuscular injection, and the CST would be anesthetized only by overflow or diffusion of the injectant.

Ultrasound guidance is a logical solution to ensure accurate injection when soft tissues are involved. Clear imaging of the muscles, fasciae, blood vessels, viscera, and bone surface makes ultrasonography superior to fluoroscopy for image-guided CST blockade. In 1995 Kapral and coworkers described an ultrasound-guided anterior technique and published the results of a case series.

The patient is placed in the supine position. A pillow can be placed under the lower part of the neck to achieve some extension. The head may be rotated slightly contralateral to the injection side to increase the distance between the carotid artery and the trachea and improve the sono-graphic view. Ultrasonography of the anterior part of the neck is performed by initially placing the transducer at the level of the cricoid cartilage, anterior to the sternocleidomastoid muscle. Short-axis ultrasonography reveals the typical appearance of the C6 transverse process: a prominent anterior tubercle, a short posterior tubercle, and the exiting C6 nerve root (Fig. 56.4). Scanning caudally and dorsally brings the C7 transverse process into view. The C7 transverse process has no anterior tubercle. The C7 nerve root is situated just anterior to the posterior tubercle (Fig. 56.5). At the C6 level, the LCM is seen as an oval structure adjacent to the base of the transverse process and vertebral body. Sometimes the caudal portion of the longus capitis muscle can be seen as well. The CST is visualized as a spindle-shaped structure (the midcervical ganglion) and is typically situated on the posterolateral surface of the LCM. If the CST cannot be identified, some widening of the tissue plane below the prevertebral fascia can usually be seen. Once the correct level for injection is localized, the surrounding anatomic structures should be identified and the feasibility of the “anterior” approach determined. Frequently, the distance between the carotid artery and the trachea is wide enough, and therefore only thyroid tissue and superficial neck muscles are seen between the needle entry point and the surface of the LCM. Gentle pressure may actually decrease the skin-to-target distance and further separate the carotid artery from the trachea. Additional scanning should be performed to confirm...
that the inferior thyroid artery is not seen immediately caudad. The injection is performed in a short-axis, out-of-plane approach (Fig. 56.6). The skin is anesthetized immediately caudad or cephalad to the transducer. The injection is performed with a spinal needle (22 to 25 gauge and 2 to 3.5 inches long), three-way stopcock, and extension tubing connecting two syringes, one with 0.9% NaCl and the other with local anesthetic. The needle is inserted under continuous ultrasound guidance and directed to the anterior surface of the LCM via a short-axis, out-of-plane approach. When the tip of the needle is visualized, either directly or indirectly (tissue movement) as the target is approached, 1 to 2 mL of saline is injected to confirm placement of the needle under the prevertebral fascia and facilitate clear separation of the tissue planes (Fig. 56.7). If the injectant is observed above the fascia or within the muscle, the needle must be carefully repositioned. If the spread is appropriate, 5 mL of local anesthetic is injected and the needle is withdrawn.

A lateral approach has recently been described and validated. The patient is placed in the lateral decubitus position with the side to be treated uppermost. Preparation and ultrasonography are performed as described previously. The ultrasound transducer is centered on the C6 transverse process and not the anterior aspect of the neck. With the transducer placed as shown in Figure 56.6, only the anterior tubercle of the C6 transverse process is visible adjacent to the projected entry point of the needle, and no visceral or neural elements are present between the entry site and the anterolateral surface of the LCM. The needle track should be entirely intramuscular and pass through the sternocleidomastoid muscle, the anterior scalene muscle, or both. Occasionally, the internal jugular vein is seen within the projected needle track, but it can readily be collapsed by placing light pressure on the transducer.

Skin anesthesia is performed immediately posterior to the ultrasound transducer. Under continuous ultrasound guidance, the needle is inserted via a short-axis, in-plane technique (Fig. 56.8). The advantage of the lateral approach, in addition to avoiding trespassing through the thyroid, is...
totally controllable, visible progression of the needle from
the skin entry point to the target. Verification of needle
position and performance of the rest of the procedure are
the same as for the anterior approach.

Injection of 5 mL of a local anesthetic typically results in
C3-T1 prevertebral spread and complete blockade of the
CST and stellate ganglion. If anesthetic blockade of the
upper cervical ganglion is not desirable, it would be pru-
dent to limit the volume of injectant to 3 mL.

COMPLICATIONS

Blind paratracheal injection produces unreliable results and
is associated with a variety of side effects and complications,
such as intravascular injection, formation of hematomas,
temporary paralysis of the recurrent laryngeal nerve, diskitis,
and esophageal injury.7,14,23-26 Narouze and associates further
emphasized the risks inherent with a blind approach25 by
pointing out that blind injection at the C6 level on the left
side may cause inadvertent esophageal puncture or may tra-
verse the thyroid. Hematoma formation is probably related to
damage to the inferior thyroid artery.

Fluoroscopic guidance may prevent adverse outcomes
related to intravascular, nerve root, or neuraxial injection.
However, visualization of the soft tissue, vessels, and cervi-
cal sympathetic ganglia makes guidance with ultrasound
superior to fluoroscopic guidance. Subfascial injection of 5
mL of an injectant reliably produces cervical sympathetic
blockade. Ultrasound guidance may prevent the complica-
tions and adverse outcomes associated with either blind or
fluoroscopically guided techniques.

CELIAC PLEXUS BLOCK

Max Kappis has frequently been cited as the person who
developed the technique of celiac plexus block (CPB).27
However, he never described this technique. Kappis showed
that pain from the upper abdominal organs is conducted
via the splanchnic nerves and that experimental abdomi-
nal pain can be relieved by infiltration of the splanchnic
nerves with procaine from the back. Theoretically, this was
not a CPB but a splanchnic nerve block. Perhaps it was
John Bonica who described the technique that is currently
named percutaneous transcervical CPB.28 Both surface
landmark–based and fluoroscopically guided approaches
were described in this seminal work. He also advocated the
use of neurolytic celiac plexus block (NCPB) with alcohol
for palliation of pain related to abdominal malignancies,
although it was Bridenbaugh and associates who published
their experience in the peer-reviewed literature.29

CLINICALLY RELEVANT ANATOMY

Innervation of the viscera originates from the T5 to T11 spi-
nal segments, with occasional contribution of the T4 and
T12 preganglionic fibers. They do not synapse in the sympa-
thetic chain but rather pass through the chain to synapse at
distal locations (i.e., the celiac, renal, and superior mesen-
teric ganglia). The T5 to T9 preganglionic fibers coalesce to
form the greater splanchnic nerve; T10 and T11 constitute
the lesser and T12 the least splanchnic nerves.30

Efferent fibers of the splanchnic nerves end up in the
ceeliac plexus. Located approximately at the level of T12 or
L1, or both, the celiac plexus is composed of several celiac
ganglia that surround the celiac trunk and the superior mes-
enteric artery at its root.31 It is located in front of the aorta
and the crus of the diaphragm and posterior to the stom-
ach and omental bursa (Fig. 56.9). The plexus in turn sup-
plies the various upper abdominal viscera through multiple
smaller plexuses and nerve fibers. These viscera include the

Figure 56.8  Lateral ultrasound-guided approach. The needle (arrow-
heads) is placed under the prevertebral fascia. Local anesthetic
(semitransparent figure) spread superficially to the longus colli muscle
(LCM) and posteriorly to the carotid artery (CA). C6, sixth cervical
vertebra; SCM, sternocleidomastoid muscle; T, trachea.

of Pain. Philadelphia: Lea & Febiger; 1953.)
diaphragm, liver, stomach, spleen, suprarenal glands, kidneys, ovaries and testes, small intestine, and colon up to the splenic flexure. The celiac plexus also sends branches to the superior and inferior mesenteric plexuses. In addition, the plexus receives parasympathetic supply from the vagus. The sensory (afferent) fibers do not synapse in the plexus but rather traverse it and ascend to spinal levels through the splanchnic nerves.

EVIDENCE FOR CELIAC PLEXUS BLOCK

Multiple clinical studies have demonstrated level I efficacy of NCPB as a minimally invasive modality for managing cancer-related pain. Bridenbaugh and colleagues performed 41 CPBs in which 50 mL of a 50% alcohol solution was used. It was effective in 40 patients and had no significant side effects.29 Ischia and coworkers compared three common techniques in a randomized controlled fashion and found that all approaches were equally effective and abolished pain in 60% to 75% until death.32 Several large-scale randomized controlled trials were published and unequivocally demonstrated superiority of CPB over oral opioid therapy.33-35 In addition, one demonstrated improved survival.34 Finally, a meta-analysis suggested that (1) NCPB produces long-lasting benefit in 70% to 90% of patients with pancreatic and other intra-abdominal cancers regardless of the technique used, (2) adverse effects are common but transient and mild, and (3) severe adverse effects are uncommon.36 CPB was somewhat efficacious in managing nonmalignant pain, such as chronic pancreatitis.37-38 A recent randomized, controlled study showed that in patients with critical illness, CPB was effective in treating feeding intolerance when intravenous drug therapy had failed to improve gastrointestinal dysfunction.39

INDICATIONS

Major causes of visceral pain include functional gastrointestinal disorders, abdominal malignancies, and chronic pancreatitis. NCPB is indicated for the management of pain related to cancer of the pancreas, stomach, duodenum, and proximal part of the small bowel. In addition, metastatic tumors in the lymph nodes may cause similar pain and might be amenable to NCPB. In the case of benign conditions, analgesic prognostic CPB is performed and may be repeated as needed. Alternatively, if the reduction in pain was significant but lasted only short-term, NCPB may be attempted.

AVAILABLE TECHNIQUES

Surface landmark–based techniques for CPB were introduced in the beginning of the 20th century. Later, fluoroscopic guidance was strongly advocated. Other high-quality and accurate images of fluoroscopically controlled transcrural CPB are presented in Bonica’s pivotal book The Management of Pain. With the overwhelming recommendation for mandatory use of imaging guidance, such as fluoroscopy, CT, and ultrasonography, these aids became standard features, although only a few studies have directly compared different imaging modalities.32,37,40,41 A variety of techniques and approaches are described in the literature, including the retrocrural, anterocrural, transcral, transdiscal, and transaortic approaches and splanchnicectomy. Both single-needle and two-needle techniques have been advocated.42-49 Each technique has its proponents and opponents claiming advantages and disadvantages. The spread of cancer, as seen on CT, may sometimes dictate the approach.49

NCPB is usually performed with either 6% to 10% phenol or 50% to 100% alcohol after a diagnostic local anesthetic injection despite a low negative predictive value of the diagnostic block.32,50

Anterior and posterior approaches to the plexus have been described.51 The anterior approach is used intraoperatively or percutaneously with ultrasound guidance. Fluoroscopic and landmark-based injections approach the plexus posteriorly. CT-guided CPB may be performed through an anterior or posterior approach, although the posterior approach is commonly preferred. CT may provide finer details about the plexus, celiac artery, and neighboring structures, which can facilitate improved safety and better targeting. Fluoroscopy is based solely on skeletal imaging and requires additional aids, such as a loss-of-resistance device and injection of a contrast dye. Open MRI guidance has been reported to result in a 57% success rate for CPB, but this method is definitely time-consuming and costly.52

Endoscopic ultrasound–guided CPB has been performed safely with clear visualization of the ganglia, but it frequently relies on a second imaging aid (e.g., radiography). Endoscopic CPB may be more cost-effective than CT-guided CPB.38 Ultrasound-guided percutaneous CPB may have several benefits when compared with other modalities. It may be performed at the bedside and has no radiation hazards. In addition, the supine position is more comfortable for patients. It allows real-time visualization of spread of the injectant. Its disadvantages include poor visualization of deeper structures, including the pancreas, and interference by air in the intestinal loops. Similar to anterior CT guidance, it may be associated with perforation of the stomach, intestine, pancreas, or liver.

POSTERIOR TRANSCRURAL (CLASSIC) FLUOROSCOPICALLY GUIDED APPROACH

The patient is positioned prone on the fluoroscopic table. Bolsters usually have to be placed under the chest and pelvis to alleviate pressure on the abdomen, which may not be tolerated by patients. Standard monitoring and supplemental oxygen are applied. To prevent a sudden decrease in blood pressure related to visceral vasodilation, 500 mL of an isotonic intravenous fluid is administered. After the usual sterile preparation, thoracolumbar spine fluoroscopy is performed and the L1 vertebra is placed at the center of the scout image. Next, the image intensifier is rotated to an oblique position. The degree of obliquity is usually judged by observing contralateral movement of the spinous process. It has to be aligned with the contralateral facet joint. In addition, a cephalad or caudad tilt is used to “eliminate” the L1 transverse process from view. The radiologic target is the middle of the L1 vertebral body. Local anesthesia is performed and a 20- or 21-gauge Chiba-type needle is inserted and advanced via a coaxial view (Fig. 56.10A). The needle has to contact the L1 vertebral body just 1 to 2 mm medial to the lateral bony shadow, or further advancement will be difficult. Some practitioners manually bend
the tip of the needle 10 to 15 degrees to improve steering. After the bone has been contacted, the image intensifier is rotated into the lateral position and further needle progress is monitored with this view. It is also advisable to remove the stylet and use a loss-of-resistance devise filled with either 0.9% NaCl or diluted radiopaque contrast dye. Typically, once the needle is advanced about 1 cm past the anterior bony shadow, the resistance drastically decreases and prevertebral/prefaortic longitudinal spread of the contrast dye is observed (Fig. 56.10B). On the anteroposterior view, a “honeycomb” contrast shadow is seen (Fig. 56.10C). The procedure is performed in the same fashion on the contralateral side. If arterial blood is obtained or the injected contrast dye produces an aortogram, the procedure may be converted to a transaortic single-needle technique. In this case, the needle is advanced through the anterior aortic wall and additional contrast dye is injected. Its spread should be confined to the retroperitoneal compartment. Once the needle’s position is verified, 5 to 10 mL of a local anesthetic mixed with contrast dye is injected and the patient is closely monitored for signs of intravascular injection or neuraxial blockade. After 3 to 5 minutes, 20 to 40 mL of 50% to 80% alcohol or 6% phenol is injected slowly. Alcohol can be mixed with the contrast dye to further ensure accurate injection.

POSTERIOR TRANSCRURAL (CLASSIC) COMPUTED TOMOGRAPHY–GUIDED APPROACH

Patient position and preparation are similar to the fluoroscopically guided approach.

CT guidance can be facilitated by using a standard planning grid or a three-dimensional reconstruction and cone beam guidance. With the former, CT planning is performed while paying attention to direction and depth. The patient is removed from the scanner and the needle is inserted; a second CT scan is obtained to confirm final needle position. If the placement is satisfactory, either contrast dye is injected and further confirmation with CT or ancillary fluoroscopy is performed or a neurolytic solution is injected slowly (Fig. 56.11). If needle placement is inaccurate, the process is repeated. This method is definitely time-consuming and associated with significant radiation exposure.

A novel cone beam CT procedure uses 50% to 70% less radiation than conventional CT scanners do and combines the capabilities of CT scanning and fluoroscopy. The procedure is planned with specialized software showing the entry point, direction, and depth of the needle (Fig. 56.12). Next, the procedure is performed with live fluoroscopic guidance overlaid on the CT image. This radiologic method may effectively reduce radiation exposure and minimize procedure time without sacrificing technical accuracy (Fig. 56.13).

TECHNIQUE OF PERCUTANEOUS ULTRASOUND-GUIDED CELIAC PLEXUS BLOCK

With the patient positioned supine, standard monitoring and preparation are performed. Patients may be instructed to control their respiration during the procedure. A low-frequency, curved-array, 3- to 5-MHz transducer is used. The ultrasound scan is performed by starting from the epigastrium and moving caudad to visualize the aorta, vertebral body, and the liver in a transverse view (Fig. 56.14). Once the celiac trunk is localized, color Doppler flow is turned on to verify the vessels. Next, the transducer is turned longitudinally to visualize the celiac trunk and superior mesenteric artery (Fig. 56.15). Color flow Doppler is used to verify the
Figure 56.12  Procedural planning with cone beam computed tomography.

Figure 56.13  Three-dimensional axial reconstruction. A contrast dye encircles the aorta (A).

Figure 56.14  Short-axis ultrasound view. A, aorta; CP, celiac plexus; CT, celiac trunk; L, liver; V, L1 vertebral body.
vessels. The target is the space between the celiac trunk and the superior mesenteric artery. The tip of the needle may be also positioned cephalad to the celiac trunk to ensure better spread of the neurolytic agent. Deviations in local anatomy related to the malignancy or previous surgery may influence spread of the injectant more than the position of the needle does.

A 22-gauge, 10- to 15-cm Chiba-type needle is advanced to the space between the celiac trunk and the superior mesenteric artery in a longitudinal view. The needle may be advanced in plane or out of plane, depending on the size of the needle, the safest path to the target area, and personal preference of the physician (Fig. 56.16). After negative aspiration, a test dose of 3 mL of 1% lidocaine with epinephrine is injected in real time to rule out any intravascular uptake. Subsequently, real-time injection of the neurolytic agent in 5-mL increments is done. The typical volume of injectant used varies from 10 to 50 mL. The concentrations of alcohol used vary from 50% to 100%. With phenol, the concentration ranges from 6% to 10%. The needle is flushed with 1 mL of local anesthetic at the end of the procedure to flush the needle track of any neurolytic agent remaining.

An alternative two-needle technique has also been described in which the celiac trunk is visualized in a transverse view and the needles are introduced from the lateral sides of the transducer. The authors claim better visualization of the injectant with this approach.

**COMPLICATIONS**

Side effects such as orthostatic hypotension and transient diarrhea are known to occur in approximately 38% and 44% of patients, respectively. A frequently reported complication is postprocedural pain, which occurs in about 90% of patients. The original abdominal pain may be aggravated, or new pain may appear in the back or shoulder. The pain usually subsides in 24 to 48 hours. Other rare complications are retroperitoneal hematoma, pneumothorax, renal and intestinal injury, and paraplegia secondary to neurolytic injection into the epidural or spinal canal or secondary to accidental injection of neurolytic agent into the artery of Adamkiewicz, all of which are reported in less than 1% of patients. Superior mesenteric vein thrombosis has been reported with alcohol NCPB. Intravascular injection of the neurolytic agent is a potential complication and can cause tremors and convulsions with phenol.

**CONCLUSION**

CPB is a century-old interventional technique that has the most rigorous evidence-based assessment of its efficacy. It is generally safe and accurate and compares favorably with conservative analgesic methods. Newer approaches, such as bedside ultrasound guidance and cone beam CT, are promising.

**SUPERIOR HYPOGASTRIC PlexUS BLOCK**

A variety of visceral and somatic causes can lead to pelvic pain. Such conditions may include endometriosis, inflammatory disease, postoperative adhesions, and cancer. Frequently, the pain is diffuse and vague, a condition called visceral pain, and may be interrupted with a targeted sympathetic blockade. The original technique of percutaneous superior hypogastric plexus neurolytic blockade for pelvic pain was developed by Plancarte in 1990 following reports of pain relief after cordotomy. This spurred investigation for alternative techniques to perform a superior hypogastric plexus block (SHPB), including the use of image guidance.

**CLINICALLY RELEVANT ANATOMY**

The superior hypogastric plexus (SHP) is a bilateral continuation of the paravertebral sympathetic chain with contribution from aortic plexus nerve fibers. It is a retroperitoneal midline structure that is usually located anterior to the lower third of the fifth lumbar vertebral body and extends caudally to the upper third of the first sacral body (see Fig. 56.1). The plexus lies anteromedial to the psoas muscle and caudal to the bifurcation of the iliac vessel. The SHP sends out multiple branches to various smaller plexuses supplying sympathetic...
innervation to all the pelvic viscera except the ovaries and fallopian tubes. It extends distally as the hypogastric nerves, which form the inferior hypogastric plexus.

**INDICATIONS**

Blockade of the SHP provides relief of pain originating from pelvic viscera secondary to various types of cancer and endometriosis. SHGB has also been reported to provide relief from postprostatectomy penile pain, urethral pain, and post-uterine artery embolization pain.\(^{59-62}\)

**EVIDENCE FOR SUPERIOR HYPOGASTRIC BLOCK**

Using a bilateral posterior paravertebral needle insertion technique under fluoroscopic guidance, SPHB provided greater than a 70% reduction in pain in 28 patients with cancer pain. This was replicated in another 26 patients with similar results and no major complications.\(^{63}\) A subsequent 3-year review of 115 neurolytic blocks from two centers showed similar success with decreased opioid consumption.\(^{64}\) A volume of 8 mL on each side provided successful pain relief in 72% of patients. The spread of tumor may hinder adequate distribution and thus require higher volumes with limited pain relief. The transdiscal approach offers similar pain relief with decreased procedure time, although infectious diskitis has been reported. There is still a potential for vascular and ureteral injury, but it may not have any long-term implications.\(^{65}\)

**AVAILABLE TECHNIQUES**

The original description outlined a posterior approach under fluoroscopic guidance for placement of needles on either side of the anterolateral part of the fifth lumbar vertebral bodies. Neurolytic blocks are performed after diagnostic local anesthetic injections have confirmed spread of the contrast dye. The main disadvantage of this approach is the necessity for multiple redirections secondary to encountering the transverse process or the nerve roots. A modification of this technique is the simpler fluoroscopically guided anterior approach\(^{66}\) or the posterior transdiscal approach.\(^{65}\) CT guidance has been used for both the posterior and anterior approaches. Anterior placement may be advantageous when a patient is unable to lie prone, and contact of the needle with the lumbar nerve roots is avoided. Antibiotic prophylaxis is recommended with the anterior and transdiscal approaches because of the potential for bowel perforation and diskitis, respectively. A single-needle technique may be possible when spread of the tumor is not extensive.\(^{67,68}\) Single-needle and two-needle techniques with the target being inferior to the aortic bifurcation and just anterior to the iliac vessels have been used.\(^{68,70}\) Fluoroscopy- and CT-guided transdiscal approaches have also been used with no complications reported.\(^{71,73}\) With the patient prone, an oblique fluoroscopic image is centered on the lateral part of the L5/S1 intervertebral disk such that about 1 cm of it is seen lateral to the S1 superior articular process. A 22-gauge Chiba-type needle is directed via the coaxial view through the disk and placed just anteriorly. Following injection of contrast dye and real-time visualization for appropriate spread, a local anesthetic or neurolytic solution is injected (Fig. 56.17). Injectants containing steroids have also reported to provide lasting pain relief.\(^{30}\) Despite better visualization of soft tissue and vascular structures, CT guidance carries the risk of an increased radiation dose. More recently, an ultrasound-guided anterior approach was described that permits visualization of the iliac vessels and vertebral body.\(^{75}\) It may be prudent to confirm spread of contrast dye with fluoroscopy, especially before instillation of neurolytic solutions, when the needle was placed under ultrasound guidance.

With a curved-array transducer and the patient supine, the aorta is traced caudally until it bifurcates into the iliac arteries (Fig. 56.18). Use of color Doppler facilitates proper identification. Medial and posterior to the bifurcation, the fifth lumbar vertebral body may be visualized. The target is over the anterior and most caudal portion of the fifth lumbar vertebral body. Planning of the trajectory is based on the location of the vessels (Fig. 56.19). The area over the possible needle entry point is prepared and draped. Using sterile technique, a 22-gauge spinal needle is advanced either out of plane or in plane to the anterolateral border of the vertebral body. Following placement it may be prudent to confirm accuracy with digital subtraction angiography before injection of local anesthetic. The typical volume used is approximately 10 mL on each side. Neurolytic agents may be
used after confirmation of pain relief with local anesthetic. Administration of antibiotic beforehand is recommended.

COMPLICATIONS

Intravascular injection, inadequate spread, incomplete pain relief, and prolonged sensory and motor deficits have all been reported. Other potential complications include diskitis with the transdiscal approach, dislodgment of atheromatous plaque from major vessels, retroperitoneal hematoma, and perforation of the bowel or urinary bladder with the anterior approach.

CONCLUSION

SHPB may be performed for relief of pelvic pain under imaging guidance through either an anterior or posterior approach. The major advantage of an anterior approach is patient comfort. Although CT- and fluoroscopy-guided approaches have been described, they have the disadvantage of excessive radiation exposure. An ultrasound-guided anterior approach may be used for needle placement with subsequent fluoroscopic contrast confirmation. The safety, reproducibility, and efficacy of this technique still need to be established.

CLINICALLY RELEVANT ANATOMY

The ganglion impar is an irregularly shaped terminal ganglion of the sympathetic chain that is usually located close to the midline. The variably shaped ganglion is approximately 4 mm long. It may be located anywhere from the anterior surface of the sacrococcygeal junction to the lower coccygeal vertebral bodies. The exact location follows a gaussian distribution centered on the first to second coccygeal vertebrae. The rectum is situated anterior to the ganglion. Fibers from the ganglion travel to the sacral spinal nerves along the gray rami communicantes.

INDICATIONS

GIB is indicated for sympathetically mediated pain in the region of the anus, distal part of the rectum, urethra, and vagina. Coccygodynia following trauma, infection, degenerative changes, and subluxation has also been relieved temporarily with this block.

EVIDENCE FOR THE USE OF GANGLION IMPAR BLOCK

Anecdotal evidence has demonstrated the usefulness of GIB and different techniques. Greater than 50% relief of pain from a variety of painful perineal disorders was obtained following GIB under fluoroscopic guidance via a trans-sacrococcygeal approach. Retrospective reviews of CT-guided GIB have shown greater than a 75% decrease in pain scores for up to 6 months. No adverse events have been reported. More recently, ultrasound-guided, fluoroscopy-confirmed GIB has also been found to be successful.

AVAILABLE TECHNIQUES AND APPROACHES

The initial description of GIB outlined a method based on insertion of a bent needle through the anococcygeal ligament with a finger in the rectum to detect perforation. Imaging guidance markedly increased technical success rates. Fluoroscopy facilitated further development, including the transcoccygeal, transarticular, transdiscal, intracoccygeal, and paracoccygeal approaches. When combined with the use of contrast agents to visualize the spread of injectant, these techniques were associated with a modicum of safety. However, bowel gas shadow, tumor infiltrates, and osteoporosis may hinder proper visualization. Other limitations include an inability to visualize adjacent soft tissues and radiation exposure. CT-guided techniques from a lateral approach provide visualization of the ganglion and soft tissues. Ultrasound-guided techniques from a lateral approach provide real-time visualization and avoidance of radiation. To enhance safety, most practitioners using ultrasound guidance recommend fluoroscopic confirmation of the spread of contrast dye before injection of neurolytic agents. Several modifications in needle design, including arc and double-bent needles, were claimed to improve the safety of the procedure. However, cryotherapy or radiofrequency ablation cannulae cannot be customized. In addition, such modifications make it more difficult to extract the stylet after proper positioning of the needle. A needle-in-needle technique may avoid trauma to the disk and coccyx, in addition
to decreasing needle breakage during the transcoccygeal approach (Fig. 56.20). It may also decrease the incidence of infection. Following diagnostic local anesthetic injection, either neurolytic injection, cryoablation, or radiofrequency ablation of the ganglion may be performed.

TECHNIQUE OF ULTRASOUND-GUIDED GANGLION IMPAR BLOCK

The patient is positioned prone with a pillow underneath the pelvis and the hips externally rotated to provide exposure of the perineum. The skin is prepared with a suitable antiseptic solution and draped in a sterile manner. A preliminary scout scan is performed in the transverse and longitudinal views with a linear-array transducer in a sterile sleeve to visualize the sacrum and coccyx. The coccyx is then brought to the middle of the field in a longitudinal view and a suitable trajectory is planned (Figs. 56.21 and 56.22). While keeping the coccyx in the longitudinal view, a skin wheal is raised with 1% lidocaine at the point of needle entry just caudal to the transducer. A Quincke-type spinal needle is then directed from the caudad to the anterior part of the first coccygeal vertebral body via an in-plane technique with real-time visualization of the needle (Fig. 56.23). The tip of the needle may not be visualized clearly beneath the coccyx because of the acoustic shadow. Alternative methods are to use an out-of-plane technique for the trans-sacroccocygeal or paracoccygeal approaches. This provides a smaller trajectory, but needle visualization is poorer.

Further confirmation is provided by a lateral fluoroscopic view, which should show the needle to be suitably positioned just anterior to the coccyx and posterior to the rectum. Under fluoroscopic guidance, 0.5 to 1 mL of contrast agent is injected to confirm proper spread of the dye, which appears as a “comma sign,” before injecting a local anesthetic, steroid, or neurolytic substance (see Fig. 56.20). Injection of a local anesthetic first to confirm pain...
reduction before steroid injection or neurolytic intervention may be recommended. The total volume required is usually about 2 to 4 mL.

COMPLICATIONS

The potential for perforation of the rectum may lead to infection. In addition, because of its proximity to the perineum, there is an additional risk for infection. Damage to the sacrococcygeal nerves is possible with the lateral approach.

CONCLUSION

Despite limited evidence, GIB is a commonly implemented technique for the management of visceral pain. Imaging guidance provides better accuracy and safety.

SUGGESTED READINGS

CHAPTER 56 — PERIPHERAL AND VISCERAL SYMPATHETIC BLOCKS

KEY POINTS—cont’d

Ganglion Impar Block

- The ganglion is the terminal midline sympathetic ganglion.
- The ganglion is commonly found over the first coccygeal vertebral body and the sacrococcygeal junction.
- A ganglion impar block provides relief of coccygodynia and pain involving the lower part of the rectum, anus, urethra, and vagina.
- Imaging guidance for performance of this block is provided by fluoroscopy, computed tomography, and ultrasound, each with its own inherent advantages and disadvantages.

SUGGESTED READINGS

The references for this chapter can be found at www.expertconsult.com.

KEY POINTS

Stellate Ganglion Block

- A stellate ganglion block has historically been used to treat numerous pain-related and unrelated conditions.
- Evidence of its efficacy is limited.
- Blind injections are inaccurate and risky.
- Ultrasound guidance is the preferred method to ensure accuracy and safety.

Celiac Plexus Block

- The celiac plexus is supplied by the greater, lesser, and least splanchnic nerves originating from T5 to T12.
- Sensory visceral nerve fibers traverse the celiac plexus and ascend to spinal centers.
- Neurolytic celiac plexus blockade is an established evidence-based method to alleviate severe abdominal pain related to inoperable malignancies.
- An analgesic or neurolytic celiac plexus block is less effective in managing nonmalignant abdominal pain.
- Bedside ultrasound guidance is particularly valuable in a palliative care setting.
- Newer cone beam computed tomography guidance is a promising technique that ensures superior procedural accuracy, limits radiation exposure, and saves time.

Superior Hypogastric Plexus Block

- The superior hypogastric plexus is a midline sympathetic center located in the retroperitoneum anterior to the fifth lumbar and first sacral vertebral bodies.
- A superior hypogastric block is an interventional technique for the management of pelvic pain.
- Fluoroscopy, computed tomography, and ultrasound have been used to guide access to the plexus.
- No formal clinical studies of ultrasound guidance for performance of this block are presently available to attest to its safety and efficacy.

Intraarticular Analgesia

Anil Gupta

INTRODUCTION

An ideal analgesic should provide pain relief locally at the site of trauma without any systemic or local side effects, preferably as long as the pain persists. Scientists have searched for this ideal analgesic for several centuries, but as yet, no such drug exists. Local anesthetics (LAs) provide excellent analgesia with minimal toxicity when they are used in safe doses. In addition, they have anti-inflammatory and anti-thrombotic effects. However, LAs have a short duration of effect, which limits their usefulness to the immediate postoperative period unless injected intermittently or continuously into traumatized tissues. Therefore, the search for LA enclosed in microspheres or administered through catheters to prolong the duration of their effect continues. Opiates are efficacious, specifically following major surgery, but have several disadvantages, including nausea and vomiting, pruritus, constipation, and rarely, respiratory depression, when administered systemically. Following the discovery and isolation of opioid receptors on peripheral nerves and joints in the late 1980s, intensive investigation into the use of opiates peripherally to obtain pain relief without significant side effects ensued. Thus, analgesia with intra-articular (IA) morphine for the relief of postoperative pain following arthroscopy and arthroscopic knee surgery has been the focus of more than 60 publications involving humans during the last 20 years, when the first reports described the clinically beneficial effects of morphine. Recently, there has been increasing focus on the use of large-volume LA injections, with or without other adjuvants, into periarticular tissue during surgery to achieve sustained analgesia following knee and hip arthroplasty. Although this method has been reported in several publications, consensus on its applicability has not yet been attained.

Most authors have used the knee joint as a model for research. However, morphine and other drugs have also been injected into other joints, including the ankle, shoulder, and elbow, for assessment of clinical effects. Among the drugs and drug combinations that have been studied, the following are the most common: LAs, opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), α₂-adrenergic agonists, anticholinesterase drugs, steroids, and ketamine (Table 57.1). Despite the relatively large number of publications on these issues, a well-designed study recruiting a sufficient number of patients and asking the relevant questions has yet to be performed. This review of the literature summarizes the findings of some of the studies published and focuses on the drawbacks, limitations, and problems that surround this complex but interesting question of the efficacy of IA analgesics in the clinical setting.

VARIATIONS IN PAIN INTENSITY AND METHODS OF MEASUREMENT

INTENSITY OF POSTOPERATIVE PAIN

Studying the efficacy of analgesics following procedures associated with only mild pain is likely to either be unsuccessful (i.e., not show analgesic efficacy) or require forbiddingly large numbers of patients to achieve statistical significance. Although a difference in pain intensity of 30% and higher is thought to be relevant, a 30% reduction in pain from 1.5 to 1.0 cm on a visual analog scale (VAS) is not necessarily of clinical importance. Therefore, when assessing the efficacy of drugs injected intra-articularly, it is likely to be more meaningful to study either patients or procedures associated with moderate to severe postoperative pain. In this way it is estimated that 20% to 30% fewer patients may need to be studied, as well as to provide meaningful assessment of drug efficacy. Because of the variation in pain intensity between operative procedures, international experts have suggested evidence-based guidelines for procedure-specific pain management, which are frequently updated with new evidence (www.postoppain.org).

BIOLOGIC VARIATIONS IN PAIN INTENSITY

Recent evidence suggests that women have more pain following arthroscopic surgery than men do, which is important when managing postoperative pain after arthroscopic procedures.79 In one study, Taenzer and colleagues studied 736 patients undergoing arthroscopic anterior cruciate ligament reconstruction (ACLR) and found that women experience greater pain intensity, which is associated with a worsened functional outcome. They concluded that these differences might result from variations in either response to analgesics or neuron processing. In another study, Rosseland and Stubhaug showed that gender might account for the differences in analgesia experienced by women after arthroscopic knee surgery, with women experiencing more pain than men do.11 Cepeda and Carr found that women have more intense pain and require 30% more morphine to achieve a similar degree of analgesia than do men.12 In addition to sex differences, variation in pain intensity during the menstrual cycle should also be considered in studies on analgesic efficacy since analgesic consumption is greater in women during the luteal phase of the menstrual cycle.13 There is also a clinically significant reduction in the intensity
of pain perception or symptoms with increasing age, which could be related to the decrease in Aβ- and C-fiber nociceptive function, delay in central sensitization, or an increase in pain thresholds.

**ASSESSMENT OF PAIN**

Pain is a subjective sensation and varies between individuals. Several methods to measure pain have been described in the literature. Although the VAS and numeric rating scale (NRS) are well described and validated in the literature, other scales have also been used. When presenting the results, it is important to specify whether pain has been assessed at rest (static pain) or during provocation (dynamic pain) since mobilization often aggravates the intensity of pain. Dynamic pain can be measured as “pain on coughing,” “pain on movement,” or pain during “knee flexion” or “leg elevation” and should be described appropriately. Measuring pain intensity at fixed time intervals after the operation may sometimes give inaccurate results, depending on the last intake of analgesics, as well as the time of the day that the pain is being measured. Thus, both pain intensity and total analgesic consumption are important when drawing conclusions. Sometimes, the “area under the curve” for pain intensity may be more relevant than the pain intensity at fixed time points. Finally, in studies on postoperative pain and analgesic consumption, it may be equally important to measure pain relief as pain intensity. However, the former is more difficult to measure since VASs or NRSs may not correctly describe pain relief, as they do for pain intensity.

**PLACEBO IN CLINICAL STUDIES**

In a randomized controlled trial, Rosseland and colleagues showed that pain after knee arthroscopy is modest and short-lived and can be treated successfully with IA saline (placebo). They also showed that the addition of 2 mg of morphine to 10 mL of saline does not reduce pain following arthroscopic knee surgery in patients with moderate to severe pain. IA saline may produce analgesia by cooling (cryoanalgesia) or by diluting IA algogenic substances. Indeed, this may represent a true therapeutic effect of saline attributable to the removal or dilution of pain-mediating substances (histamine, potassium, or vasoactive polypeptides) in the wound. Alford and Fadale also found that IA saline infusions provide similar pain relief as bupivacaine infusion following anterior cruciate ligament repair, thus suggesting that local pain mediators may be washed away by the infusion of saline. The placebo effect is well defined in the literature in studies on analgesics, and therefore it is important to include this group in randomized, double-blind trials, specifically when studying new analgesics or techniques. However, the use of placebo groups in pain trials is controversial, and this has been highlighted in the updated Helsinki declaration of 2001.

**DRUGS USED INTRA-ARTICULARLY**

**LOCAL ANESThetics**

Single doses of LAs administered intra-articularly are used frequently. LAs have been used successfully as the sole anesthetic for minor arthroscopic procedures and, when used in this way, provide adequate analgesia of short duration. In the only systematic review published in the literature on the efficacy of LA injected intra-articularly, Møiniche and associates evaluated randomized, double-blind controlled trials comparing LA with placebo or no treatment for the relief of postoperative pain following arthroscopic knee surgery. They found a significant prolongation of pain relief lasting between 30 and 50 minutes in only 2 of 6 studies; in addition, these authors also found that in 9 (of 20) studies, consumption of supplementary analgesics was reduced by 10% to 50% during observation periods of up to 4 hours. However, in most cases, the

*For studies on intra-articular morphine, the reader is referred to already published systematic reviews with extensive reference lists. NSAIDs, nonsteroidal anti-inflammatory drugs.
analgesic requirements were small to moderate, thus suggesting mild pain intensity in these studies. They concluded that the pain relief obtained with LA injected intra-articularly is mild to moderate and of short duration. This may, however, be of clinical significance in day-case surgery. In another recent systematic review and meta-analysis of the literature, the efficacy of LA injection via catheters was assessed following non–orthopedic-related surgery. The authors found very little benefit of this technique, except for short-lasting effects in patients undergoing obstetric surgery. LAS have been administered via catheters as intermittent injections or as continuous infusions into the knee joint intra-articularly, subacromially, intra-abdominally following hysterectomy, and subcutaneously following cesarean section, as well as during peripheral nerve blocks, with variable success.

MAJOR KNEE SURGERY

A summary of the articles published and the conclusions drawn by the authors during knee surgery is presented in Table 57.2. The anterior synovium, infrapatellar fat pad, and joint capsule are very sensitive to pain stimuli. Chew and coworkers tested the analgesic efficacy of 0.25% or 0.5% bupivacaine administered into the infrapatellar fat pad via a catheter after ACLR. A self-administered infusion pump (50 mL) allowed the patients to administer 4-mL doses of bupivacaine. The authors found no significant difference between 0.5% and 0.25% bupivacaine, thus suggesting absence of correlation between the dose of bupivacaine and pain intensity. It is likely that there is no direct relationship between the concentration and volume of LAS injected intra-articularly. Continuous catheter techniques were used for pain relief after knee replacement in three studies. In one study, DeWeese and associates compared continuous infusion of 0.5% bupivacaine at 2 mL/hr intra-articularly with a historical group in which patients were given controlled epidural analgesia with 0.125% bupivacaine plus fentanyl, 2 µg/mL. The IA infusion was less efficient, and higher analgesic consumption was registered during the 24-hour test period. In a double-blind study, 0.25% bupivacaine, 5 mL/hr, was compared with saline during a 48-hour IA infusion. The authors noted a significant reduction in opioid consumption, which resulted in less nausea, fatigue, and malaise and even enhanced rehabilitation and increased satisfaction. In another study, Hoenecke and colleagues found that patients undergoing knee surgery and receiving an LA infusion postoperatively experience less pain and require fewer doses of narcotic. They also found that the disposable pump allows administration of the medication on an outpatient basis. The site of LA injection (IA vs. intraperitoneal) was studied. In this study no differences were found between the groups, and the authors concluded that intraperitoneal LA has similar analgesic efficacy as IA LA after total knee arthroplasty. Warming of lidocaine appears to improve intraoperative anesthetic and postoperative analgesic conditions. Several published studies have focused on a new technique of high-volume LA (with or without adjuvants) infiltration peri-articularly, often called local infiltration analgesia, for relief of postoperative pain. Although the majority of these studies appear to be promising, some have not been equally positive. It is possible that a combination of drugs rather than simply LAS injected during surgery will offer better analgesia without significant side effects. Further studies on short- and long-term outcomes following this technique are awaited.

In summary, IA injection of LA after total knee replacement, specifically, the recently used technique of local infiltration analgesia, offers an efficacious and inexpensive method for achieving good pain relief following total knee arthroplasty.

Favors treatment Favors control
TOTAL HIP ARTHROPLASTY

Several studies have assessed the analgesic effects of LAs, with or without adjuvants, following IA and periarticular infiltration during surgery. A majority of these studies have shown better analgesia, a shorter duration of hospital stay, and improved mobilization, with some exceptions. Ropivacaine combined with ketorolac and adrenaline and infiltrated periarticularly reduced rescue analgesic consumption and decreased postoperative hospital stay when compared with epidural analgesia. Busch and colleagues found a reduction in pain during rest and on mobilization with LA infiltration and multimodal pain management in comparison to saline. In another study, no benefit of continuous infusion of 0.5% bupivacaine was noted when compared with saline for relief of pain after arthroplasty. Prolonging analgesia with postoperative infusion of drugs following hip arthroplasty does not seem to reduce pain intensity. Finally, adding LA infiltration to a multimodal pain management protocol involving the use of several analgesics does not add to the pain relief already achieved with these drugs. In summary, local infiltration analgesia using a combination of drugs is probably beneficial, but not the use of LAs alone. When using multimodal analgesia, adding LA infiltration does not add to the analgesia, and postoperative infusion of LA is not recommended for pain relief following total hip arthroplasty.

SHOULDER SURGERY

A summary of articles published on continuous LA infusion during shoulder surgery and the conclusions drawn by the authors is presented in Table 57.3. To treat postoperative pain, various local anesthetics were used with different delivery methods and concentrations. The table includes the drug/ concentration, method of drug delivery, type of surgery, type of study, and the effect on pain or analgesic intake.

*Effect of IA LA on postoperative pain following shoulder surgery. The list of studies shown is not exhaustive.

IA, intra-articular; LA, local anesthetic; VAS, visual analog scale.
pain after acromioplasty, LA administered subacromially has recently been found to be effective. In seven studies, pain was administered subacromially, and in four studies, patient-controlled regional analgesia (PCRA) was used. Savoie and colleagues found that 0.25% bupivacaine infused at a rate of 2 mL/hr decreases not only VAS scores during 48 hours of LA administration but also analgesic consumption during the first 5 postoperative days. Others reported significantly decreased VAS scores in comparison to saline when 0.5% bupivacaine was administered at an infusion rate of 2 mL/hr. In contrast to studies following knee surgery, the analgesic effect was dose dependent when 0.2% and 0.375% concentrations of ropivacaine were compared (Fig. 57.3). In two other studies, however, continuous IA bupivacaine infusion resulted in only minor analgesic effects. The use of chilled compressive dressings and NSAID medication may have contributed to the small difference seen between the test drug and placebo.

Klein and coworkers evaluated postoperative pain relief when a long-acting preoperative interscalene block (0.5% ropivacaine) was compared with continuous IA infusion of 0.5% ropivacaine, 2 mL/hr for 24 hours. IA ropivacaine resulted in lower VAS scores both at rest and during movement. Delaunay and associates compared interscalene block with subacromial LA infusion following arthroscopic rotator cuff repair. A continuous interscalene block provides better analgesia than does continuous subacromial infusion, but with an increased incidence of minor side effects. In an open study, Mallon and Thomas described a patient-controlled catheter technique based on both continuous subacromial infusion of 2% lidocaine at 2 mL/hr and self-administration of 1-mL lidocaine boluses at 15-minute intervals as needed. During the 72-hour infusion, pain relief was significantly increased in the lidocaine relative to the placebo group. In another PCRA study, 0.2% ropivacaine infused at 5 mL/hr was combined with 2-mL boluses of 0.2% ropivacaine with a 15-minute lockout time. The authors reported a significant 44% decrease in VAS scores during 48 hours. We have tested the combined analgesic effect of LA administered both into the subacromial bursa and intra-articularly via a PCRA technique (Fig. 57.4). Patients given LAs both in the bursa and subacromially had significantly lower VAS scores early postoperatively and lower morphine consumption than did those administered saline.

**PITFALLS IN STUDIES ON INTRA-ARTICULAR LOCAL ANESTHETICS**

**Intermittent versus Continuous Techniques**

Intermittent injection of drugs offers an advantage in that it prevents “overdosing” since pain is not continuous but exacerbated during certain maneuvers, such as movement, and can be either prevented or treated by the self-injection of fixed amounts of drugs intra-articularly through a catheter and an infusion pump. This technique, called PCRA and originally described by Rawal and colleagues, has now been used effectively in several studies for postoperative
injected intra-articularly by Stein in 1991 found a reduction in pain intensity following shoulder surgery,22 hand surgery,52 laparoscopic cholecystectomy,53 and cesarean section.27 In contrast, continuous infusion of LA or other analgesic combinations has an advantage in that the patient may be pain free during an unplanned movement, but at the cost of drug overdose. This method also has the disadvantage that pain relief may be inadequate during maximal pain intensity. Perhaps a combination of low-dose infusion and intermittent injections as needed may be best.51

Site of Injection of Local Anesthetic
Injections of LA at portal sites may reduce postoperative pain for short periods in a similar way as has been shown for IA injections. However, the anterior synovium, infrapatellar fat pad, and joint capsule are very sensitive to pain stimuli,34 and injections into these areas may provide better pain relief. Subacromial injections of LA have been found to provide good pain relief in comparison to placebo following shoulder surgery.22,51,54 No differences were seen in one study in which the authors injected LA intracapsularly versus extracapsularly. However, the study was small in size, and this issue has not been resolved to date.

Use of Adrenaline
Although adrenaline has been known to have analgesic efficacy for more than 100 years and recent evidence suggests that its pharmacodynamic effect is exerted via \( \alpha_2 \) adrenoceptors in the substantia gelatinosa in the dorsal horn of the spinal cord,52 controlled studies on the use of adrenaline intra-articularly as an analgesic are lacking. Certainly, epidurally administered LA with fentanyl added to adrenaline provides better pain relief than do LA and fentanyl alone.56 Whether adrenaline has a preventive, pharmacologic (\( \alpha_2 \) adrenoceptors), or physiologic effect (decrease in blood flow) remains uncertain. More studies on this important subject are warranted.

Volume and Dose of Local Anesthetic Injected Intra-articularly
Both the volume and the dose (milligrams) of LA injected intra-articularly may play a role in the analgesic efficacy of LA postoperatively. Small volumes of LA injected intra-articularly may theoretically leak out of the IA space, thus limiting its usefulness. It is difficult to fill the entire joint with LA because of the sensitive joint capsule. Similarly, small doses of LA may not have the desired effects. In one study, Gottschalk and coworkers found a reduction in pain intensity postoperatively at some time points in patients receiving 3.75 mg/mL versus 2 mg/mL ropivacaine.44 (see Fig. 57.3). In a systemic analysis of the effect of IA LA on postoperative pain by Meiniche and colleagues, a mean dose of 90 mg bupivacaine was recommended with an injection volume of between 20 and 40 mL.1 Recent studies have found no relationship between the volume, concentration, or dose of LA and postoperative pain, except perhaps following shoulder surgery.

MORPHINE
The presence of peripheral morphine receptors has been noted.2 The first clinical study on the efficacy of morphine injected intra-articularly by Stein in 1991 found a reduction in pain intensity during the first 6 postoperative hours following minor arthroscopic surgery.2 This analgesic effect could be confirmed due to morphine via peripheral receptors since IA injection of naloxone reversed the analgesic effect.3 Since then, interest in the IA effects of morphine has grown by leaps and bounds, with more than 50 published studies assessing the efficacy of morphine injected intra-articularly into the knee joint. The results and conclusions have, however, been contradictory in these studies. In a systematic review of the literature in 1997, Kalso and coauthors concluded that “intra-articular morphine may have some effect in reducing postoperative pain intensity and consumption of analgesics.”7 Gupta and colleagues evaluated 45 studies in a meta-analysis of the literature and found “a definite but mild analgesic effect, which could be dose-dependent” (Fig. 57.5). However, these authors could not completely exclude a systemic effect of IA morphine.8 Another systematic review by Kalso and coworkers found that 5 mg of morphine injected intra-articularly into the knee joint provides relief of postoperative pain for up to 24 hours.9 They also concluded that when there is “no pain, there is no gain,” thus suggesting that pain intensity must be at least moderate to detect any significant analgesic effects of morphine administered intra-articularly. Rosseland and colleagues confirmed that a postoperative analgesic effect of IA morphine is found only in a subgroup of patients with greater pain intensity in the immediate postoperative period.57 They also found that women perceive greater pain than men do, and therefore it is important to consider sex differences in studies on pain, thus adding another dimension to this complex problem. In one published systematic review, the authors showed that when only high-quality studies were considered in which pain intensity was moderate to severe, 5 mg IA morphine provided no significant analgesia postoperatively.3 This was in contrast to the findings of Kalso and associates presented earlier.9

PITFALLS IN STUDIES ON INTRA-ARTICULAR MORPHINE
Use of Systemic Opioids Intraoperatively
A substantial number of studies have used intraoperative analgesics such as fentanyl, which complicates the issue since analgesic efficacy (when seen) could be due to the preemptive or pharmacologic effect of these opiates in the early postoperative period. Studies in which only LAs are used intraoperatively without general anesthesia or in which general anesthesia is given without opioids may be more important to exclude this possibility. In two studies, the authors assessed postoperative pain following arthroscopy performed under LA without intraoperative opioids. In one study, Gupta and colleagues found no benefit of morphine, 3 mg intra-articularly, over saline.58 In another published study, Ng and coworkers found improved analgesia when morphine and ketorolac are combined with ropivacaine versus ropivacaine or bupivacaine alone.59 Whether this effect was due to ketorolac alone or its combination with morphine remains unclear.

Method of Injection of Drugs Intra-articularly
Variations in techniques of injection of drugs intra-articularly may account for some of the differences seen between studies. For instance, drugs have been injected via the arthroscope
under direct vision or at the end of surgery intra-articularly via a needle. Injection of drugs through the arthroscope before it is removed may result in some of the drug either “running out” from the site of injection into tissue planes or, in the worst scenario, exiting through the incision sites. This depends naturally on the volume of the injectant and the meticulousness of the operator. A small volume of injectant that leaks out of the sore would not have any meaningful effect, whereas large volumes may not remain in the limited IA space. Similarly, a quick injection through the arthroscope and immediate removal may not ensure that the drugs remain where they are intended to be. Thus, the volume of drug remaining in the IA space may vary and account for some of these differences. Injections of drugs postoperatively through a catheter placed intra-articularly via an arthroscope may enable the entire volume of the drug to remain intra-articularly, but very few studies have used this simple but effective method. Finally, intermittent or continuous infusion of drugs via a catheter may prolong the analgesic effects and has been used recently in many studies. This technique, as opposed to a single injection of the drug via the arthroscope or a needle, needs to be further evaluated.

**Systemic Effect of Intra-articular Morphine**

It remains unclear whether the analgesic effects of IA morphine are due to its systemic absorption. Therefore, a similar dose of morphine was injected by the intramuscular (IM), intravenous (IV), and IA routes in several studies. The results were equivocal, with some studies documenting an equianalgesic effect and others documenting better analgesia with IA morphine. No clear relationship appears to exist between the dose of morphine and analgesia when comparing IA with IM/IV morphine. Plasma concentrations of morphine were measured after IA injection of 1 and 5 mg morphine in one study and after IV and IA injection (5 mg) in another study. In the first study, two patients had spuriously large concentrations and two others had undetectable levels (<1 ng/mL). In the remaining 6 of 10 patients, the authors found lower concentrations of morphine than usually described after parenteral morphine administration. In the second study, the plasma concentration measured 2 hours after IA morphine administration was approximately 50% of the concentration achieved after the same dose administered by the IV route. In a third study, although the maximum plasma concentration following IA injection was lower than after IV injection, the area under the curve during hours 0 to 6 was similar, thus suggesting that substantial amounts of morphine are absorbed into the systemic circulation over time. In conclusion, whether there is a systemic effect of morphine following IA injection remains unclear.

**Dose-Response Effect**

The effects of increasing IA doses of morphine on postoperative analgesia have also been studied. Better postoperative analgesia was obtained with 5 mg than with lower doses. Denti and coworkers found that 2 mg of morphine is adequate for minor arthroscopic procedures but 5 mg is necessary for anterior cruciate ligament surgery, thus suggesting that the dose of IA morphine is dependent on pain intensity. Although low doses of IA morphine (<1 mg) should theoretically produce a high concentration of IA morphine, a dose-response effect was demonstrated by Likar and associates with IA doses of 1 to 4 mg. Kalso and colleagues also demonstrated in their systematic review of the literature that all studies in which 5 mg of morphine was injected intra-articularly showed a positive result at all time periods. Thus, clinical data seem to suggest that larger IA doses of morphine result in better pain relief.

**Use of a Tourniquet**

Use of a tourniquet on the thigh has been proposed to reduce pain intensity and may account for the differences in results. The mechanism for this effect is unclear, and
Further clinical studies in this area are urgently needed. However, this was not confirmed by others. Many surgeons do not use a tourniquet while performing arthroscopic procedures on the knee, and some joints are not accessible to a tourniquet, so this method may not always be applicable.

Role of Inflammation

Marchal and colleagues classified procedures a priori into low inflammatory (diagnostic arthroscopy, partial meniscectomy) or high inflammatory (synovial plica removal, patellar shaving, anterior cruciate ligament repair) and found that operative procedures associated with low-inflammatory states respond best to bupivacaine whereas those associated with high-inflammatory states respond better to IA morphine, thus supporting the theory that inflammation is a prerequisite for the peripheral analgesic effect of opioids. Others have suggested that upgrading of morphine receptors during states of inflammation may account for its improved efficacy, a phenomenon that has been well documented in a rat model. However, this was not confirmed by others. Many surgeons do not use a tourniquet while performing arthroscopic procedures on the knee, and some joints are not accessible to a tourniquet, so this method may not always be applicable.

PETHIDINE

In addition to being an opioid, pethidine is unique in having LA effects and has been used as the sole anaesthetic during spinal anesthesia and analgesia. Therefore, the analgesia following IA injection of pethidine may have an effect as an LA, as well as via peripheral morphine receptors. IA administration of 5% pethidine with adrenaline was found to be comparable to 5% lidocaine with adrenaline during arthroscopy of the ankle. However, lower pain scores at rest were found postoperatively than with IA prilocaine. In another study, 1 mg morphine, 10 mg pethidine, or 10 µg fentanyl resulted in similar pain intensity and analgesic consumption regardless of whether the drugs were administered intra-articularly or systemically. The authors concluded that the analgesia seen following IA pethidine may be identical to that following its systemic administration. Lyons and coworkers compared the effects of morphine, pethidine, and placebo and concluded that the LA effect of pethidine may be responsible for the improved early analgesia but that its duration of action was shorter than that of morphine. Finally, Ekblom and colleagues found that pethidine, 200 mg intra-articularly, provides the best analgesia and that the effect is not potentiated by the addition of adrenaline and prilocaine. However, in the dose range of 50 to 200 µg of pethidine intra-articularly, analgesia is due to both peripheral and central mechanisms. A summary of the studies on IA administration of pethidine is presented in Table 57.4.

FENTANYL

Studies published on IA fentanyl are summarized in Table 57.5. Fentanyl, like pethidine, has been shown to have some LA effect. In a randomized double-blind study, IA fentanyl, 50 µg, was compared with IA bupivacaine after knee arthroscopy. During the first 2 postoperative hours, patients receiving 0.25% IA bupivacaine had superior analgesia in comparison to IA fentanyl. However, VAS pain scores during the next 18 hours were similar between IA bupivacaine and fentanyl. In another study, 50 µg fentanyl was compared with placebo. Pain scores were lower during 8 hours in the IA fentanyl group than in the placebo group. Thus, fentanyl at a dose of 50 µg does produce analgesia that is better than placebo but similar to that with bupivacaine. However, more studies are warranted, specifically to compare IV with IA fentanyl. Plasma concentrations of fentanyl have not been measured following IA injection to exclude a possible systemic effect.
PART 6 — NERVE BLOCK TECHNIQUES

SUFTENANIL

Studies published on IA sufentanil are summarized in Table 57.5. Sufentanil is very fat soluble and can therefore easily cross the synovial membrane. When 10 µg of IA or 5 µg of IV sufentanil was compared with placebo after arthroscopic knee surgery, it was found that VAS scores at rest and during movement are significantly lower in the sufentanil groups than in the control group postoperatively and at day 1. In addition, analgesic consumption was significantly lower and time until discharge home from the postanesthesia care unit was significantly shorter in the sufentanil groups. However, there was no significant difference between IA and IV sufentanil. Therefore, a systemic effect of IA sufentanil could not be ruled out. In another study, Kizilkaya and colleagues injected sufentanil, 10 µg intra-articularly, and found better postoperative analgesia and less analgesic consumption than with saline following knee arthroscopy. In yet another study, a continuous 5-mL/hr infusion of ropivacaine, 2 mg/mL, plus sufentanil, 0.2 µg/mL, combined with patient-controlled analgesia boluses of 5 mL, each with a lock-out period of 2 hours, was administered intra-articularly and compared with epidural analgesia or continuous femoral blockade with the same infusion regimen postoperatively. In one study, the authors did not find improved analgesia when IA sufentanil was added to a multimodal analgesic regimen following anterior cruciate ligament repair. The analgesic effect of the IA infusion was insufficient when pain scores were higher.

STERoidal AND nONSTERoidal ANTI-INFLAMMATORY DRUGs

Several studies published in the literature have assessed the effects of NSAIDs, specifically, ketorolac and tenoxicam injected intra-articularly, on postoperative pain following arthroscopic surgery (Table 57.6). Studies on IA methylprednisolone are few and involve mostly chronic pain states, which does not allow any definite conclusions to be drawn. In one study on acute pain, the authors injected methylprednisolone combined with LA and morphine into the ankle joint and compared it with placebo. This combination reduced pain, joint swelling, time of immobilization, duration of sick leave, and return to sports after the arthroscopic procedure. However, 1 of 18 patients had transitory purulent arthritis requiring antibiotics and arthroscopic synovectomy. In another study, sufentanil was compared with sufentanil and methylprednisolone during arthroscopic meniscectomy. The combined use of IA...
KETOROLAC

In a study on the effects of ketorolac and bupivacaine, it was noted that the group that received a combination of IA bupivacaine and IA ketorolac had decreased postoperative pain, decreased need for postoperative analgesics, and increased analgesic duration. Some studies using IA ketorolac for postoperative pain management have been withdrawn from the literature since the previous edition of this book and are therefore excluded from this review. Gupta and colleagues found a dose-dependent reduction in pain intensity following ketorolac injected intra-articularly, with the maximal effect occurring with 60 mg. Calmet and coworkers found that 60 mg ketorolac provides a better analgesic effect than does 10 mL of 0.25% bupivacaine or 1 mg of morphine when injected intra-articularly. In another study, Convery and associates showed that 5 mg IA ketorolac provides similar analgesia as 10 mg IV ketorolac following knee arthroscopy. It is possible that the large doses of ketorolac administered intra-articularly by Gupta and colleagues and Calmet and coworkers may exert their effects via systemic absorption of the drug injected intra-articularly. However, as in the case of morphine, it is not known whether therapeutic plasma concentrations of IA ketorolac can be achieved, which may suggest a systemic as well as a peripheral effect.

TENOXICAM

Colbert and associates showed that IA tenoxicam results in superior postoperative analgesia and reduces postoperative analgesic requirements when compared with IV tenoxicam in patients undergoing day-case knee arthroscopy. Elhakim and coworkers showed that IA tenoxicam, 20 mg, provides better analgesia and decreases the requirement for postoperative analgesics when compared with IV tenoxicam, 20 mg. Guler and colleagues found that better analgesia is attained with IA tenoxicam than with saline. Talu and associates found that IA injection of tenoxicam, 20 mg, and bupivacaine is a simple, safe, and effective method of analgesia after arthroscopic meniscectomy with high patient satisfaction. Cook and coworkers showed that the use of IA tenoxicam, 20 mg, at the end of arthroscopy reduces oral analgesic requirements during the first day after the operation but does not alter the patient’s perception of pain. Finally, in a systematic review of the literature, Rømsing and associates found four studies comparing IA NSAIDs with systemic administration (Fig. 57.7). The results showed a statistically significant effect in favor of IA NSAIDs. The authors concluded that there is evidence for a clinically relevant peripheral analgesic action of IA NSAIDs.

In summary, when comparing ketorolac or tenoxicam with placebo injected intra-articularly, all studies found a better analgesic effect of these drugs. The duration of postoperative analgesia varied in these studies. Several studies reported better pain relief following IA than following IV
tenoxicam, which would suggest that analgesia is mediated via peripheral IA receptors.

### CLONIDINE

α₂-Adrenergic agonists have been shown to have a central effect via the dorsal horn of the spinal cord and even supratentorially, as well as via peripheral analgesic receptors. All studies using IA clonidine have universally found improved analgesia when injected alone or in combination with other drugs (Table 57.7). Gentili and colleagues found that 150 µg clonidine administered intra-articularly provides analgesia unrelated to vascular uptake of the drug since subcutaneous administration of a similar dose is not equally effective.97 In a second study comparing the effects of 150 µg clonidine with 2 mg morphine, Gentili and associates found a similar analgesic effect of both drugs.98 In another study, peripheral codelivery of an opioid and an α₂-agonist resulted in improved postoperative pain relief when compared with each single agent given alone.99 IA administration of 150 µg clonidine was also found to have longer-lasting pain relief postoperatively than was 5 mg of preservative-free morphine.100 The combination of morphine (3 mg) and clonidine (1 µg/kg) resulted in decreased postoperative pain and analgesic use, as well as an increased analgesic duration when compared with either drug alone in patients undergoing knee arthroscopy101 (Fig. 57.8). There was also a significant benefit from the individual IA administration of both clonidine and morphine versus placebo.102 Furthermore, there was an increased time to first analgesic request and a decreased need for postoperative analgesics. Finally, in a comparative study of several different IA analgesics, the authors found that clonidine or neostigmine provides the best analgesia.103

In summary, clonidine produces analgesia when injected intra-articularly, and the effects are probably comparable to that of morphine or neostigmine alone. Clonidine combined with morphine appears to increase analgesia but not combinations with neostigmine. However, hypotension can be a problem when 150 µg clonidine is administered intra-articularly.

### KETAMINE

In an animal study, Zhou and colleagues found that peripheral injections of ketamine and other N-methyl-D-aspartate (NMDA) receptor antagonists reduce glutamate-induced

*The list of studies is not exhaustive. IA, intra-articularly; VAS, visual analog scale.*
Long-lasting analgesia was found in humans following IA ketamine, which was comparable to IA neostigmine but less effective than IA bupivacaine. Rosseland and coworkers studied patients with moderate to severe pain after IA arthroscopy. In this study, IA ketamine, 10 mg, had no analgesic effect on pain after arthroscopy when compared with IA injection of saline, 10 mL. IM ketamine, however, showed significantly better early pain relief than IA administration did, thus suggesting a systemic effect. In another study, no differences were found when ketamine, 0.5 mg/kg, was injected intra-articularly versus saline injected intra-articularly. Batra and colleagues found that the combination of bupivacaine-ketamine appears to provide better pain relief than IA ketamine alone after day-case arthroscopic knee surgery. In conclusion, the efficacy of IA ketamine, if any, is limited, and therefore it cannot be recommended today for postoperative pain management following arthroscopic surgery.

### TRAMADOL

Tramadol is a weak µ-agonist and serotonin antagonist. In three studies, IA tramadol has been found to be equianalgesic to fentanyl or morphine administered intra-articularly. In a dose-response study, 20, 50, and 100 mg of IA tramadol was compared with IV tramadol in the same doses. It was found that IA administration of tramadol prolongs the duration of analgesia, which was longest when 100 mg was administered. However, nausea and vomiting were most frequent when using this dose. In another study, IA tramadol, 1.5 mg/kg, resulted in pain relief comparable to that with IA fentanyl, 1.5 µg/kg. It has been reported that 50 mg IA tramadol provides analgesia equivalent to that with 5 mg IA morphine. The combination of IA tramadol plus periarticular bupivacaine has also been shown to give better pain relief with less analgesic requirement following arthroscopic outpatient partial meniscectomy. However, the pain relief was better only during minutes 0 to 30. In another study, the authors found that an IA admixture of 100 mg tramadol with 0.25% bupivacaine provides a pronounced prolongation of analgesia when compared with either drug alone. In summary, mild analgesic effects of tramadol comparable to those of IA morphine have been demonstrated, but side effects, including postoperative nausea and vomiting, dominate when the dose is 100 mg or higher.

### NEOSTIGMINE

Cholinergic agonists and cholinesterase inhibitors administered systemically display a dose-dependent analgesic effect mediated through the activation of ascending and descending cerebral cholinergic pathways. These effects are even more profound when the drugs are administered spinally. Although Gentili and colleagues found that neostigmine, 500 µg, is equianalgesic to clonidine, 150 µg, but better than placebo, others have not found any analgesic effect of IA neostigmine over placebo but an excellent effect when injected epidurally. In another study, IA neostigmine was found to be equianalgesic to ketamine. Alagol and associates compared the analgesic efficacy of neostigmine with that of clonidine, tenoxicam, bupivacaine, morphine, and placebo and reported that the best analgesia is produced by neostigmine or clonidine. In a dose-response study it was found that neostigmine, 500 µg, produces moderate but significant analgesia. Shafer argued that release of acetylcholine does not occur at the nerve endings within the IA space and, therefore, neostigmine cannot have an effect via anticholinesterase activity. However, other mechanisms such as hyperpolarization of neurons, reduction in the release of pronociceptive neurotransmitters, or activation of the nitric oxide–cyclic guanosine monophosphate pathway might mediate this peripheral cholinergic antinociception by elevating endogenous acetylcholine levels.

In summary, it is difficult to draw any definite conclusions on the effects of neostigmine injected intra-articularly because of opposing results in the literature. Although some studies have found it to be efficacious, a theoretical explanation for its analgesic effect is currently lacking.

### DRUG COMBINATIONS

Many drugs have been used in combination to potentiate the effects of single agents. Combining analgesics with different mechanisms of action has the advantage of reducing the side effects of individual drugs. However, few studies have compared these combination of drugs administered by the IV or IA route to exclude a systemic effect.
INTRA-ARTICULAR INJECTIONS WITHOUT CATHETERS

Ketorolac has been combined with morphine and ropivacaine and shown to reduce pain after arthroscopic knee surgery. In a recent study, Ng and colleagues compared the analgesic efficacy of a combination of ropivacaine, morphine, and ketorolac with that of ropivacaine administered alone intra-articularly and found that morphine and ketorolac enhance the analgesia produced by LA alone, reduce postdischarge analgesic consumption, and improve activities of daily living without increasing side effects after ambulatory arthroscopic knee surgery. Ketorolac has also been combined with LAs and, when compared with ketorolac alone, was found to reduce pain intensity. Similarly, clonidine has been combined with morphine, as well as with LAs, and was demonstrated to improve analgesia. When comparing the analgesic effects of clonidine with those of neostigmine, it was shown that IA administration of 150 µg clonidine, 500 µg neostigmine, or both produces postoperative analgesia and that their combination is not more effective. However, a significantly greater number of patients who had received clonidine had at least one episode of hypotension or bradycardia. The combination of lidocaine, pethidine, and tenoxicam given intra-articularly resulted in superior analgesia and reduced oral analgesic requirement during the first day after arthroscopy when compared with lidocaine and pethidine alone. It has also been shown that soft tissue and IA injection of a long-acting LA with epinephrine and morphine provides better pain control in the immediate postoperative period, decreases blood loss, and decreases the need for rescue narcotics and reversal agents. As mentioned earlier, several studies have been performed in the last few years in which the authors used a combination of LA, NSAID, and epinephrine periarticularly and intra-articularly in large volumes via the local infiltration analgesia technique during knee and hip arthroplasty, and most studies have shown positive effects on pain intensity, rescue analgesic requirements, duration of hospital stay, and pain satisfaction.

SAFETY OF INTRA-ARTICULAR ANALGESICS

INTRA-ARTICULAR INJECTIONS VIA CATHETERS

In contrast to single injections, intermittent injections or infusions of analgesics have been used intra-articularly to prolong analgesia. Thus, in one study, 0.2% ropivacaine was combined with sufentanil, 0.2 µg/mL, as an infusion (5 mL/hr) during arthroscopic ACLR. The authors concluded that either an epidural or continuous femoral nerve block results in adequate pain relief in patients undergoing ACLR. However, IA analgesia seemed to be insufficient for pain management. In contrast, Rasmussen and Kehlet used a continuous infusion of a combination of ropivacaine and morphine following total knee replacement in a non-randomized nonblinded study and found that it reduces pain and enhances rehabilitation. Morphine administered intra-articularly may reduce postoperative pain when combined with other drugs. In one study, morphine combined with ketorolac for IA pain relief following minor arthroscopic procedures resulted in a synergistic effect. When using PCRA, the combination of IA ropivacaine, morphine, and ketorolac has also been demonstrated to be superior to saline or a combination of ropivacaine and morphine administered intra-articularly following repair of the anterior cruciate ligament. A continuous infusion of morphine and bupivacaine has been used for pain relief after subacromial arthroscopy. These authors studied the analgesic effect of a continuous subacromial infusion of bupivacaine and morphine and found that pain scores at rest and supplemental analgesic requirements were lower postoperatively than in patients receiving saline infusion.

In summary, combinations of drugs may be used for pain relief postoperatively after knee surgery with the following results: ketorolac combined with morphine, LA, or both results in better pain relief than either drug alone. Clonidine combined with morphine or LA offers better pain relief in some studies but not all. Morphine and LA combined together have mild benefits and are not as efficacious as when they are combined with NSAIDs.

SAFETY OF DELIVERY SYSTEMS

For ambulatory practice, the IA catheters are connected to either disposable elastometric pumps (Homepump, I-Flow Corp; Infusor, Baxter) or electronic pumps (Grasby PCA, Microject Sorensen Medical). The IA analgesic techniques are based on continuous, patient-controlled, or both continuous and patient-controlled infusions. When the continuous-infusion technique with elastomeric pumps is used, the rate of flow is controlled by the lumen of the catheter. By using simple techniques (i.e., opening a clamp [Homepump] or pressing a button [Infusor or Homepump]), the patient may self-administer analgesics using the concept of patient-controlled regional analgesia (PCRA). Ilfeld and colleagues tested different pumps for continuous regional analgesia and found that accuracy differed significantly among the pumps, with variations in flow rate of ±15%. An increase in temperature also affected flow rates to varying degrees, with infusion rates increasing from
0% to 25% for different models. Capdevila and associates\textsuperscript{125} compared an elastomeric pump (Infusor) and electronic pumps (Graseby and Microject) and found that the elastomeric pump is as effective as the electronic pump and that the elastomeric pump is less expensive, has fewer technical problems, and gives better patient satisfaction.

**TECHNICAL PROBLEMS WITH CATHETERS**

In some studies it has been reported that the catheter can be dislodged,\textsuperscript{22} disconnected,\textsuperscript{126} or partially blocked at the outlet.\textsuperscript{29} Better methods need to be explored to retain the catheter firmly in position while allowing easy removal. With the older elastomeric balloon pump technique there was a risk that the patient would fail to close the clamp, thereby resulting in the contents of the pump emptying within 1 hour. However, no case of systemic LA toxicity has been reported in the literature. The risk for systemic toxicity is low because absorption of LA from the joint structure is slow, which results in low plasma concentrations of LA\textsuperscript{22,44,59,127} (see below for further details). Also, newer and safer elastomeric pumps allow delivery of LA only if the patient presses a button, thus reducing the risk for accidental delivery of large volumes of LA. Long-acting LAs with low systemic toxicity, such as ropivacaine and levobupivacaine, are therefore recommended rather than bupivacaine.

**LOCAL AND SYSTEMIC INFECTIONS**

Infections at the site of drug injection or systemic infections are a major concern, but the reported incidence is very low. A summary of studies published in the literature in which culture specimens were taken from the catheter tip following IA placement is presented in Table 57.8. In two studies, positive isolated bacterial cultures from the catheter tip were reported in a few patients without any sign of clinical infection.\textsuperscript{22,121} In one of these studies,\textsuperscript{123} despite an increase in body temperature and higher level of C-reactive protein, the patient responded well to antibiotics and wound healing was considered to be normal. However, in two other studies,\textsuperscript{30,94} two patients were reported to have deep infection that required long antibiotic therapy. Thus, proper catheter technique using bacterial filters, sterile preparation and injection of drugs, and aseptic catheter placement during surgery is vital, particularly during orthopedic surgery.

**LOCAL ANESTHETIC TOXICITY**

Plasma concentrations of LAs have been measured following IA injection in several studies (Table 57.9). It was found that free and total plasma concentrations are much lower than known toxic plasma concentrations in humans despite sufficiently high doses of LA.\textsuperscript{22,59,127,128} Single injections of up to 500 mg ropivacaine subacromially have not produced toxic symptoms in humans.\textsuperscript{22} In the only study published on continuous infusion of ropivacaine following shoulder surgery, a dose higher than 1000 mg resulted in a free plasma concentration of less than 0.6 µg/mL, which is far below known toxic concentrations in humans.\textsuperscript{129} Therefore, the likelihood of any significant LA toxicity when the drugs are used in these doses appears to be small.
**SIDE EFFECTS AND COMPlications**

Before a new technique is used in daily clinical practice, it is important to show efficacy, as well as a low incidence of side effects and complications, in relation to existing techniques. Although the IA technique has been used extensively, reports of side effects and complications have been few. This could be because authors have not adequately documented side effects or because the incidence of side effects with this technique is truly low. Among the side effects of IA morphine that have been reported, itching is probably the most frequent but the least worrisome. Other side effects have included nausea and vomiting at the injection site when catheters have been used. There has also been a serious concern with the IA use of NSAIDs and their effect on bone healing. Though shown to be true in animal studies, there is a lack of evidence in human studies, particularly during single-dose administration. A single dose of ketorolac injected intra-articularly in rats was found to result in significantly more inflammation than occurred with saline on histologic examination after 5 days that was not attributable to the alcohol in the injectant. Morphine and ketorolac have both been found to produce mild histopathologic changes in rabbit knee joints, with morphine causing more changes than ketorolac. However, the authors concluded that both these drugs can be used intra-articularly with safety. In another study by the same group, IA bupivacaine and neostigmine were also found to cause histopathologic changes in rabbit knee joints, with neostigmine having a greater effect than bupivacaine. More studies, however, are needed on this important question. Operative site bleeding following the administration of NSAIDs is a real risk when these drugs are administered systemically. Nonetheless, apart from spontaneous IA bleeding following the use of clopidogrel or aspirin, no significant bleeding complications have been reported following IA injection of NSAIDs. Finally, evidence seems to suggest that chondrotoxicity may be a rare but serious complication of injecting LA intra-articularly. This has been specifically documented when using bupivacaine in higher concentrations and over a longer period. Therefore, we are currently using 0.2% ropivacaine without additives intra-articularly, and although our patients have been monitored for up to 6 months after surgery, no such complication has been described after more than 10 years of clinical practice. Other minor side effects do not appear to be significantly different between patients given IA neostigmine, morphine, tenoxicam, clonidine, or bupivacaine.

**FUTURE STUDIES**

Despite the large volume of information available, as well as the enormous number of studies published on the subject, the impact of individual drugs on postoperative pain management remains unclear. Combinations of drugs have been shown to produce maximum benefit with the lowest risk, and optimal selection of the different combinations of drugs and doses needs to be established through well-designed studies that include a sufficiently large number of patients. The question of the analgesic efficacy of morphine following IA surgery is still unclear because of deficiencies in study design and choice of the patient population. The ideal opioid for pain relief intra-articularly needs to be identified and perhaps more specific drugs effective on peripheral receptors developed. Prolonging the effects of LAs, opioids, and other IA analgesics through the use of IA catheters needs further documentation. In view of the huge costs involved in the development and marketing of pumps for use with the catheter techniques, both the safety and cost-effectiveness of these techniques need to be further analyzed. The risk for infection in joints has been one of the concerns of orthopedic surgeons when LAs are injected via catheters intra-articularly. Therefore, considering that insertion of a catheter at the end of the operation is a simple procedure, it would be important to exclude any significant risk for infection when using IA catheters. Specifically, IA analgesia should be assessed during procedures associated with moderate to severe pain, such as anterior cruciate ligament repair and total knee replacement, with assessment of not only the efficacy of this technique but also its side effects and complications, such as postoperative infections. The answer to all questions cannot be provided by retrospective analysis of data or by systematic reviews but by well-designed large prospective studies that take into consideration some of the problems highlighted earlier. Safety is only in numbers, and authors should therefore be asked to report not only efficacy variables but also any and all adverse effects. Analysis of the side effects of drugs injected intra-articularly should be obligatory in future studies on IA analgesia to confirm that they indeed have advantages that overweight their disadvantages. Issues relating to the cost of drugs and equipment in relation to the benefits offered should also be documented.

**CONCLUSION**

IA analgesics have been used for more than a decade with variable results. In studies in which postoperative analgesia was provided with IA morphine, the effects have been mild, and it has been difficult to exclude systemic effects. In contrast, NSAIDs (ketorolac and tenoxicam) have consistently shown efficacy. However, the important question on the effect of NSAIDs on bone healing has not been answered. Combinations of several drugs, including LA, ketorolac, adrenaline, and even morphine, have shown efficacy in several studies, but the exact combination of drugs and doses needs to be elucidated. It is difficult to draw any conclusions on drugs such as clonidine, neostigmine, ketamine, fentanyl, and pethidine because of the limited number of studies published in a varying patient population. The use of catheters intra-articularly has the advantage of prolonging analgesia when LA or a combination of drugs is used, and this method needs to be developed further. Local infiltration analgesia using large volumes of diluted LA combined with an NSAID may provide such good analgesia of sufficiently long duration that the catheter technique may become obsolete in the future.
SUGGESTED READINGS

The references for this chapter can be found at [www.expertconsult.com](http://www.expertconsult.com).

**KEY POINTS**

- Several analgesics have been injected alone or in combination intra-articularly, primarily into the knee and shoulder joints, to achieve relief of postoperative pain. Drugs that have been tested in clinical studies include local anesthetics, opiates (morphine, pethidine, fentanyl, and sufentanil), nonsteroidal anti-inflammatory drugs (NSAIDs—ketorolac, tenoxicam), clonidine, ketamine, corticosteroids, and neostigmine.
- Local anesthetics provide good pain relief but of short duration. Some concern exists about the risk for chondrolysis when higher concentrations of bupivacaine are injected into the shoulder joint, specifically over longer periods of time.
- Although evidence of the existence of peripheral opiate receptors exists, clinical studies have been equivocal. The analgesic effect, if any, is mild but relatively long lasting.
- NSAIDs appear to be efficacious in most studies, but some concern remains from animal studies regarding delay in bone healing.
- Clonidine is also efficacious when used in low doses intra-articularly. However, it remains unclear whether this effect is local or occurs via systemic absorption.
- The results of studies using ketamine, neostigmine, and corticosteroids are equivocal, or very few studies have been performed to be able to draw any definite conclusions.
- Combinations of drugs, specifically NSAIDs and local anesthetics, have produced added effects, and possibly even a synergistic effect of certain combinations has been described but not confirmed.
- Recently, high volumes of local anesthetics combined with NSAIDs have been used periarticularly during surgery (local infiltration analgesia) to produce analgesia of long duration. Most studies have shown good results, but the technique is under continuous development.
- The major advantage of intra-articular analgesia appears to be its efficacy combined with a low risk for side effects. The main uncertainty remains whether the effect is indeed local or occurs via systemic absorption of components of the analgesic mixture of drugs.

REFERENCES
Neurolytic therapy remains a therapy of last resort. However, for the appropriate patient, it can result in significant improvement of quality of life and possibly improved function. Few other interventional pain therapies have such extreme risk/benefit profiles requiring targeted patient selection and meticulous procedural technique. Evaluating neurolysis as a therapeutic option is usually reserved for end-stage therapy, primarily patients with refractory cancer pain resulting from the significant possibility of severe side effects. For instance, neuraxial neurolysis can provide profound pain relief for patients with pain related to invasive tumors involving the pelvis, but this approach often also leads to loss of bowel or bladder function and may well also produce weakness in the lower extremities. It should also be emphasized that relief from neurolytic blocks is usually not complete, as most patients with cancer pain have multiple sources of their pain. Although this therapeutic modality is no longer novel in development or application, neuraxial neurolysis is an important treatment modality for patients in extremis. Neurolytic agents available in the United States for common use in the neuraxis include ethanol and phenol. The five criteria for neurolysis are (1) the presence of severe pain, (2) the failure of less invasive techniques to relieve the pain, (3) the presence of well-localized pain, (4) the relief of pain with diagnostic local anesthetic blocks, and (5) the absence of undesirable effects after diagnostic blocks (Box 58.1).

Neurolytic blocks can be peripheral, neuraxial, or visceral. Of the three, visceral blocks are most commonly performed (this subject will be covered in Chapter 60), whereas neuraxial and peripheral neurolytic blocks are performed less frequently for many reasons. In the case of peripheral neurolytic nerve blocks, blocking mixed motor and sensory nerves can cause motor deficit leading to loss of functionality for the patient. In addition, peripheral neuritis and deafferentation pain are potential painful consequences, whereas the block itself is not predictably permanent. Finally, the patient may also be dissatisfied with the subsequent numbness of the area and complain of symptoms of anesthesia dolorosa. Neuraxial neurolytic blocks, including both intrathecal and epidural alcohol or phenol neurolytic blocks, are rarely used today because neuraxial analgesics including opioids, local anesthetics, and clonidine can effectively and safely be used to treat cancer pain. Where an intrathecal drug delivery system can provide widespread pain relief that can be adjusted to accommodate many scenarios, a successful neurolytic block may have to be repeated with changes in pain pathology, such as the presence of new metastatic lesions. In such cases, it is impractical to perform subsequent subarachnoid neurolytic injections because of their attendant risks, whereas an indwelling intrathecal (and occasionally epidural) drug delivery system will cover new areas of pain and continue to be useful. This chapter reviews the technical approaches and pharmacological agents used for neurolytic blocks.

**NEUROLYTIC AGENTS (Table 58.1)**

**ALCOHOL**

Ethyl alcohol (ethanol) is the classic neurolytic agent first reported by Dogliotti in 1931 for intrathecal injection. Anhydrous ethanol is commercially available undiluted (100% concentration) but will absorb a small amount of water from the air upon exposure to the atmosphere. Although neurolytic blocks have been shown to require a concentration of 33% or greater to effect neurolysis, the most common concentrations used are 280% when diluted with contrast medium or local anesthetic. The neurolytic action of alcohol is produced by the extraction of neural cholesterol, phospholipids, and cerebrosides, and the precipitation of mucopolysaccharides. These actions result in sclerosis of the nerve fibers and myelin sheath, leading to demyelination. The basal lamina of the Schwann cell sheath remains intact, allowing for new Schwann cell growth, thereby providing the framework for subsequent nerve fiber growth. This framework encourages the regeneration of axons, but only if the cell bodies of these nerves are not completely destroyed. The pathway of degeneration is nonselective and can be observed in peripheral nerves and spinal nerve roots following intrathecal injection. Areas of demyelination can be seen in posterior columns, Lissauer’s tract, and the dorsal root, followed by Wallerian degeneration to the dorsal horn. Intrathecal alcohol injection results in rapid uptake of alcohol and variable injury to the surface of the spinal cord.

Ethanol is quickly absorbed from the cerebrospinal fluid (CSF) so that only 10% of the initial dose remains in the CSF after 10 minutes and only 4% after 30 minutes. The rapid spread from the injection site means larger volumes are required than for phenol, which in turn may result in local tissue damage. In the case of celiac plexus blocks, alcohol is rapidly absorbed into the bloodstream. It has been shown that serum ethanol levels up to 54 mg/dL can occur after a celiac plexus block. However, following the intrathecal administration of alcohol, it is unlikely that there will be significant vascular uptake. Ethanol has a specific gravity of less than 0.8, and CSF has a specific gravity of slightly greater than 1. Within the CSF, alcohol is hypobaric and will move against gravity, “floating” upward. Therefore, positioning...
of the patient is an extremely important factor to consider when planning the procedure.

The use of ethanol as a neurolytic agent has been associated with a disulfiram-like effect, acetaldehyde syndrome. Case reports include patients taking moxalactam, a β-lactam antibiotic that inhibits aldehyde dehydrogenase, documented disulfiram-like effects, and another taking 1-hexyl carbamoyl-5-fluorouracil, an anticancer drug, experienced similar symptoms. The patients experienced flushing, hypotension, tachycardia, and diaphoresis within 15 minutes of alcohol administration. The symptoms resolved 4 to 6 hours later, and efforts were undertaken to stabilize hemodynamics. Both cases occurred after celiac plexus blocks. It is important for the pain practitioner to recognize medications that may cause disulfiram-like effects, such as chloramphenicol, beta-lactams, metronidazole, tolbutamide, chlorpropamide, and disulfiram, after peripheral neurolytic blocks with alcohol.

Perineural administration of ethanol is associated with burning dysesthesias in the distribution of the nerve. This sensation is often extremely unpleasant for the patient and can last from a few minutes to a few weeks. To alleviate this outcome, local anesthetic is administered prior to the use of ethyl alcohol. The use of this initial dose of local anesthetic can also provide diagnostic guidance on the correct location for the neurolytic that has enormous importance. The administration of ethanol for the purpose of neurolysis can have catastrophic consequences. It has been associated with both transient and permanent paraplegia in both celiac plexus and intrathecal blocks. It has been postulated that these effects are secondary to vasospasm of the spinal arteries by the direct action of alcohol or direct damage to the spinal motor nerves.

**PHENOL**

Phenol is a benzene ring with one hydroxyl group substituted for a hydrogen atom. It is usually prepared by the hospital pharmacy because it is not commercially available in premixed liquid form. Phenol is poorly soluble in water and, at room temperature, forms only a 6.7% aqueous solution. It has a shelf life of approximately 1 year if refrigerated and shielded from light exposure. When phenol is exposed to room air, it oxidizes and turns a reddish color. Phenol is frequently prepared with contrast and sterile water, sterile saline, or glycerin. When it is prepared with glycerin, it has limited anatomic spread, and, hence, injections are well localized. In rats, the aqueous solution of phenol has greater ability to penetrate the perineurium and produce greater endoneurial damage than glycerin preparations, but there is no difference in results following intraneural injection. Unlike alcohol, phenol injection has an initial local anesthetic effect. It is not associated with localized burning but instead creates a sensation of warmth for a short time after injection. The distribution of this sensation can help the practitioner verify proper needle placement similar to a diagnostic local anesthetic injection. Concentrations of 4% to 10% are typically used for neurolysis. When phenol is prepared in glycerin, it has a specific gravity of 1.25, making it hyperbaric. Preparations of phenol in glycerin are highly viscous, which may make administration through a small (22 or 25 gauge) spinal needle difficult.

Putnam and Hampton first used phenol as a neurolytic agent in 1936. Mandl used it for a sympathetic ganglion block in animals in 1947. Phenol was first used as a medication in an intrathecal injection in humans in 1955. It was once believed that phenol’s neurolytic effects might be due to local ischemia because of its greater affinity for vascular tissue compared to neural tissue. Racz found that unlike epidural injection, tissue destruction resulted after intrathecal injection even though the vasculature was intact in the areas of spinal cord destruction. This finding points toward direct neurotoxic effects rather than effects secondary to local ischemia. Phenol’s effects may be a combination of direct neurotoxic and ischemic effects. Originally, it was surmised that phenol had a selective effect on small-diameter, unmyelinated nerve fibers, such as C-fiber afferents and lightly myelinated A-δ afferents. Subsequent studies have shown that phenol concentrations determine the type and extent of nerve disruption. Dilute intrathecal phenol can produce a transient local anesthetic blockade, whereas increased concentrations can produce significant neural damage. At concentrations less than 5%, phenol results in protein denaturation of axons and surrounding blood vessels. At concentrations >5%, phenol can produce protein coagulation and nonselective segmental demyelination. Nathan confirmed the nonselective effects of phenol using histologic studies combined with evidence of electrophysiologic changes to Aα and Aβ fibers.
that intrathecal phenol injections in cats and humans primarily destroyed axons in dorsal rootlets and in the dorsal columns of the spinal cord. It was also noted to exert some effects on the ventral root axons.22 Maher and Mehta noted that motor blocks by phenol were possible at concentrations greater than 5%, whereas intrathecal injections of less than 5% produced mostly sensory blocks.23 At higher concentrations, the extent of damage can increase significantly, with the potential of axonal nerve root damage and spinal cord infarcts. Injections of high-concentration phenol have also been associated with arachnoiditis and meningitis.24

Systemic doses of phenol in excess of 8.5% are associated with toxic side effects. These effects initially are convulsions, followed by central nervous system depression, and, finally, cardiovascular collapse. Chronic long-term exposure may be followed by central nervous system depression, and, finally, with toxic side effects. These effects initially are convulsions, depression of compound action potentials.25

When compared to alcohol, phenol seems to facilitate axonal regeneration in a shorter period of time. Electrophysiologic studies comparing peripheral nerve destruction in cats showed that those injected with phenol had returned to normal by 2 months, whereas at the end of the same time period, those injected with alcohol still demonstrated depression of compound action potentials.25

**Glycerol**

Glycerol is a colorless, odorless, viscous, liquid, polyol compound. It has three hydroxyl groups that result in high water solubility and it is hygroscopic in nature. The glycerol backbone is central to all lipids known as triglycerides. When placed on nervous tissue, myelin disintegration and axonolysis occur in both myelinated and unmyelinated fibers. In the uninjured nerve, the c-fiber and lightly myelinated fibers are the most sensitive to neurolysis, requiring higher concentrations to destroy the heavily myelinated fibers. However, this order is altered in the injured nerve; the heavily myelinated fibers become very sensitive to the neurolytic properties of glycerol. In 1981, Hakanson was the first to use glycerol for neurolysis of the trigeminal ganglion.26 The success is most likely related to a combination of the viscous nature of glycerol and resultant lack of spread into other sensitive structures, the low concentration required to destroy the abnormally firing myelinated fibers while preserving the uninjured sensory afferents. The use of glycerol for neurolysis is now primarily restricted to the neurolysis of the Gasserian ganglion.

**Neurolytic Blocks**

Neurolytic agents can be injected surrounding peripheral nerves, along the neuraxis within the intrathecal or epidural spaces, or adjacent to visceral sympathetic nerves. Each of these sites of injection is associated with specific benefits, risks, and complications. Peripheral neurolysis can include injection into the trigeminal ganglion, truncal, upper, and lower extremities.

**Head and Neck**

**Gasserian Ganglion Neurolysis.** Peripheral nerves in the head and neck are destroyed for a variety of reasons. These include blockade of the trigeminal ganglion for trigeminal neuralgia that is not responsive to medical management and for relief of cancer pain secondary to invasive tumors of the orbit, maxillary sinus, and mandible; and blockade of individual peripheral nerves in the head.

The gasserian ganglion is formed from two trigeminal roots that exit the ventral surface of the brainstem at the midpontine line.27 The roots pass forward and in a lateral direction, in the posterior fossa of the cranium, across the border of the petrous temporal bone. It then enters the Meckel’s cave in the middle cranial fossa. The gasserian ganglion contains the ophthalmic, maxillary, and mandibular divisions. A smaller motor root joins the mandibular division as it exits the foramen ovale. It should be noted that a dural pouch, the trigeminal cistern, lies behind the trigeminal ganglion. In gasserian ganglion block, the needle is inserted approximately 2.5 cm lateral to the side of the mouth and advanced, perpendicular to the middle of the eye (with the eye in the midposition), in a cephalad direction toward the auditory meatus.28 When contact is made with the base of the skull, the needle is withdrawn and “walked” posteriorly toward the foramen ovale (Fig. 58.1). A free flow of CSF is usually noted, and fluoroscopy is then used to confirm correct needle placement. Very small amounts (i.e., 0.1-mL increments) of local anesthetic or neurolytic agent (commonly glycerol) are injected to a total of 0.4 to 0.5 mL. Because of their different baricity, the patient remains supine if alcohol is used but placed in a sitting position with the chin on the chest prior to the injection of phenol. This maneuver localizes the phenol around the maxillary and mandibular divisions of the trigeminal nerve, avoiding the ophthalmic division and the risk of keratitis from loss of the conjunctival reflex. If glycerol is used, the patient is kept in a “seated”/head-up position. The pterygopalatine space is highly vascular, and significant hematoma of the face and sub-scleral hematoma of the eye can occur. Veins in the subtemporal region can be punctured, causing hemorrhage in the temporal fossa. Local anesthetic injection can lead to spinal anesthesia because the ganglion lies within the cerebrospinal fluid. Blockade of the motor fibers of the trigeminal nerve can interfere with mastication.29 Oculomotor palsy, which results in diplopia and strabismus, is usually temporary. Abducens palsy is also temporary, although cases of permanent lateral rectus palsy have been reported.30 Spread of the neurolytic agent into the facial nerve results in paralysis of the facial muscles and inability of the eyelid to close, resulting in keratitis or corneal ulceration. Blockade of the greater superficial petrosal nerve may result in lack of tear formation and conjunctivitis. Blockade of the acoustic nerve may result in deafness or dizziness. The delayed effects of gasserian ganglion neurolytic block include trophic problems such as keratitis, ulcers in the nose, and erosions in the mouth. These disturbances usually occur after trauma to the area. Another delayed complication is anesthesia dolorosa seen more commonly with alcohol and phenol neurolysis. Because the neurolytic block of the gasserian ganglion is associated with myriad devastating complications, many neurosurgeons and pain medicine physicians choose to perform radiofrequency rhizotomy of the ganglion instead.30 The technical difficulty and complications associated with gasserian ganglion block led some investigators to perform peripheral branch (supraorbital, infraorbital, and mandibular nerves) injections with 10% phenol to relieve the pain of tic douloureux.31
Other Neurolytic Blocks of the Head and Neck. Neurolytic blocks of individual cranial nerves and their branches have also been performed, and complications are related to nerve location and the tissues it innervates. Neurolytic block of the maxillary nerve at the foramen rotundum or of the infraorbital nerve may cause ulceration and sloughing of the alar of the nose and the cheek, ischemic necrosis of the palate, or sloughing of the posterior portion of the superior ridge of the maxilla. Blockade of the mandibular nerve at the foramen ovale may result in weakness of the muscles of mastication in the blocked side, whereas blockade of the facial nerve causes weakness or paralysis of the facial muscles. Blockade of the glossopharyngeal nerve is rarely performed because of the proximity of the nerve to the vagus, spinal accessory, and hypoglossal nerves. The close location of the other nerves led investigators to recommend blockade of the glossopharyngeal nerve under fluoroscopic control or to use radiofrequency rhizotomy. The sensory area of innervation of the glossopharyngeal nerve includes the nasopharynx, eustachian tube, uvula, tonsil, soft palate, base of the tongue, and part of the external auditory canal. Paralysis of the pharyngeal muscles is a consequence of blockade of the glossopharyngeal nerve. The authors do not recommend any of these neurolytic procedures for use by pain physicians.

PARAVERTEBRAL SYMPATHETIC NEUROLYSIS

 STELLATE GANGLION NEUROLYSIS

The cervical sympathetic trunk contains the superior, middle, and inferior cervical ganglia. In 80% of the population, the lowest cervical ganglion is fused with the first thoracic ganglion, forming the cervicothoracic (stellate) ganglion. The cervical sympathetic chain lies anterior to the prevertebral fascia, which encloses the prevertebral muscle. The sympathetic chain is enclosed within the alar fascia, a thin fascia that separates the cervical sympathetic chain from the retropharyngeal space. The carotid sheath is connected to the alar fascia by a mesothelium-like fascia. The fascial plane that encloses the sympathetic chain may be in direct communication with several spaces and structures, including the brachial plexus, vertebral artery, endothoracic fascia, and the thoracic wall muscle at T1-T2. At the C6 level, the cervical sympathetic trunk is located posterolaterally to the prevertebral fascia on the surface of the longus colli muscle. The carotid vessels are anterior, whereas the nerve roots that contribute to the inferior portion of the brachial plexus are lateral to the ganglion. The vertebral artery passes over the ganglion and enters the vertebral foramen posterior to the anterior tubercle of C6. The communications of the fascia covering the stellate ganglion with several structures, as noted previously, and the proximity of the stellate ganglion to the vertebral and carotid vessels, phrenic nerve, and the recurrent laryngeal nerve explain some of the potential complications of the stellate ganglion block (Fig. 58.2). Several techniques of stellate ganglion block have been described. These include insertion of the needle at the level of C6, placement of the needle at C7, and the posterior thoracic approach. With C6 placement, the needle is placed in contact with either the C6 tubercle or the junction between the C6 vertebral body and the tubercle. The needle is withdrawn 1 to 2 mm and an initial test dose of 0.5 to 1 mL
is injected, or volumes of 5 to 10 mL can be injected. If the patient is positioned in reverse Trendelenburg, the injectate travels caudad and reaches the stellate ganglion and the upper thoracic sympathetic ganglia. A smaller volume of drug is adequate when the needle is placed at the level of C7. However, there is increased incidence of vertebral artery injection with this approach because the artery lies anterior to the C7 transverse process. There is also an increased risk of pneumothorax because the dome of the lung is closer to the injection site. These risks are reduced when an oblique approach aiming at the uncinate process of C7 is taken.

The posterior thoracic approach requires fluoroscopic guidance to identify the lamina of T1 or T2, and dye injection is recommended to document the spread of the drug. In this approach, the needle contacts the lamina of T1 or T2, is moved laterally off the lamina, and is advanced to pass the costotransverse ligament at a depth of 2 cm beyond the lamina. Either loss of resistance is used or dye is injected to confirm proper needle placement.

Kapral developed a technique, involving the use of ultrasound, to visualize the stellate ganglion. Since the initial technique was developed, many modifications have been made to increase the safety, efficacy, and speed of the block. The patient is positioned supine with the neck slightly hyperextended, and an ultrasound probe is placed at the level of C6, providing a cross section of the anatomy at this level. Visible are the trachea, esophagus, thyroid gland, carotid artery, jugular vein, longus colli muscle, and transverse process of C6. A 22G × 2-inch needle can be advanced in plane with the ultrasound probe paratracheally toward the longus colli muscle, while avoiding the other structures, and stopping once the tip reaches the prevertebral fascia. At this point, 5 to 10 mL of local anesthetic is deposited under direct visualization and can be seen spreading along the prevertebral fascia.

The complications of an intravascular injection of local anesthetic are well known. These include loss of consciousness, apnea, hypotension, and seizures. Local anesthetic blocks of the stellate ganglion have been performed for complex regional pain syndrome, vascular insufficiency of the upper extremities, and hyperhidrosis of the face and upper extremities. Neurolytic blockade of the stellate ganglion has been performed for complex regional pain syndrome when there is consistent relief after diagnostic block with local anesthetic and without prolongation of the duration of pain relief. The overall incidence of complications is 0.17%. The exact incidence of pneumothorax is not known. Aside from Horner’s syndrome, hoarseness, blockade of the brachial plexus, subarachnoid and epidural spread, and cord infarction have been reported. Brachial plexus block is secondary to the needle being inserted too lateral or from the spread of the drug along the prevertebral fascia. Ptosis can be corrected by suspension operation of the upper eyelid. Additionally, retropharyngeal hematomas...
have been reported, ranging from minimal patient discomfort to complete loss of airway.\textsuperscript{44,45} An unusual reported complication is transient locked-in syndrome, in which the patient is paralyzed and cannot breathe or speak, but can only move his or her eyes due to accidental intravascular anesthetic injection.\textsuperscript{46} These complications led other investigators to use alternative techniques to cervicothoracic sympathectomy, including radiofrequency rhizotomy and thoracoscopic sympathectomy.

**LUMBAR SYMPATHETIC NEUROYLYSIS**

Paravertebral sympathetic blocks are performed for the treatment of complex regional pain syndromes, vascular insufficiencies of the lower extremities, phantom limb pain, and other conditions such as hyperhidrosis. Percutaneous thoracic paravertebral sympathetic neurolysis is rarely performed because of the high incidence of pneumothorax. A thoracic surgeon who does a surgical sympathectomy under direct vision usually performs treatment of this region. Lumbar paravertebral sympathetic neurolysis can be more safely performed. In this technique, the needles are placed in the anterolateral surface of L2 or L3. Fluoroscopy is used to confirm vertebral level of placement, correct position of the needle tip, and adequate spread of the dye along the anterolateral aspect of the vertebral bodies. Although a single needle technique can be used, two needles (one at L2 and the other at L3) are recommended for chemical neurolysis so that a smaller volume can be injected per needle. One to 2 mL of local anesthetic is injected, and if it is followed by a temperature increase, 3 to 4 mL of 6% to 10% phenol is injected per needle. The reported complications of the block include subarachnoid injection secondary to injection near the dural cuff at the intervertebral foramen, sensory and motor block resulting from nerve root injury, paresthesias, and backache. The ureter can be injured from the needle or from phenol-induced thrombosis of the branch of the ovarian artery supplying the ureter. Genitofemoral neuralgia occurs in 7% to 20% of patients and may last 4 to 5 weeks.\textsuperscript{47} Postsympathectomy dysesthesias result in numbness and pain in the thigh and may last several months. The use of guidance (fluoroscopy, computed tomography [CT], or ultrasound) is mandatory when neurolytic block of the sympathetic chain is performed. Alternate nonchemical neurolytic techniques, including radiofrequency rhizotomy of the lumbar sympathetic nerves, have been employed to avoid the complications from spillage of the neurolytic agent; however, this technique did not result in long-term relief,\textsuperscript{48} although other studies have found benefit.\textsuperscript{49,50} Compared with phenol neurolysis, incomplete neurolysis appears to be more common with radiofrequency rhizotomy,\textsuperscript{51} but the incidence of postsympathectomy neuralgia was higher in the phenol group (33% versus 11%).

**NEUROYLYSIC BLOCKS OF THE TRUNK AND EXTREMITIES**

**INTERCOSTAL NEUROYLYSIS**

Peripheral neurolysis is a controversial subject. Although some argue that it has no real use in pain management, it has found a role in intercostal neurolytic blocks for the management of malignant chest wall pain. The use of peripheral neurolysis follows successful diagnostic blocks using local anesthetics. Peripheral neurolytic blocks are frequently associated with neuritis and deafferentation pain, in addition to postinjection dysesthesias (Box 58.2). Although these complications are unpleasant, they may be preferable to the patient’s current pain, or the patient may succumb to his or her primary disease before these complications fully manifest themselves.\textsuperscript{52} Intercostal blocks are used in the treatment of thoracic or abdominal wall pain and as adjunct in surgery.\textsuperscript{53,54} Complications include pneumothorax, intravascular injection, intrapulmonary injection with consequent bronchospasm, and neuraxial spread (Table 58.2). The incidence of pneumothorax detected by radiograph is 0.082 to 2%.\textsuperscript{55} Clinically significant pneumothorax occurs at a low rate and chest tube insertion is rarely required. Another reported complication is total spinal anesthesia after intraoperative intrathoracic injection.\textsuperscript{56} The intrathoracic injection at a medial location resulted in the injection of the local anesthetic into a dural cuff or into the nerve itself, with proximal spread of the drug. Bronchospasm from intrapulmonary injection of phenol has been reported.\textsuperscript{57} Persistent paraplegia from intercostal block with 7.5% phenol has additionally been reported, with the authors suspecting the damage occurred via spread of phenol through the intervertebral foramen and subsequent destruction of motor and sensory nerve roots.\textsuperscript{58} Similar to the advantages of its use in other peripheral nerve blocks, ultrasound has made intercostal nerve block a safer technique in that the pleura is visualized, preventing its puncture and avoiding pneumothorax.\textsuperscript{59}

**ILIOINGUINAL AND ILIOHYPOGASTRIC NEUROYLYSIS**

Ilioinguinal and iliohypogastric nerve blocks are used in the perioperative management of pain after inguinal herniorrhaphy. Preoperative wound infiltration can decrease pain scores and analgesic requirements after inguinal herniorrhaphy. The preemptive analgesic effect of the preincisional

**Box 58.2 Limitations of Peripheral Neurolytic Blocks**

- Motor deficits are likely when mixed sensory-motor nerves are blocked.
- Neuritis/deafferentation pain may occur and can be more severe than preexisting pain.
- Neurolytic blocks are not permanent.
- Sensory loss following peripheral neurolysis can in some cases become more distressing than the original pain.
infiltration of local anesthetic before herniorrhaphy has not been firmly established. In the pain clinic, ilioinguinal and iliohypogastric nerve blocks are performed in the diagnosis and treatment of inguinal and suprapubic pain after lower abdominal surgery or inguinal hernia repair. Complications of the block include unintentional blocks of the lateral femoral cutaneous and femoral nerves. The incidences of these complications are not known. Neurolytic blocks of these nerves are presently being supplanted by pulsed radiofrequency treatment (this is not a neurolytic procedure) and radiofrequency rhizotomy. The advantage of radiofrequency techniques includes the ability to first stimulate the nerves to provide exact localization in a manner similar to sensory and motor testing of medial branch nerves in facet joint denervation. Diagnostic blocks are recommended before neurolytic (chemical or thermal) procedures are performed.

NEUROLYSIS OF OTHER PERIPHERAL NERVES

Neurolytic injections have been reported to be useful in patients with palpable painful neuromas (0.2 to 0.5 mL of 5% phenol), patients with poststernotomy pain secondary to scar neuroma (2 to 3 mL of 6% phenol) and patients with painful surgical scars (1 mL of absolute alcohol). Neurolysis of peripheral nerves has not been reported after these peripheral neurolyses.

Nerve root destruction in the extremities is rarely performed because of the attendant paralysis of the extremity. Mullin reported neurolytic blockade of the brachial plexus with 10 mL of 10% phenol in a patient with a painful arm. The patient had short-term relief with minimal motor block. The complications from neurolysis of peripheral nerves include painful dysesthesias and sensory and motor block. The exact incidences of these complications are not known but are high enough that this treatment is not recommended.

NEUROLYSIS FOR MYOFASCIAL PAIN AND SPASTICITY

Neurolytic blocks of peripheral nerves are useful in patients with acquired spasticity in order to facilitate rehabilitation and restore normal position of the limb for maintenance of hygiene. Examples of these blocks include obturator block to relieve hip adduction, musculocutaneous nerve block for elbow flexion, and posterior tibial nerve block for plantar flexion. Peripheral nerve blocks with phenol have been performed in patients with spasticity to improve their gait and balance and to assist in their rehabilitation. In this technique, the motor or mixed nerves are targeted preferentially. A nerve stimulator is used for nerve identification. Injections of small volumes of 3% to 5% phenol are effective in relieving the hypertonicity of affected muscles, and relaxation of the muscle usually lasts 2 months. During this time, extensive physical therapy is employed for functional training of the limb. It appears that ethanol treatment can extend the therapeutic benefit. In a randomized controlled trial (RCT) of 20 patients evaluating phenol (5%) versus ethanol (50%) in neurolysis of tibial motor branches for gastrocnemius spasm after stroke, ethanol maintained its effect for 6 months in 9 of the 10 patients, whereas phenol lasted the same amount of time in 7 of the 10 patients. The reported complications include focal motor weakness in 15% of patients and dysesthesias in 10% of patients, but there were no differences between those that received ethanol and those that received phenol. The motor weakness usually lasts 1 week, whereas the dysesthesias last several days to weeks. Others have reported a rare complication of arterial occlusion of the patient’s upper limb after phenol block of the brachioradialis and musculocutaneous nerves. Of note, the development and widespread use of botulinum toxin has made neurolysis a therapy of last resort for this condition.

NEURAXIAL NEUROLYSIS

Intrathecal Alcohol

A neurolytic intrathecal procedure should be performed at the level where the targeted dorsal root leaves the spinal cord and not at the level where it passes through the intervertebral foramen. The latter is not recommended due to mismatch of the spinal cord level and vertebral bone level (especially as one progresses from thoracic spinal cord to lower lumbar). An accurate determination of the level to be blocked should be evaluated according to dermatome and sclerotome charts, as well as selective local anesthetic intrathecal blockade. The patient should be positioned laterally so that the rootlets (dorsal root entry zone [DREZ]) are above the injection site. This positioning is necessary given that alcohol will float in the CSF due to its hypobaric nature. The patient should also be turned 45 degrees toward the prone position (Fig. 58.3). This will raise the targeted area (DREZ) horizontally so it will be superior to the ventral nerve rootlets, and it makes contact with the neurolytic. After proper patient positioning, a short beveled (e.g., small Touhy, 22 gauge) needle is placed into the predetermined level slowly until arriving at the epidural space. This is best confirmed using loss of resistance to air and guided by fluoroscopy. After ascertaining that the epidural space has been reached, the needle should be advanced slowly while aspirating continuously until it reaches the intrathecal space and contrast dye administration (Fig. 58.4). The physician should then inject a low volume/high concentration of rapidly acting local anesthetic to provide anesthesia and clinical feedback of needle location. The lack of pretreatment with local anesthetic will result in significant discomfort and the possibility of patient movement. Using a 1-mL syringe, the alcohol is injected in 0.1-mL increments, with at least 60 to 90 seconds between repeat administrations. The maximum dose per nerve is usually 0.3 mL and the total alcohol volume should not exceed 0.5 to 0.7 mL when several nerve roots are neurolyzed. After injection, the patient should remain in the same position for 15 to 30 minutes. This immobilization allows the alcohol to exert its maximal effect at the desired location, with minimal spread to adjacent levels. After the 30-minute time period, a neurologic exam should be performed. Three to 5 days after the alcohol injection, the patient’s pain should be reassessed to determine the effectiveness of the procedure.

Intrathecal Phenol

The same considerations that occur prior to the injection of alcohol also apply to that of phenol. The pain location should be determined with dermatome and sclerotome mapping and isolated with a diagnostic injection of local anesthetic or contrast dye under fluoroscopy. There are two fundamental differences between alcohol and phenol

790 PART 6 — NERVE BLOCK TECHNIQUES
administration. When using phenol, the patient’s targeted anatomy must be facing down, the patient must be leaned 45 degrees supine, and the spinal needle diameter must be larger because of the increased viscosity of phenol. The hyperbaric nature of phenol in glycerin requires positioning so that the phenol sinks to targeted DREZ and rootlets. A short, 20-gauge needle should allow the thick phenol solution to be injected in most situations. However, if this proves difficult, warming the injectate in a warm water bath before drawing may ease the flow of the injection.

Although positioning can be challenging, a common technique involves elevating the head of the bed slightly, with the bed under the target flexed, and the patient turned 45 degrees supine (Fig. 58.5). Using supporting devices such as pillows, towels, and foam and a judicious amount of intravenous sedation can facilitate a reasonable level of comfort to prevent failure of the technique resulting from patient movement. Unlike alcohol, phenol does not require pretreatment with local anesthetic to provide analgesia of the site; however, the diagnostic value (needle localization) of the local anesthetic is still imperative. Similar to alcohol neurolysis, phenol is injected in 0.1-mL increments, with 60 to 90 seconds between subsequent injections. Phenol is injected up to a total dose of 0.5 to 0.7 mL. The feeling of warmth from the phenol is fleeting and may provide some pain relief. Although there is less diffusion with phenol compared to alcohol, the patient should be maintained in position for 30 minutes after phenol administration. The full effect of phenol manifests over approximately 24 hours.

**Epidural Neurolytic Block**

Epidural neurolysis is used for abdominal cancer pain of both visceral and mixed somatic and visceral origin. Epidural neurolysis remains popular in comparison to intrathecal neurolysis, not only because of its increased safety index and the ease for repeated injections but also for its greater efficacy on thoracic and cervicothoracic junction pain. However, it often provides less complete anesthesia of the patient’s painful areas when compared with intrathecal administration. Although the traditional technique is described in this chapter, one study demonstrated that the use of a transforaminal approach when necessary provided excellent results. Selecting the appropriate size needle depends on the agent used, as discussed previously. If alcohol is used, the physician may use an epidural catheter for delivery. An epidural catheter approach provides advantages of repeated injections and can be performed without accessing the epidural space multiple independent times; however, the indwelling catheter can be an entry site for epidural infection. The most appropriate catheter to use is a soft-tipped styletted catheter that can be maneuvered with
precision and allows confirmation of position with the injection of a small amount of contrast and local anesthetic.

Unlike the intrathecal administration of neurolytic agents, needle or catheter tip location should be chosen near the vertebral bone that corresponds to the dermatomal levels manifesting in the patient’s pain area in order to deposit the medication over the appropriate nerve roots. The injections should be performed under sterile conditions. It has been recommended that injections be repeated over the course of several days to improve efficacy and outcome. Once needle and patient positioning have been established, contrast-enhanced fluoroscopic imaging and a local anesthetic test dose can be performed to confirm proper needle depth and location. The appropriate volume of injectate depends on the level of the neurolysis being performed. Doses ranging from 2 to 5 mL are usually adequate, with doses increasing as location moves more caudally. Racz and colleagues endorse daily injections until noticeable changes in pain levels no longer occur or the patient is pain-free after 24 hours. For up to 3 days after the initial placement of an epidural catheter 3 to 5 cm into the epidural space, ethanol can be injected daily. Before each daily administration, the researchers reconfirmed placement with a local anesthetic test dose.73 Using 0.2-mL increments, they administered 3 to 5 mL of alcohol over a period of 20 to 30 minutes. Although initial relief was achieved in all cancer patients, results are less significant in patients with chronic nonmalignant pain.74 In four studies, the results of thoracic epidural neurolysis revealed a significant improvement of cancer pain.6 Pain relief, ranging from 65% to 100%, was achieved in 80% of patients. Pain relief varied among populations and reflected the severity of disease; nonetheless, many patients were pain-free until the time of their death. In the patients who survived, the duration of pain relief varied from less than 1 month to in excess of 3 months.

Neuraxial neurolytic procedures for cancer pain are rarely used now because intrathecal opioid pumps have supplanted it. Intrathecal medication infusion pumps have the advantage of managing pain from progression of the disease or future sites of painful metastases, which are common occurrences in a patient with malignancy.

**Other Complications Associated with Intrathecal and Epidural Neurolysis**

Although ease of administration is a factor, there does not appear to be an increased margin of safety of epidural neurolysis compared to intrathecal neurolysis. A study done by Katz showed that 2 weeks after the lumbar epidural injection of phenol in a group of primates, predominant posterior nerve root damage was noted, in addition to anterior nerve root and spinal cord damage. These test subjects also demonstrated lower extremity motor weakness on physical examination.75 Complications with neurolysis range in frequency from 1% to 14%, and in severity between incomplete block to limb weakness or bladder/rectal paresis.5 Like most interventional pain procedures, the most common complication is failure of the procedure to provide significant pain relief. Poor pain relief can have numerous etiologies. It is not unusual for patients to have high expectations for pain relief and have those expectations not met by neurolysis. Therefore, it is important for the pain physician to have clear communication and discuss rational expectations with the patient prior to the procedure to prevent these disappointments. Another cause of inadequate pain relief may be as simple as an incomplete block that can be remedied with a repeat dose. If tumor growth is extensive or crosses several dermatomes, neurolysis may be less effective. Unfortunately, there is always the possibility that the block works well but that local spread of the neurolytic agent may have produced peripheral damage.

There are complications due to entry into the anatomic space where these medications are administered. They include postdural puncture headache, meningitis, arachnoiditis, and neural damage from trauma. Postdural headaches usually resolve quickly, within 1 to 5 days. Complications related to neurolytic agents include loss of motor function due to neurolysis of the ventral rootlets, loss of touch and proprioception, and loss of sphincter tone. Of these potential complications, loss of bowel or bladder sphincter tone is relatively common. The complications resulting from the neurolytic agents are usually transient. According to Gerbershagen, who observed the duration required for resolution of neurolytic complications, 28% resolved within 3 days, 23% within 1 week, 21% within 1 month, 9% within 4 months, and 18% longer than 4 months.76 Complication rates appear to be similar between alcohol and phenol as shown by Swerdlow, who analyzed complications in a series of 145 patients.77

---

**Figure 58.5** A, Proper positioning of a patient with left-sided pain for intrathecal phenol in glycerin. Note the 45-degree posterior tilt, intended to bathe the dorsal (sensory) nerve roots with hyperbaric phenol, while sparing the ventral (motor) roots. B, Cross-sectional diagrammatic depiction of the above. (Reprinted with permission from Candido K, Stevens RA. Intrathecal neurolytic blocks for the relief of cancer pain. *Best Pract Res Clin Anaesthesiol.* 2003;17:407-428, Figure 5.)
Complications can be specific to location along the spine where the neurolysis is performed. At the cervical level, damage can occur to the brachial plexus, most often manifesting as limb paresthesias. Complications at the thoracic level are the least common relative to the cervical and lumbar level. Below the L1 spinal level, injections may travel into the cauda equina, where anterior and posterior roots are not separated. This factor may make the degree of motor or sensory effect difficult to predict.

Changes in opioid use may occur after a neurolytic block. Patients who have typically been on high doses of opioids for long periods of time will have reduced requirements for pain control with a successful neurolysis. Rapid discontinuation of opioids will cause withdrawal side effects; without pain as a stimulus, preneurolysis opioid doses may produce excessive sedation and respiratory depression. Careful observation of the patient in the hours to days post successful neurolysis can circumvent these problems.

The references for this chapter can be found at www.expertconsult.com.

**KEY POINTS**

- Chemical neurolytic therapy should only be considered after other pain modalities have been exhausted. These therapies are usually reserved for patients with terminal disease. Very clear therapeutic goals and limitations need to be communicated between patient and practitioner.

- Chemical neurolytics can offer patients the ability to decrease their systemic pain medications that can improve their quality of life and allow them the opportunity to clearly communicate with loved ones during difficult times.

- Alcohol and phenol are the primary agents used in intrathecal and epidural chemical neurolysis. Alcohol is associated with burning upon injection, so it is preceded by local anesthetic injection. Phenol injection is relatively painless and is associated with a feeling of warmth. Glycerol is used or trigeminal neurolysis.

**KEY POINTS—cont’d**

- Pain location should be pinpointed with sclerotome, dermatome mapping, and radiologic survey. For neuraxial injections, the patient’s positioning for injection is determined by patient comfort and by which agent is to be injected. Alcohol is hypobaric and “floats” in CSF, whereas phenol is hyperbaric and “sinks” in CSF.

- The most common complication is poor pain relief. Proper location is paramount. Often, pain relief may require several injections. Other complications related to intrathecal or epidural neurolytics are loss of motor function, loss of touch or proprioception, and loss of bowel or bladder sphincter tone.

**SUGGESTED READINGS**

REFERENCES

REFERENCES

Neurolytic blocks of the sympathetic axis were procedures that were widely used in the past for control of chronic upper abdominal pain or pelvic pain in patients with cancer. However, recent studies suggest that these blocks are not effective in treating pain that is not visceral in origin. Consequently, when there is evidence of disease outside the viscera, for example, lymphadenopathy, the success rate decreases significantly. Moreover, a controlled randomized study has shown that even in the best-case scenario, the duration of full pain control is 2 months. Thus we should reconsider the indications for these procedures, and when indicated, they should be performed early in the course of the disease.

Stretching, compressing, invading, or distending visceral structures can result in poorly localized, noxious visceral pain. Patients experiencing visceral pain often describe the pain as vague, deep, squeezing, crampy, or colicky. Other signs and symptoms include referred pain (e.g., shoulder pain that appears when the diaphragm is invaded by tumor) and nausea and vomiting as a result of vagal irritation.

Visceral pain associated with cancer may be relieved by oral pharmacologic therapy, which classically includes combinations of nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and co-adjuvant therapy. NSAIDs have begun to fall out of favor with some clinicians for the treatment of chronic pain because they have been implicated in thrombotic events. In addition to pharmacologic therapy, neurolytic blocks of the sympathetic axis are also effective in controlling visceral cancer pain and should be considered as important adjuncts to pharmacologic therapy for relief of severe visceral pain. These blocks rarely eliminate cancer pain because patients frequently experience somatic and neuropathic pain as well. Therefore, oral pharmacologic therapy must be continued in the majority of patients with advanced stages of their disease. The goals of performing a neurolytic block of the sympathetic axis are to maximize the analgesic effects of opioid or nonopioid analgesics and reduce the dosage of these agents to alleviate side effects.

Since neurolytic techniques have a narrow risk-to-benefit ratio, undesirable side effects and complications from neurolytic blocks can be minimized by sound clinical judgment and by assessment of the potential therapeutic effect of the technique on each patient. This chapter discusses pertinent information regarding neurolytic block of the celiac plexus, superior hypogastric plexus, and ganglion impar.
through the aorta on the left side until no more blood flow is noted through the needle. This is why the anterocrural approach is also known as transaortic approach. In the case of a splanchnic nerve block, the needle is directed toward the body of T12 (Fig. 59.2). Perfect needle positioning in this case is achieved when the tip of the needle is at the anterior portion of the T12 vertebral body on the lateral view (Fig. 59.3).

More recently, computed tomography (CT) and ultrasound techniques have allowed pain specialists to perform neurolysis of the celiac plexus via a transabdominal approach. This approach is frequently used when patients are unable to tolerate either the prone or lateral decubitus position or when their liver is so enlarged that a posterior approach is not feasible. Moreover, CT guidance allows an anterocrural technique to be performed without piercing the aorta, thus adding an element of safety in this case (see the section “Complications”).

DRUGS AND DOSING

For neurolytic blocks performed via the retrocrural or anterocrural approaches, 50% to 100% alcohol is used. Injected by itself, alcohol can produce severe pain. Thus, it is recommended that 5 to 10 mL of 0.25% bupivacaine first be injected 3 to 5 minutes before injection of the alcohol or at the time of the injection by diluting 100% alcohol to a 50% concentration with the same amount of local anesthetic (0.25% bupivacaine). Phenol in a 6% to 10% final concentration may also be used; it has the advantage of being painless on injection, and both agents seem to have the same clinical efficacy. The dose of alcohol or phenol administered varies with the approach to be used. For the retrocrural approach, 20 to 25 mL of alcohol is injected on each side. Consequently, the need to inject this high volume precludes the use of phenol in the retrocrural approach. For the anterocrural approach, 8 to 10 mL of either neurolytic agent is used per side. For splanchnic nerve blocks, 6 to 8 mL of phenol per side is recommended.
COMPICATIONS

The incidence of complications from neurolytic celiac plexus blocks (NCPBs) was evaluated by Davis \(^8\) in 2730 patients who had blocks performed from 1986 to 1990. The overall incidence of major complications (e.g., paraplegia, bladder and bowel dysfunction) was 1 in 683 procedures. However, the report does not describe which approach or approaches were used to perform the blocks.

Complications associated with celiac plexus block appear to be related to the technique used: retrocrural, \(^5\) transcrural, \(^6\) or transaortic. \(^7\) In a prospective, randomized study of 61 patients with cancer of the pancreas, Ischia and colleagues \(^4\) compared the efficacy and incidence of complications associated with these three approaches with those of celiac plexus neurolysis. Orthostatic hypotension occurred more often when the retrocrural (50%) or splanchnic (52%) technique was used, thus suggesting associated neurolysis of the sympathetic chain. In contrast, the anterocrural approach produced a 10% incidence of hypotension. Conversely, transient diarrhea was more frequent with the anterocrural approach (65%) than with the splanchnic nerve block technique (5%) or the retrocrural approach (25%). The incidence of dysesthesia, interscapular back pain, reactive pleurisy, hiccups, or hematuria was not statistically different among the three groups.

The following paragraphs discuss several aspects involved in the diagnosis and management of specific complications.

**Malposition of the needle** is avoided with radiologic imaging before injection of a neurolytic agent inasmuch as the tip of the needle may be intravascular, in the peritoneal cavity, or in a viscus. Imaging guidance techniques currently used include biplanar fluoroscopy, CT, and ultrasound. However, no study has evaluated the superiority of one technique over the others. Wong and Brown \(^9\) suggested that the use of radiologic imaging does not alter the quality of the block or the incidence of complications based on a retrospective study of 136 patients with pancreatic cancer pain treated with a celiac plexus block with or without radiologic control of the position of the tip of the needle. However, it is not clear how many of these patients underwent radiologic imaging. Assuming that half the patients did not, the upper 95% confidence limit for complications would be 5%. \(^10\)

**Orthostatic hypotension** may occur up to 5 days after the block. Treatment includes bed rest, avoidance of sudden changes in position, and replacement of fluids. Once the compensatory vascular reflexes are fully activated, this side effect disappears. Wrapping the lower extremities from the toes to the upper part of the thighs with elastic bandages has been successful in patients in whom orthostatic hypotension developed and thus enabled them to walk during the first week after the block.

**Backache** may result from local trauma during needle placement and subsequent retroperitoneal hematoma or from irritation of retroperitoneal structures by alcohol. Patients with a backache should have at least two hematocrit measurements at a 1-hour interval. If there is a decrease in the hematocrit, radiologic imaging is indicated to rule out a retroperitoneal hematoma. Urinalysis positive for red blood cells suggests renal injury.

**Retroperitoneal hemorrhage** is rare; however, in patients with orthostatic hypotension, the possibility of hemorrhage must be ruled out before assuming that it is a physiologic response to the block. Patients in whom backache and orthostatic hypotension develop after a celiac plexus block should be admitted to the hospital for serial hematocrit monitoring. If the hematocrit level is low or decreasing, patients should undergo radiologic evaluation to rule out injury to the kidneys, the aorta, or other vascular structures. Surgical consultation should be obtained as soon as feasible.

**Diarrhea** may occur as a result of sympathetic block of the bowel. Treatment includes hydration and antidiarrheal agents. Oral loperamide is a good choice, although any anticholinergic agent may be used. Matson and colleagues \(^11\) reported nearly fatal dehydration from diarrhea following this block. In debilitated patients, diarrhea must be treated aggressively.

**Abdominal aortic dissection** has also been reported. \(^12\) The mechanism of aortic injury is direct damage with the needle during performance of the block. As expected, the anterocrural approach is more frequently associated with this complication. Thus, this approach should be avoided in patients with atherosclerotic disease of the abdominal aorta.

**Paraplegia and transient motor paralysis** have occurred after celiac plexus block. \(^14\) These neurologic complications may be due to spasm of the lumbar segmental arteries that perfuse the spinal cord. \(^21\) In fact, canine lumbar arteries undergo contraction when exposed to both low and high concentrations of alcohol. \(^22\) Thus, these data suggest that alcohol should not be used if there is evidence of significant atherosclerotic disease of the aorta because the circulation to the spinal cord may also be impaired and be dependent only on lumbar artery flow. However, there is also a report of paraplegia after the use of phenol, \(^14\) which suggests that other factors (e.g., direct vascular or neurologic injury or retrograde spread to the spinal cord) may come into play. These complications further support the need for radiologic imaging when performing these blocks.

EFFICACY

To date, only three randomized, controlled trials \(^1\), \(^22\) and one prospective study \(^24\) have evaluated the efficacy of celiac plexus neurolysis in relieving pain caused by upper abdominal cancer. In a prospective, randomized study, Ischia and coworkers \(^4\) evaluated the efficacy of three different approaches to celiac plexus neurolysis for pancreatic cancer. Of 61 patients with pancreatic cancer pain, 29 (48%) experienced complete relief of pain after the neurolytic block. The remaining 32 patients (52%) required further therapy for residual visceral pain secondary to technical failure in 15 patients and neuropathic or somatic pain in 17 patients. The second trial, \(^22\) which compared the procedure with oral pharmacologic therapy in 20 patients, concluded that celiac plexus neurolysis results in an equal reduction in visual analog scale (VAS) pain score as does therapy with a combination of NSAIDs and opioids. However, opioid consumption was significantly lower in the group of patients who underwent neurolysis than in the group receiving oral pharmacologic therapy during the 7 weeks of the study. Moreover, the incidence of side effects was greater in patients who received oral pharmacologic therapy than in those who underwent neurolytic block. Regarding the third randomized controlled study, Wong and collaborators \(^25\) are to be congratulated for...
designing and completing this study. Their results are welcome in light of a lack of properly designed comparative studies between neurolytic techniques and comprehensive medical management (CMM). However, several issues in the design and results of this study need to be highlighted:

1. Patients enrolled in the study did not have severe pain at study entry. Mean pain scores at baseline were 4.4 ± 1.7 in the NCPB group and 4.1 ± 1.8 in the CMM group. This is a surprising finding in patients with this type of malignancy and may reflect ethnic and racial differences in pain perception and reporting by the population enrolled in the study.

2. Although the authors reported a significant statistical reduction in pain scores 1 week after therapy when comparing the NCPB group with the CMM group, the difference between the two groups may not be clinically important. Patients assigned to the NCPB group reported mean pain scores of 2.1 ± 1.4, whereas those randomized to the CMM group reported pain scores of 2.7 ± 2.1 at that time interval. Moreover, statistical difference was found only when the percent reduction from baseline in the NCPB and the CMM group was analyzed separately (53% reduction from baseline in the NCPG group, \( P = 0.05 \), versus a 27% reduction observed in the CMM group, \( P = 0.01 \)).

3. In analyzing these results it is critically important to note that most patients (93%) took opiates during the first week of therapy, with similar amounts of opiates being administered to the two treatment groups. In fact, opiate consumption increased with time with no differences between groups at the different time intervals during the study. Furthermore, the incidence of side effects was not different between the two treatment groups at any point in time.

4. Likewise, quality-of-life measurements and the physical and functional well-being subscales of the Functional Assessment of Cancer Therapy for Prostate Cancer did not differ between the two groups at any evaluation point.

Two important questions stem from these results:

1. Can the authors truly conclude that the major finding of the study was that NCPB significantly improves relief of pain in patients with advanced pancreatic cancer when compared with those who received optimized CMM?

2. Based on these results, are we justified to submit a patient with advanced pancreatic cancer to NCPB in view of the potential side effects and complications associated with this procedure?

We do not believe that the authors can conclude that NCPB significantly improves pain relief in patients with advanced pancreatic cancer. This is partly because the levels of analgesia achieved by the patients assigned to either group after 1 week of therapy can be considered clinically acceptable. Additionally, statistical difference was found only when the authors analyzed the percent reduction in pain from baseline in each of the treatment groups.

Likewise, based on these results we do not believe that we would recommend NCPB to a patient with advanced pancreatic cancer because in this not so perfect world, complications do occur, as has been addressed earlier.

Given these reservations, does this mean that we should not perform NCPB in patients with pancreatic malignancy? As with every clinical study, the results of Wong and associates apply only to the population studied and under the conditions of the study protocol design. The critical issue is that all patients had nonresectable disease, which suggests that the patients were likely to have other pain components such as somatic or neuropathic, which are not responsive to NCPB. This is because neurolytic blocks of the sympathetic axis are effective in treating visceral pain only. Moreover, previous studies have suggested that in patients with evidence of disease outside the pancreas, such as celiac or portal adenopathy, the success rate of this block decreases significantly.

In the study by De Cicco and collaborators, long-lasting pain relief was described in 9 of 9 patients (95% confidence interval of 60 to 100) when contrast medium spread into the four quadrants and in 10 of 21 patients (95% confidence interval of 26 to 70) when contrast medium spread into three quadrants. None of the 75 patients with spread of contrast agent into two or one quadrant experienced long-lasting pain relief. Thus, the presence of adenopathy secondary to metastasis is a poor prognostic factor for success of the block. This decrease in effectiveness is not due to a mechanical factor such as big lymph nodes blocking spread of the neurolytic agent; rather, it is simply a marker of more extensive disease that often includes nonvisceral pain components and is therefore less amenable to NCPB. The results of the study by Wong and collaborators further support the notion that NCPB should not be performed in patients with advanced unresectable carcinoma of the pancreas. This block should be reserved for patients without evidence of disease outside the viscera so that one is guaranteed that the patient has a visceral pain component only.

A prospective, nonrandomized study compared 41 patients treated according to the World Health Organization guidelines for relief of cancer pain with 21 patients treated by NCPB. The authors concluded that this technique can play an important role in managing pancreatic cancer pain.

Since one of the three randomized, controlled studies compared different approaches to the celiac plexus and had no control group and the other study compared the procedure with an analgesic drug it is not possible to estimate the success rate of this technique. In contrast, the results of a meta-analysis that evaluated the findings of 21 retrospective studies with a total of 1145 patients concluded that adequate to excellent pain relief can be achieved in 89% of patients during the first 2 weeks following the block.

Partial to complete pain relief continued in approximately 90% of the patients who were alive at the 3-month interval and in 70% to 90% of patients during the 3-month interval before death. Moreover, its efficacy was similar in patients with pancreatic cancer as in those with other upper intra-abdominal malignancies. However, these results are based on retrospective evaluation, which may not yield reliable information or may be subject to publication bias. In addition, the statistical techniques used for the analysis must account for the heterogeneity produced by patient selection criteria, technical differences in performance of the blocks, choice of neurolytic agents and doses used, diversity in the tools for evaluation of pain, goals of therapy, and other factors. Thus, the meta-analysis must be interpreted with caution because the report may be overly enthusiastic.
As discussed previously, oral pharmacologic therapy with opioids, NSAIDs, and co-adjuvants is used frequently for the treatment of cancer pain. However, the evidence suggests that chronic use of high doses of opioids may have a negative effect on immunity. Thus, analgesic techniques that lower opioid consumption may have a positive effect on patient outcomes. Lillemore and colleagues showed in a prospective, randomized trial that patients with unresectable cancer of the pancreas who underwent splanchnic neurolysis lived longer than did those who did not undergo neurolysis. These findings may be the result of lower opioid use in the neurolysis patients, who not only had better-preserved immune function but also experienced fewer side effects (e.g., nausea and vomiting), thus allowing them to eat better. Although the study by Wong and colleagues did not show that patients randomized to the neurolytic arm of the study lived longer, this may be explained by their high intake of opioids during the study period, which negated the effect of the blocks. Consequently, the effects of this procedure on long-term survival will need further experimental investigation.

**SUPERIOR HYPOGASTRIC PLEXUS BLOCK**

Cancer patients with extension of tumor into the pelvis may experience severe pain that is unresponsive to oral or parenteral opioids. In addition, excessive sedation or other side effects may limit the acceptability and usefulness of oral opioid therapy. Therefore, a more invasive approach is needed to control pain and improve the quality of life of these patients.

Pelvic pain associated with cancer and chronic nonmalignant conditions may be alleviated by blocking the superior hypogastric plexus. Analgesia of the organs in the pelvis is possible because the afferent fibers innervating these structures travel in the sympathetic nerves, trunks, ganglia, and rami. Thus, sympathectomy for visceral pain is analogous to peripheral neurectomy or dorsal rhizotomy for somatic pain. One study has suggested that visceral pain is an important component of the cancer pain syndrome experienced by patients with cancer of the pelvis, even in advanced stages. Thus, percutaneous neurolytic blocks of the superior hypogastric plexus should be considered more often for patients with advanced stages of pelvic cancer.

A Japanese study group investigated 35 patients with abdominal or pelvic pain (or both) that had a large visceral component. They performed three blocks at one time on all the patients: celiac plexus, inferior mesenteric, and superior hypogastric. They reported a 100% immediate success rate, with all patients’ VAS pain scores dropping to zero. The statistically significant decrease in pain scores following the procedures persisted for 3 months. They also found a significant decrease in opiate use following the intervention that persisted for the first month. This again underscores the need for selecting patients with visceral pain for neurolysis.

The superior hypogastric plexus is situated in the retroperitoneum; it extends bilaterally from the lower third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body. The technique for the blockade has been described elsewhere. The patient is placed in the prone position with a pillow under the pelvis to flatten the lumbar lordosis. Two 7-cm needles are inserted with the bevel directed 45 degrees medially and 30 degrees caudad so that the tips lay anterolateral to the L5-S1 intervertebral disk space. Aspiration is important to avoid injection into the iliac vessels. If blood is aspirated, a transvascular approach can be used (see the section “Complications”). Accurate placement of needle is verified by biplanar fluoroscopy. Anteroposterior (AP) views should reveal the tip of the needle to be at the level of the junction of the L5 and S1 vertebral bodies. This is an important safety step to avoid potential spread of the neurolytic agent toward the L5 roots (see “Complications”). Lateral views will confirm placement of the needle’s tip just beyond the vertebral body’s anterolateral margin. Injection of 3 to 5 mL of water-soluble contrast medium is used to verify accurate needle placement and to rule out intravascular injection. In the AP view, spread of contrast material should be confined to the midline region. In the lateral view, a smooth posterior contour corresponding to the anterior psoas fascia indicates that the needle is at the appropriate depth. For a prognostic hypogastric plexus block or for patients with non–cancer-related pain, local anesthetic alone is used. For therapeutic purposes in patients with cancer-related pain, phenol is typically used as the neurolytic solution.

Mastering this technique is not easy because the transverse process of L5 makes it difficult to access the anterior portion of the L5-S1 region. Consequently, a transdiscal approach has been suggested (Figs. 59.4 to 59.6). However, this approach may be associated with the inherent risk of puncturing the intervertebral disk.

**COMPLICATIONS**

The combined experience of more than 200 cases from the Mexican Institute of Cancer, Roswell Park Cancer Institute, and M.D. Anderson Cancer Center indicates that neurologic complications have not occurred as a result of this block. However, extreme care should be exercised because placing the tip of the needle in the upper middle portion
of L5 may be associated with retrograde spread to the nerve roots. If such spread is not recognized, injection of the neurolytic agent could result in predictable neurologic deficits (Figs. 59.7 and 59.8).

EFFICACY

Effectiveness of the superior hypogastric plexus block was originally demonstrated by a significant decrease in pain via VAS pain scores. In their study, Plancarte and colleagues showed that the block was effective in reducing VAS pain scores in 70% of patients with pelvic pain associated with cancer. The majority of the patients enrolled had cervical cancer. In a subsequent study, 69% of the patients experienced a decrease in VAS pain scores. Moreover, a mean daily reduction in opioid use of 67% was seen in the success group (736 ± 633 reduced to 251 ± 191 mg/day) and 45% in the failure group (1443 ± 703 reduced to 800 ± 345 mg/day). In a later multicenter study, 159 patients with pelvic pain associated with cancer were evaluated. Overall, 115 patients (72%) had satisfactory pain relief after one or two neurolytic procedures. Mean opioid use decreased by 40% from 58 ± 43 to 35 ± 18 mg/day of morphine equivalents 3 weeks after treatment in all the patients studied. This decrease in opioid consumption was significant in both the success group (56 ± 32 reduced to 32 ± 16 mg/day) and the failure group (65 ± 28 reduced to 48 ± 21 mg/day). Success was defined in the two studies as the ability to reduce opioid consumption by at least 50% in the 3 weeks following the block and a decrease in VAS pain scores to below 4 of 10.

In a case report, Rosenberg and colleagues reported on the efficacy of superior hypogastric plexus block in a patient with severe chronic nonmalignant penile pain after transurethral resection of the prostate. Although the patient did not
receive a neurolytic agent, a diagnostic block performed with 0.25% bupivacaine and 20 mg methylprednisolone acetate was effective in relieving the pain for more than 6 months. The usefulness of this block for chronic benign pain conditions has not been adequately documented.

**GANGLION IMPAR BLOCK**

The ganglion impar is a solitary retroperitoneal structure located at the level of the sacrococcygeal junction. This unpaired ganglion marks the end of the two sympathetic chains. Visceral pain in the perineal area associated with malignancy may be treated effectively by neurolysis of the ganglion impar (Walther’s). Patients who will benefit from this block frequently have vague, poorly localized pain that is frequently accompanied by sensations of burning and urgency. However, the clinical value of this block is not clear because the published experience is limited.

**ANATOMY**

The ganglion impar has gray nerve fiber communication from the ganglion to the spinal nerve but appears to lack white nerve fibers, which communicate pulses from the spinal nerves to the ganglion in the thoracic and upper lumbar regions. Visceral afferents innervating the perineum, vulva, and distal third of vagina converge at the ganglion impar. The original technique was described by Plancarte and collaborators. The technique calls for the patient to be placed in the lateral decubitus position with the hips fully flexed. A standard 22-gauge, 3.5-inch spinal needle is bent 1 inch from its hub to form a 30-degree angle. The needle is then introduced under local anesthesia through the anococcygeal ligament with its concavity oriented posteriorly, and under fluoroscopic guidance it is directed along the midline at or near the sacrococcygeal junction while placing a finger in the rectum to avoid puncturing this structure. Retroperitoneal location is verified by observation of the spread of 2 mL of water-soluble contrast medium. An alternative needle geometry, in which the needle is bent to the shape of an arc, has been proposed by Nebab and Florence. An easier technique is the trans-sacrococcygeal approach, in which the tip of the needle is placed directly into the retroperitoneal space by inserting a 20-gauge, 1.5-inch needle through the sacrococcygeal ligament under fluoroscopic guidance so that the tip of the needle is just anterior to the anterior portion of the sacrum. This technique avoids invasion of more caudal structures (rectum) by the needle and the need to insert a finger in the rectal lumen.

For diagnostic blocks, local anesthetic alone is used. For neurolytic blocks, 6% phenol is recommended. Cryoablation of the ganglion impar has also been described for repeated procedures via a trans-sacrococcygeal approach in a patient with chronic benign pain after abdominoperineal resection.

**EFFECTIVENESS**

Three studies evaluated the efficacy of ganglion impar blocks in a prospective, nonrandomized, noncontrolled fashion. Plancarte and colleagues evaluated 16 patients with advanced cancer (cervix, 9; colon, 2; bladder, 2; rectum, 1; endometrium, 2) and persistent pain despite treatment (pharmacologic management resulted in a 30% global reduction in pain). Localized perineal pain was present in all cases and was characterized as burning and urgent in eight patients and of mixed character in the other eight. Pain was referred to the rectum (seven patients), perineum (six patients), or vagina (three patients). After a neurolytic block via a transanococcygeal approach, eight patients reported complete pain relief, whereas the remainder experienced a significant reduction in pain (60% to 90%). Blocks were repeated in two patients, and follow-up was carried out for 14 to 120 days, depending on survival.

Swafford and Ratzman reported on the efficacy of the trans-sacrococcygeal approach. Twenty patients with perinatal pain unresponsive to previous intervention were studied, 18 with a bupivacaine/steroid block and 2 with a neurolytic block. In the bupivacaine/steroid group, 5 patients reported complete (100%) pain relief, 10 reported greater than a 75% reduction in pain, and 3 reported greater than a 50% reduction in pain. Both neurolytic blocks resulted in complete pain relief. Duration of the pain relief varied from 4 weeks to long-term.

Vranken and colleagues studied the effect of a ganglion impar block for long-lasting, treatment-resistant coccydynia. Twenty patients, 17 women and 3 men, with a diagnosis of coccydynia (spontaneous, 7; fracture, 3; injury, 10) received a 5-mL injection of 0.25% bupivacaine. There was no reduction in pain or increase in quality of life associated with the procedure. Thus, based on this study, it would appear that this block is not effective for the treatment of coccydynia.

**COMPLICATIONS**

Although there is always a risk of damaging structures adjacent to the ganglion impar, no complications have been reported with this technique. Plancarte and collaborators reported one case in which epidural spread of contrast medium within the caudal canal was observed. In this case, repositioning the needle resolved the problem. Although published experience is limited and criteria for predicting success or failure are not available, patients with poorly localized perineal pain with a burning character are considered candidates for a ganglion impar block. The procedure is safe and no complications have been reported.

**SUMMARY**

Neurolysis of the celiac plexus/splanchnic nerves, superior hypogastric plexus, or ganglion impar may be used in patients with visceral pain of the upper part of the abdomen, pelvis, and perineal region, respectively. Use of this technique in patients who do not have a significant visceral pain component is not warranted. The presence of disease in the corresponding lymph nodes is a poor prognostic marker for these blocks. The incidence of reported complications is low. However, they may occur and have significant implications on the quality of life of the patient. Thus, strict adherence to the technique is important to prevent potential problems.
**SUGGESTED READINGS**

*The references for this chapter can be found at www.expertconsult.com.*

---

**KEY POINTS**

- Neurolytic blocks of the sympathetic axis are used for the control of chronic upper abdominal and pelvic pain in patients with cancer.
- A study has shown that even in the best-case scenario, the duration of full pain control with a neurolytic block is 2 months.
- Visceral pain associated with cancer may be relieved by oral pharmacologic therapy.
- The goals of a neurolytic block are to maximize the analgesic effect of pharmacotherapy and reduce the dosage of these agents to alleviate side effects.
- The celiac plexus is situated retroperitoneally in the upper part of the abdomen at the level of the T12 and L1 vertebrae, anterior to the crura of the diaphragm.
- Patients with upper abdominal cancer who have a significant visceral pain component have responded well to celiac plexus blocks.
- Three approaches to block the celiac plexus include the retrocrural (or classic) approach, the anterocrural approach, and neurolysis of the splanchnic nerves.
- Studies have suggested that when there is evidence of disease outside the pancreas (including adenopathy), the success rate of a celiac plexus block decreases significantly.
- The superior hypogastric plexus is situated in the retroperitoneum and bilaterally extends from the lower third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body.
- Pelvic pain associated with cancer and chronic nonmalignant conditions may be alleviated by blocking the superior hypogastric plexus.
- The ganglion impar is a solitary retroperitoneal structure located at the level of the sacrococcygeal junction.
- Visceral pain in the perineal area associated with malignancy may be treated effectively by neurolysis of the ganglion impar.
- Use of this neurolytic technique in patients who do not have a significant visceral pain component is not warranted.
REFERENCES

The Institute of Medicine’s report on chronic pain in America estimated that more than 100 million citizens are living with chronic pain.1 Of this group, chronic low back and often associated radicular pain is the most prevalent type of pain and results in significant health care expenditure and adverse social, emotional, and financial consequences in the populace.2 Radiculopathy is a syndrome of neurologic conductive loss (sensory or motor) arising from any compressive force (e.g., impingement of a disk on the foraminal spinal nerve, spondylosis, vertebral subluxation, ligamentum flavum cyst, infection).3 Experimentally, displacement of the spinal nerve with a silk loop can mimic the effects of lumbar disk protrusion and produce deficits in sensory and motor conduction.4 Radiculopathy is not uniformly associated with radicular pain. Radicular pain, or pain in the distribution of a spinal nerve, probably requires both pathologic compression of the nerve and inflammation. The resulting radiculitis is largely driven by glial production of cytokines.

Surgical treatment of acute radiculopathy is widely accepted by patients, but very few studies comparing surgery with comprehensive nonsurgical care have been reported.5-7 The efficacy of surgical procedures for many spinal conditions has come under greater scrutiny, though, because of disparate geographic practice patterns and inconsistent outcomes.8 Previous studies suggested that radicular pain can be treated effectively by discectomy.5,6 These studies also demonstrated a favorable natural history of lumbar radicular pain syndromes,5,6 which compares well with the previous epidemiologic study of cervical radicular pain.9 Recent data from the Spine Pain Outcomes Research Trial (SPORT) regarding nonsurgical versus surgical care of lumbar disk herniation,7 however, demonstrated no statistically significant superiority of surgical discectomy over conservative care for primary study outcomes, and thus conservative treatments such as injections for radicular pain will probably continue to increase (Fig. 60.1A to C). In addition, SPORT agreed with previous trials5,6 that the natural history of disogenic radicular pain consists of slow improvement over time. Recent 5-year follow-up data from an earlier controlled trial of transforaminal epidural steroid injections suggest that conservative care may be effective in decreasing the need for disk surgery over time, with potentially lower morbidity.10

During the period 1993 to 1999, the number of injections billed to the U.S. Medicare system steadily increased to 680,000 epidural steroid procedures per year, with a large number of other spinal injections increasing as well. Cervical and thoracic epidural procedures increased the most, from 10,105 to 48,210 procedures (377%).11 Because large studies suggest that the natural history of radiculopathy secondary to disk herniation is favorable,5-8 the challenge of successful treatment of radicular pain is to achieve a reduction in pain and restoration of function while minimizing risk or harm to the patient. The uncertainty regarding nonsurgical best practice with a seemingly increasing number of serious complications12 poses a significant challenge to interventional pain physicians.

**HISTORY**

Mixter and Barr were the first to suggest that intervertebral disk herniation might be responsible for radicular pain via mechanical compression on the exiting spinal nerve root.13 Four years before the idea that the disk was somehow involved, Evans had proposed treating the syndrome of primary or idiopathic sciatica with injections of 120 mL of 2% procaine (Novocaine) via the trans-sacral canal.14 Kelly15 later suggested that inflammatory changes on the nerve might be the cause of the pathophysiological injury. Building on these ideas, Lindahl and Rexed15 demonstrated that inflammation, as evidenced by lymphocyte infiltration and edema, could be seen on histologic section of dorsal root nerve biopsy specimens in 7 of their 10 patients at the time of surgical discectomy. Kelly16 later suggested that inflammatory changes on the nerve might be the cause of the pathophysiological injury.

Early work on injectable corticosteroids by Hench, Kendall, and colleagues was a Nobel Prize–winning effort that culminated in synthesis of the drug hydrocortisone.17 Soon thereafter, corticosteroids were used in injections, initially reported as a series of knee joint injections by Hollander and associates.18 Theorizing that inflammation might be amenable to injection in the epidural space, the first injection of epidural corticosteroids took place in Europe in 1952 by Robecchi and Capra.19 Then in 1953, Li’evre and associates described their results in 20 patients in whom hydrocortisone was injected into the epidural space.20

In 1961, Goebert and colleagues discussed their results of 121 injections in 113 patients over the preceding 5-year period. Of the total, all but 27 of these injections were caudal and only 3 were cervical. The injections consisted of a mixture of 1% procaine in 30-mL volumes with 125 mg hydrocortisone acetate, usually on 3 consecutive days.21 Between 1960 and the late 1980s, interlaminar and caudal approaches to the epidural space predominated, largely via non–image-guided
techniques using surface landmarks and “loss-of-resistance” techniques. In 1988, el-Khoury and coworkers published a study suggesting that a large percentage of these “blind” epidural injections were not placed appropriately, either not being in the epidural space or not properly communicating with the target area of the injection. In a subsequent large review, Johnson and colleagues described their experience with 5,489 consecutive injections that resulted in only four complications. They proposed that use of an epidurogram allowed one to provide accurate localization within the epidural space while also demonstrating that the injectant reached the target area. Furthermore, only 10 patients in the entire series required sedation, thus suggesting that the procedure was exceedingly safe on an outpatient basis.

Epidural steroid injections are now most widely used for radicular pain caused by herniated disk material. Guidelines from organizations such as the International Spinal Intervention Society, which are based on evidence, have become accepted by some practices.

### PATHOPHYSIOLOGY

Inflammation of the spinal nerve root caused by proinflammatory mediators such as prostaglandins and cytokines and by mechanical compression are now thought to be key inciting events of radicular symptoms. Corticosteroids, through their anti-inflammatory effects, may reduce these inflammatory changes in or around the nerve and thereby decrease pain and improve function.

Until recently the pathophysiology of nociceptive pain emanating from the disk has been poorly understood. Nociceptive neural structures have been demonstrated in the outer third of the annulus fibrosus with modern immunohistochemistry techniques. The nociceptive neural fibers are small unmyelinated C fibers that are activated by peptidergic neurotransmitters such as calcitonin gene–related peptide or substance P. In diskography-proven pathologic disks, nerve ingrowth into the disk may extend farther into the disk matrix, usually accompanied by neovascularization and further degradation of the disk matrix. These nerves appear to be originating from the vertebral end-plate region, which may be the progenitor of the pathologic pain attributed to the disk itself. The disk is relatively avascular, and homeostatic attempts to improve disk nutrition may explain why new blood vessels (and associated nerve fibers) invade the disk from the vertebral end-plate region. Blood flow is predominantly via passive diffusion. Circulation in the end plate is probably controlled by local neurotransmitters, which suggests that neural fibers are present as well.

The processes that lead to disk degeneration and disease may ultimately lead to herniation of the disk. Herniated nucleus pulposus results in local release of cytokines and other inflammatory mediators that cause a chemical radiculitis. Burke and associates found increased levels of the inflammatory cytokines interleukin-6 (IL-6) and IL-8 in disk material taken from patients with known disk disease. Olmarker and coworkers found that the application of disk material onto spinal nerve roots induced functional and morphologic changes in these nerves. In addition, disk cells express tumor necrosis factor-α (TNF-α), which when applied to spinal nerve roots, causes similar changes as those seen after the application of disk material, and selective inhibition of TNF-α may reduce the intraneural edema seen in this context.

### CORTICOSTEROID ALTERNATIVES

Because corticosteroids have specific dose limitations and side effects, many researchers are interested in finding alternative agents for therapeutic injection in and around the epidural space and dorsal root ganglion. Systemic delivery of specific anti-inflammatory agents for the treatment of radicular syndromes in humans has shown early promise. Korhonen and colleagues used intravenous infliximab, a TNF-α inhibitor, to treat patients with disk herniation and radicular pain and found that pain scores were reduced at the 1-year follow-up when compared with controls. Etanercept, another TNF-α inhibitor, has also shown promising but preliminary efficacy as systemic treatment of lumbosacral...
radicular syndromes.34 Cohen and associates35 performed a novel double-blind trial involving varying doses of etanercept in patients with subacute lumbosacral radiculopathy. The results revealed significant improvement in pain scores at 1 month when compared with saline. Unfortunately, in a follow-up, randomized, controlled, parallel-group design of epidural etanercept, saline, or steroid in which the patients and investigators were blinded, no significant difference was found between the groups.36 Potential shortcomings of this study were that the doses of corticosteroid were somewhat lower than in previous studies and that all patients received a small dose of bupivacaine before injection of the study drug. Previously, both human and animal data have suggested that local anesthetics may not be inferior to corticosteroids in their effects.37-39 Manchikanti and colleagues37 performed a prospective, randomized, double-blind trial comparing local anesthetic only with local anesthetic mixed with steroid (nonparticulate betamethasone) in fluoroscopically guided cervical interlaminar epidural injections. The study group included 60 patients with central cervical spinal stenosis and upper extremity pain. Thirty patients were randomized to each group. Multiple outcome measures were studied, including the numeric rating scale (NRS), Neck Disability Index, employment status, and opioid intake at 3, 6, and 12 months after treatment. Significant pain relief was noted in 73% in group 1 (local anesthetic only) and 70% in group 2 (local anesthetic with betamethasone); however, the preliminary results showed no significant difference in pain relief or functional status whether patients received injections with or without steroid. One of the significant limitations of the study was the small sample size (N = 60).

Ohtori and colleagues conducted a more recent trial to test the effect of epidural etanercept on lumbar radicular pain in patients with spinal stenosis and found that etanercept was more effective than dexamethasone for leg and low back symptoms without any adverse events noted.40

In another study evaluating the use of alternatives to corticosteroids, Burgher and coworkers41 studied the difference between clonidine and corticosteroid (triamcinolone) in transforaminal epidural injections for the indication of acute lumbosacral radiculopathy. Thirty-three patients were screened and randomized; ultimately, 26 patients were divided into two groups, clonidine (11) and steroid (15). Although no difference was seen between the groups in the primary outcome (11-point pain intensity NRS at 1 month), both groups showed significant improvement in pain scores at 2 weeks and 1 month when compared with baseline (P < 0.05). The corticosteroid group showed additional functional improvement at 1 month in comparison to clonidine (P = 0.022). Even though adverse effects did occur, none resulted in serious complications.

Prolonged continuous delivery of anticytokine agents to the site of inflammation has not yet been studied.

EVIDENCE-BASED THERAPY

Many reviews of trials of epidural steroid injections suggested that the early studies either were not well controlled or had methodologic deficiencies.42-44 The effect of epidural corticosteroid injections in treating radicular pain syndromes overall appears to be a transient improvement.45 There are multiple examples of controlled trials of procedural therapies that demonstrate little significant clinical benefit when previous noncontrolled observational studies and case series had suggested benefit.46-48 Furthermore, “epidural” describes an anatomic space that can be accessed by injection via different approaches to reach the epidural space: interlaminar, transforaminal, and caudal. The different technical approaches to the epidural space additionally complicate the study because different approaches may have different efficacy and risks. Further complicating the clinical scenario is whether the pathology is cervical, thoracic, or lumbar, given the significant pathologic differences between different areas of the spine.12

Several well-designed studies have corroborated a short-term benefit with epidural steroid injections. These short-term benefits must be recognized when selecting a technique for the injection, as discussed further in the section “Complications.” Given the favorable natural history of the majority of patients with radicular pain syndromes, especially those related to disk protrusion, a thorough understanding of benefits and risks associated with epidural steroid injections for radicular pain syndromes is needed. A selection of these studies with respect to interlaminar, transforaminal, and caudal epidural steroid injections is reviewed in this section.

Carette and colleagues45 performed a randomized, placebo-controlled trial to investigate the efficacy of lumbar interlaminar epidural steroid injections (up to three) for sciatica (Table 60.1). The study group included 138 patients with unilateral or bilateral lower extremity pain, signs of nerve root irritation or compression, and computed tomography (CT) evidence of nerve root compression at the appropriate levels. A total of 78 patients were allocated to the methylprednisolone group (80 mg) and 80 to the placebo group (saline). The primary outcome was patient function as measured by the Oswestry Disability Index. The epidural injections were not fluoroscopically guided, which may have led to a significant frequency of misplaced injections.22 The treatment group received 80 mg of methylprednisolone acetate mixed with 8 mL of isotonic saline or 1 mL of isotonic saline in the epidural space. The study did not show a statistically significant change in functional improvement as assessed by Oswestry scores, but it did find a reduction in leg pain as assessed by the visual analog scale (VAS) at 6 weeks in the corticosteroid treatment group (difference of −0.11 in mean change; 95% confidence interval, −21.1 to −0.9; P = 0.03); however, this improvement was no longer significant at 3 months.

Arden and colleagues46 performed a randomized, placebo-controlled trial to examine the efficacy of lumbar interlaminar epidural steroid injections (up to three) for sciatica as well. The study group included 228 patients with unilateral lower extremity pain and signs of nerve root irritation. A total of 120 patients were allocated to the triamcinolone group (80 mg) and 108 allocated to the placebo (saline) group. The primary outcome was patient function as measured by the Oswestry Disability Questionnaire (ODQ). A number of secondary outcomes were studied, including a 100-mm VAS for leg and back pain. The epidural injections were not fluoroscopically guided. The treatment group received 80 mg of triamcinolone and 10 mL of 0.25% bupivacaine at weeks 0, 3, and 6. The placebo group received injections of 2 mL of normal saline into the interspinous ligament. The treatment
group reported a statistically significant improvement in self-reported function as compared with placebo at 3 weeks (improvement in the ODQ adjusted for baseline, 10.3 [14.8] vs. 6.6 [15.6]; \( P = 0.017 \)). The number of patients achieving a 75% improvement in the ODQ was greater in the active group than in the placebo group (15 [12.5%] vs. 4 [3.7%]; \( P = 0.016 \)). At 3 weeks the number needed to treat to achieve a 75% improvement in the ODQ over and beyond placebo injection was 11.4. There were no statistically significant differences between the groups at 6 weeks or beyond on any outcome measure.

In response to the review of Koes and coworkers, Karppinen and colleagues hypothesized that the poor efficacy reported may be a result of insufficient penetration of corticosteroid into the locus of nerve root irritation when administered via an interlaminar approach (Table 60.2). They conducted a randomized, double-blind trial to test the efficacy of periradicular corticosteroid injection for sciatica. The study group included 163 patients with unilateral lower extremity pain. Magnetic resonance imaging (MRI) was performed, but nerve root compression was not part of the inclusion criteria. Eighty patients were randomized to a single injection of methylprednisolone-bupivacaine and 80 were allocated to a saline injection, for a total of 160 patients. Three patients were not randomized because of an inability to produce a neurogram with fluoroscopic guidance. The primary outcome measure was back and leg pain on a 100-mm VAS. Transforaminal epidural injections were performed under fluoroscopic guidance, with injection of contrast dye to produce a neurogram. The injection consisted of 2 to 3 mL, depending on the level, of either methylprednisolone (40 mg/mL) plus bupivacaine (5 mg/mL) or isotonic (0.9%) saline. The results showed that the effect of treatment on leg pain was significantly better in the steroid-bupivacaine group at 2 weeks, with a 45% reduction in pain versus 24% for placebo (\( P < 0.01 \)), but not thereafter. Back pain was better in the steroid group at 3 months. Back and leg pain was better in the saline group than in the steroid group at 6 months (difference of \(-16.2 [-26.8 to -5.6] \), \( P = 0.003 \) for leg pain). No difference in groups was noted at 1 year. However, only one injection was used in the study. Interestingly, they noted that a single transforaminal corticosteroid injection seemed to be associated with a rebound phenomenon at 3 and 6 months.

Ng and colleagues performed a randomized, double-blind controlled trial of transforaminal epidural steroid injections for sciatica as well. The study group included 88 patients with unilateral leg pain. Symptoms had to be consistent with the MRI diagnosis of nerve root compression secondary to either lumbar disk herniation or foraminal stenosis. Two patients were withdrawn because of blinding...
failure. A total of 43 patients were allocated to treatment with a transforaminal injection of 40 mg methylprednisolone and bupivacaine, along with 45 patients allocated to the placebo group (local anesthetic injection only). The primary outcome was a 10% change in the Oswestry Disability Index. Secondary outcomes assessed included the VAS (100 mm, with a 20% change being regarded as significant), change in walking distance, and the patient’s level of satisfaction. The study demonstrated no statistically significant difference in outcome measures between the groups assessed at 3 months.

Riew and colleagues\textsuperscript{50} published a prospective randomized trial of lumbar transforaminal epidural steroid injection versus local anesthetic injection in which lumbar spine surgery was used as a primary outcome. The study group included 55 patients with lower extremity pain and MRI- or CT-confirmed disk herniation or spinal stenosis. A total of 28 patients were allocated to a bupivacaine-betamethasone injection and 27 to a transforaminal bupivacaine injection only. Injections were performed under fluoroscopic guidance. They found a significant reduction in the frequency of lumbar spine surgery in patients treated with up to four transforaminal epidural steroid injections. Recent literature has suggested clinical improvement in radicular symptoms with transforaminal epidural steroid injection.\textsuperscript{57-59} No direct studies comparing cervical interlaminar with transforaminal administration of corticosteroid exist.\textsuperscript{56}

Bush and Hillier\textsuperscript{52} studied caudal epidural corticosteroid injections in patients with intractable sciatica in a double-blind, placebo-controlled fashion (Table 60.3). Patients with lower extremity pain and a positive straight-leg raise test were included in the study. Patients with suspected cauda equina syndrome or symptoms of less than 4 weeks’ duration were excluded. The study group included 23 patients with lower extremity pain and signs of lumbar nerve root irritation. A total of 12 patients were allocated to the steroid group and 11 to the placebo group. The caudal epidural injection was performed without fluoroscopic guidance, with 25 mL of injectant being administered, including 80 mg triamcinolone and 0.5% procaine hydrochloride. The placebo group received 25 mL of saline. Outcome measures included a symptomatology questionnaire and a VAS. The treatment group showed statistically significant improvement in lifestyle and reduction of pain at 4 weeks (VAS score of 16 vs. 45, \( P = 0.02 \)). At 1 year, both groups showed statistically significant resolution of their symptoms. No major side effects were reported.

Dashfield and colleagues\textsuperscript{53} performed a prospective, randomized, double-blind trial comparing caudal steroid injection with targeted steroid placement during spinal endoscopy for chronic sciatica. The study group included 60 patients with lower extremity pain in the distribution of a lumbar nerve root. A total of 30 patients were allocated to the caudal injection group and 30 to the endoscopy-guided targeted injection group. Spinal endoscopy could not be performed in three patients, who were then assigned to the caudal injection group. Injections were not fluoroscopically confirmed. The caudal injection group received 10 mL of 1% lidocaine with 40 mg triamcinolone. The endoscopy group had 10 mL of 1% lidocaine and 40 mg triamcinolone injected at the painful nerve root. The primary outcome measure was the VAS score. Additional outcome measures included the Short-Form McGill Pain Questionnaire and anxiety and depression using the Hospital Anxiety and Depression Scale. The results showed no significant difference between the groups. A significant reduction in pain as recorded by VAS was reported at 6 weeks \(( P = 0.034)\), 3 months \(( P = 0.026)\), and 6 months \(( P = 0.01)\) in the caudal injection group. Postprocedure adverse events included nonpersistent low back discomfort in both groups that was insufficient to require hospitalization. Otherwise, no serious complications were reported.

Few randomized, placebo-controlled studies of cervical epidural steroid injections, interlaminar or transforaminal, have been conducted to date.\textsuperscript{54} Retrospective studies have suggested clinical improvement in radicular symptoms with interlaminar epidural steroid injections.\textsuperscript{55,56} A number of prospective cohort studies and retrospective analyses have demonstrated benefit with transforaminal cervical epidural steroid injection.\textsuperscript{57,59} No direct studies comparing cervical interlaminar with transforaminal administration of corticosteroid exist.\textsuperscript{56}

In summary, the evidence seems to support the use of interlaminar, caudal, and transforaminal corticosteroid injections for radicular pain secondary to spinal stenosis or disk pathology for short-term analgesia. Most studies suggest modest benefit for variable periods of 2 weeks to perhaps 3 months. The short-term benefit from epidural injections and the natural history of radicular pain may complement

each other with respect to clinical improvement. The impact of other aggressive conservative therapies such as medications, exercise, physical therapy, and cognitive-behavioral strategies combined with epidural corticosteroids has not been studied. Significant complications of epidural steroid administration can occur (see “Complications”). Certain safety measures may reduce these complications, but their effect is unclear and difficult to study given the relative rarity of these serious complications. Head-to-head studies are necessary to compare interlaminar, transforaminal, and caudal approaches to the epidural space, which may be relevant given the unique risks to the patient with each approach.

## SELECTED EPIDURAL INJECTION TECHNIQUES

### CERVICAL TRANSFORAMINAL

For cervical transforaminal injections, the patient is positioned supine and the head is elevated and turned slightly opposite the side being targeted. Great care is taken to mark the great vessels of the neck to avoid placement of needles through these areas. The skin is prepared with chlorhexidine solution and draped in sterile fashion. A subcutaneous skin wheal is raised, and a 25- or 22-gauge bent-tipped needle is selected for a coaxial fluoroscopic technique. An oblique lateral radiograph is adjusted to maximize the optimal transverse view of the intervertebral foramen. The superior articular process (SAP) is seen at the posterior aspect of the foramen and is optimally seen as a straight line. The needle is introduced laterally into the neck toward the SAP in the posterior foramen when the foramen is viewed in maximal breadth. From the SAP, the needle is “walked” into the posterior aspect of the foramen at its midpoint while making sure that an anteroposterior (AP) projection does not show the tip of the needle extending beyond the midsagittal plane of the cervical articular pillar. Once the needle is in position, various safety measures are used, as discussed in the section “Complications,” including local anesthetic test dosing, real-time fluoroscopic contrast dye injections, and digital subtraction techniques.

As noted previously in dissections of the cervical transforaminal space, “critical arteries are located in the posterior aspect of the intervertebral foramen,” and anastomoses between the vertebral and cervical arteries are variable. Given the risk of introducing steroid into the cervical circulation, nonparticulate steroids should be considered.

### TRANSFORAMINAL LUMBAR EPIDURAL

The patient is placed prone on the fluoroscopy table, and an oblique view is obtained with the SAP at the desired injection level. The target point, the lateral surface of the SAP, is marked along a line that bisects the sagittal plane of the pedicle. The target is thus at approximately the 6-o’clock position of the pedicle at the same level (Fig. 60.2). A chlorhexidine-based solution is spread over the skin in circular fashion and sterile drapes applied. A skin wheal is raised and deeper subcutaneous infiltration is provided, usually with 1% lidocaine, and the needle is usually gently bent at the tip to allow greater steerability. Either a Quincke-type needle or a blunt needle with a side port opening may be used, depending on preference, with some authors contending that a blunt needle may be less apt to enter blood vessels. The needle is advanced with incremental fluoroscopic images until the tip approaches the appropriate depth. AP and lateral images are obtained to verify that the needle is either within the “safe triangle area” as proposed by Bogduk and Cherry or is dorsal to the dorsal root ganglion (Fig. 60.3). Murthy and colleagues performed 113 angiograms to determine the most likely position of the artery of Adamkiewicz (Fig. 60.4). Digital subtraction imaging is useful to substantiate absent vascular uptake (Fig. 60.5). Local anesthetic test dosing with 1 mL of 1% to 2% lidocaine is also useful to prevent accidental administration of particulate corticosteroid into a spinal segmental medullary artery. Once safe needle location is confirmed, injection of corticosteroid or other agent can commence.

Kim and coworkers studied 182 patients who received cervical and lumbar transforaminal injections to evaluate the incidence of intravascular injections. Fifty-six patients (30.8%) showed intravascular spreading patterns with real-time fluoroscopic visualization. Forty-five of them occurred during cervical injection, significantly higher than the 11 that occurred during lumbar injection ($P < 0.001$). One suggestion that came about was to inject a proper volume of contrast agent (deemed to be 3 mL) to detect vascular flow given the relatively high incidence in this study.

CHAPTER 60 — INTERLAMINAR AND TRANSFORAMINAL THERAPEUTIC EPIDURAL INJECTIONS

CERVICAL INTERLAMINAR EPIDURAL

Generally, the cervical interlaminar approach is most safely performed at the C7-T1 or T1-2 levels. The epidural space is widest at these levels and may be 1.5 to 2 mm. There are occasionally discontinuous areas of the cervical epidural space, and often the width is drastically narrowed by underlying disease such as spinal stenosis or intervertebral disk herniation, which can produce significant compression of the posterior epidural space. It is almost always advisable to have MRI available before performing any cervical epidural injections. Once the safety of the potential interlaminar approach is verified, chlorhexidine-alcohol preparation is performed and sterile drapes placed. The interlaminar opening is viewed in maximal diameter, usually with a caudocephalad angulation of the image intensifier. The lamina immediately inferior to the interlaminar opening target is marked. An epidural needle is chosen, generally a Tuohy or otherwise blunt-tipped needle. A skin wheal is raised and subcutaneous infiltration is performed with 1% lidocaine. The epidural needle is advanced slowly down to the inferior laminar bone via intermittent fluoroscopic guidance. Once the inferior laminar bone is contacted, the needle is gradually walked superiorly and medially into the center of the interlaminar opening until it just slips superiorly past the lamina.

At this point, a glass or plastic syringe containing 3 mL or less of saline is attached, and a lateral fluoroscopic view is obtained. The needle is then advanced slowly while the operator is correlating the tactile loss-of-resistance technique with the lateral fluoroscopic view until the anterior extent of the spinous processes is reached. A subtle loss of resistance will be detected as the needle enters the epidural space. Paresthesia or a cerebrospinal fluid aspirate should prompt abandonment of the procedure. Once the needle is in position, injection of 0.5 mL of nonionic contrast dye will

---

**Figure 60.3** The “safe” triangle depicts the confines of the classic transforaminal epidural technique. The needle is safely placed inferior to the pedicle’s inferior border, superior to the tangentially exiting spinal nerve, and lateral to the dural sleeve.

**Figure 60.4** Spread of contrast dye is seen along the medial border of the pedicle and outlining the exiting spinal nerve.

**Figure 60.5** Digital subtraction sequence of a left L2 transforaminal epidural injection. The contrast dye outlines the exiting spinal nerve and displays no vascular uptake despite the high likelihood of proximity to the great segmental medullary artery of Adamkiewicz (see Fig. 60.9).
Complications from epidural steroid injections can generally be categorized as being (1) specifically related to the technique used (interlaminar, caudal, or transforaminal); (2) related to needle trauma, that is, whether a direct neural injury has occurred or any accidental puncture of the dura (post–dural puncture cerebrospinal hypotension); (3) vasospastic or ischemic (accidental injection into a vascular structure causing ischemia—anterior spinal artery syndrome); (4) infectious (epidural abscess, meningitis, diskitis); (5) related to the drug injected; or (6) related to the drug diluent or additives, for example, benzyl alcohol or polyethylene glycol (PEG). Injected corticosteroids have been associated with multiple complications, including osteoporosis and osteopenia, avascular necrosis, steroid-induced myopathy, arachnoiditis, cushingoid signs and symptoms (stria, truncal obesity, weight gain, hirsutism, edema, increased blood sugar), cataracts, risk for infection, and many others. To minimize these adverse effects, recommendations to either arbitrarily limit corticosteroid exposure or use steroid-sparing treatments have become common clinical practice. Early studies of epidural or intrathecal corticosteroids used one to four doses of 80 mg methylprednisolone over the course of days to weeks until the symptoms improved. It is still recommended that no more than three doses be given in 6 months. Many studies have evaluated the effects of certain commercial preparations of corticosteroids. PEG can cause nerve damage; only concentrations of 20% or higher did so in isolated nerve preparations, but they responded within an hour to washout of the PEG. Several studies have examined the effects of various preparations containing 0.9% benzyl alcohol, but none of these animal models demonstrated irreparable harm to tissues. It is becoming more common for various compounding pharmacies to make steroid solutions to the specifications of client physicians, which may lessen issues of unwanted substances added as preservatives but raise the specter of infectious agents or errors in compounding to the surface. Therefore, alternative interventions with reproducible beneficial effects in the treatment of radicular pain that lack significant systemic toxicity with repeated administration would potentially represent a significant therapeutic advance over corticosteroids.

A large review of the literature from 1960 to 1994 of complications that occurred with cervical and lumbar epidural steroid injections documented 6947 cases of patients receiving one or more epidural steroid injections. Overall, the incidence of complications was very low. Another large study of 1214 patients receiving predominantly lumbar interlaminar epidural injections at two university pain clinics demonstrated no major complications resulting in neurologic damage and an incidence of post–dural puncture headache of just 0.8%. Other authors have proposed that the foramininal technique may be safer because they believe that dural puncture is less likely. For example, Botwin and colleagues studied 322 patients and noted no dural punctures but, instead, a 3.1% incidence of transient, non–position-related headache. Cervical interlaminar epidural injections with or without fluoroscopic guidance were similarly successful in treating radicular symptoms in approximately two thirds of patients with no major neurologic complications in past studies. Case reports of spinal cord injury have illustrated the potential for catastrophic neural injury as a result of spinal cord puncture in sedated or anesthetized patients, and also that fluoroscopic
Imaging is not necessarily protective. In an examination of the American Society of Anesthesiology closed claims reports during the years 1970 to 1999, 5,175 total claims were noted, and it was found that injuries reported as a result of procedures for chronic pain were increasing. Epidural steroids made up most of the total number (83%) of all injections but accounted for 40% of the claims. Thirty percent of the chronic pain claims leading to payment were associated with a disabling injury and increased from the previous 2 decades by 17%. 80

The American Society of Anesthesiologists closed claims reports from 2005 to 2008 were studied by Rathmell and colleagues to determine the injury and liability associated with cervical procedures for chronic pain. 81 Of 1627 total reports from 2005 to 2008 were studied by Rathmell and colleagues to determine the injury and liability associated with cervical procedures for chronic pain. Of those, 64 were related to cervical procedures (22% of the 294). Most (74%) of the claims cited events from 2000 or later. Overall, patients undergoing cervical procedure were healthier (P < 0.001) and more often women (P = 0.011). Of the cervical procedures, 59% of the patients experienced spinal cord damage, with direct needle trauma being the predominant cause (31%). General anesthesia or sedation was also more prevalent in cervical claims associated with spinal cord injuries. In fact, 25% of those who had spinal cord injuries were nonresponsive during the procedure as compared with 5% of those who did not sustain spinal cord injuries (P < 0.05, κ = 0.52).

Regarding dosages, a recent study by Ahadian and associates82 investigated the potential differences between using 4-, 8-, and 12-mg doses of dexamethasone in lumbar transforaminal epidural injections. Although improvement in radicular pain was noted 12 weeks after injection in all groups (P < 0.05), no significant differences were found between each group.

A contradictory study was performed by Park and associates83 in which particulate and nonparticulate steroids were compared in lumbar transforaminal epidural injections. Dexamethasone, 7.5 mg, was compared with triamcinolone acetate, 40 mg; the triamcinolone group showed a statistically significant improvement in VAS scores when compared with the dexamethasone group (P = 0.001).

INFECTIOUS COMPLICATIONS

Until recently, many of the cases of epidural abscess and meningitis in the literature were reported in the context of perioperative epidural catheter infusions, which is not necessarily similar to the incidence after a single corticosteroid injection. Gaul and associates84 reviewed every patient admitted to their neurologic unit with meningitis during the years 1992 to 2000. This review yielded 128 patients, 8 of whom had previously received corticosteroid spinal injections. Review of the cases reported in the literature85 yielded a total of 11 abscesses and 3 abscesses plus meningitis after spinal injections of corticosteroid. The cases of abscess and meningitis associated with injections appeared to overwhelmingly be caused by the Staphylococcus species, with 8 of 14 infections occurring in immunocompromised patients (mostly patients with diabetes and metastatic cancer). The patients were usually seen within the first 2 weeks after injection, with back pain being the most prominent symptom. A high clinical index of suspicion and laboratory findings (erythrocyte sedimentation rate and C-reactive protein) may be more helpful than the white blood cell count in screening. Ultimately, MRI is necessary to make the diagnosis (Fig. 60.7).

ISCHEMIC INJURY (ANTERIOR SPINAL ARTERY SYNDROME)

Carette and Fehlings have called for further studies on cervical epidural steroid injections because of increasing performance of these techniques, which have less evidence of efficacy than lumbar procedures do but a substantial number of complications.12 Several recent reports of anterior spinal artery syndrome during cervical transforaminal epidural steroid injections have raised concerns of safety.54,60,83-89 Anatomic studies have demonstrated that the segmental medullary arteries that supply the anterior spinal artery may be vulnerable. These arteries could be branches of the vertebral artery, ascending cervical artery, or deep cervical arteries.60 Branches entering the posterior aspect of the cervical intervertebral foramen (Figs. 60.8 and 60.9) or anastomosing with the vertebral artery may explain some complications.60 Likewise, a lumbar safe zone may not protect one from catastrophic injection into a tributary of the artery of Adamciewicz.90
Figure 60.8  Anatomic cadaver dissection demonstrating the vertebral artery (pink, large arrow) and the exiting left C5 spinal nerve lifted by the probe. The tip of the needle is pushing on a spinal branch of the ascending cervical artery (small arrow) at the outer aspect of the C4-5 intervertebral foramen.

KEY POINTS

• The natural history of discogenic radicular pain is favorable for conservative management.
• Randomized, placebo-controlled trials show short-term benefit with epidural steroid injection via multiple techniques.
• The best practice for nonsurgical radicular pain syndromes is yet to be defined. Few comparative, nonsurgical trials have been conducted.
• Devastating complications of epidural steroid injection have occurred, especially in the cervical spine.
• Because of the rare, but catastrophic nature of some of these complications and the favorable natural history of discogenic radicular pain, safety should be of primary concern.
• Future directions in research may look at alternative pharmacologic agents or techniques to address the pathophysiology of radicular pain syndromes. Use of these agents via continuous or prolonged delivery is of interest.

REFERENCES

Low back pain (LBP) and neck pain represent an epidemic throughout the industrialized world. More than 75% of patients reporting spine pain are between 18 and 65 years old, thereby adding cost through lost productivity and wages.\(^1\) Although the prevalence of LBP varies greatly throughout the literature, some lifetime estimates are as high as 84% to 90%,\(^2,3\) and the 5-year recurrence rate of LBP may be as high as 69%.\(^4\) The lifetime prevalence of neck pain has been estimated to be about 67%.\(^5\) The estimated cost of treatment and lost wages for spine pain in the United States each year is estimated to be more than $140 billion.\(^1,4\) As the population ages, the impact of LBP and neck pain will continue to grow.

The zygapophyseal (facet) joint (z-joint) is a potential source of neck, shoulder, midback, low back, and leg pain. In addition, cervical facet disease can cause headaches. Interventions on the z-joints are second only to epidural steroid injections as the most common type of procedure performed in pain management centers in the United States.\(^6\) Despite a great deal of research on the diagnosis and treatment of facet pain, the issue still remains controversial. This chapter discusses the relevant anatomy, mechanisms of injury, prevalence, pain referral patterns, diagnosis, and treatment of facet arthropathy.

### ANATOMY AND FUNCTION

The spine is normally composed of 7 cervical, 12 thoracic, and 5 lumbar vertebrae (see Fig. 61.1). The z-joints are paired structures situated posterolateral to the vertebral body. In conjunction with the intervertebral disk, they make up what is commonly known as “the three-joint complex.” Together, these joints function to support and stabilize the spine and prevent injury by limiting motion in all planes of movement. The lumbar z-joints are true synovial joints formed from the superior articular process of one vertebra and the inferior articular process of the vertebra above. The volume capacity of these joints is approximately 1 to 1.5 mL in the lumbar region and 0.5 to 1.0 mL in the cervical region.\(^7\) The articular surfaces are covered by hyaline cartilage and contain a fibrous capsule. The fibrous capsule is about 1 mm thick and is formed mostly of collagenous tissue arranged in a transverse fashion to provide resistance to forward flexion.\(^8,9\) The superior and inferior joint borders are formed by the fibrous capsule. In the lumbar spine, the multifidus muscle serves as the posterior joint border, and the ligamentum flavum replaces the fibrous capsule at the anterior border.\(^10\) The position of the joint relative to the sagittal and coronal planes helps determine the role that the joint plays in protecting the spine against excessive motion. Joints oriented parallel to the sagittal plane provide little resistance to backward and forward shearing forces but allow a greater degree of rotation, flexion, and extension. Joints oriented closer to the coronal plane will allow less rotation, flexion, and extension but serve as excellent protection against shearing forces. The cervical z-joints are inclined at roughly 45 degrees from the horizontal plane and angled 85 degrees from the sagittal plane. This alignment functions to prevent excessive anterior translation and to assist the disks in weight bearing.\(^11\)

The medial branch of the posterior rami supplies sensory innervation to the facet joint. Each exiting spinal nerve splits into an anterior and posterior primary ramus (Fig. 61.2). The anterior ramus is the largest of the two branches and the main source of motor and sensory fibers. The posterior ramus divides into lateral, intermediate, and medial branches. In the lumbar region, the lateral branch provides innervation to the paraspinous muscles, thoracolumbar fascia, and sacroiliac joint and variable sensory fibers to the skin overlying the spinous processes. The small intermediate branch supplies the longissimus muscle. The medial branch is the largest branch of the posterior primary ramus and innervates not only the lumbar z-joint but also the multifidus muscle, interspinal muscle and ligament, and periosteum of the neural arch. To block sensory input from one facet joint, two adjacent medial branches must be anesthetized. In some people, facet joint innervation may be derived from other sources.

Facet joints are imbued with a rich innervation containing encapsulated (Ruffini-type endings, pacinian corpuscles), unencapsulated, and free nerve endings.\(^12\) In addition to being a potential pain generator, the z-joint capsule is thought to serve in a proprioceptive capacity as well, as evidenced by the presence of low-threshold, rapidly adapting mechanosensitive neurons. Kallakuri and colleagues used immunocytochemistry to characterize the presence of substance P and calcitonin gene–related peptide–reactive nerve fibers in the cervical facets of 12 human cadavers.\(^13\) In addition to substance P and calcitonin gene–related peptide, a
substantial percentage of nerve endings in the facet capsules contain neuropeptide Y, which is indicative of the presence of sympathetic efferent fibers.\textsuperscript{14,15} Nerve fibers have been found in subchondral bone and intra-articular inclusions of facet joints, thus signifying that facet-mediated pain may originate in structures besides the joint capsule.\textsuperscript{16,17} Inflammatory mediators such as prostaglandins\textsuperscript{18} and the inflammatory cytokines interleukin-6 and tumor necrosis factor-\(\alpha\) have been found in facet joint cartilage and synovial tissue in degenerative lumbar spinal disorders.

**LUMBAR FACET JOINTS**

The lumbar facet joints are aligned lateral to the sagittal plane and vary in angle (Fig. 61.3). The inferior articular process faces anterolaterally, and the superior articular process faces posteromedially.\textsuperscript{10,20} In an anatomic study published in 1940 by Horwitz and Smith,\textsuperscript{21} the authors found that the L4-5 \(z\)-joints tended to be more coronally positioned (almost 70 degrees with respect to the sagittal plane), whereas the L2-3 and L3-4 joints were likely to be oriented more parallel (<40 degrees) to the sagittal plane. In more recent studies by Masharawi and coworkers\textsuperscript{11} and Punjabi and associates,\textsuperscript{22} the investigators found that the upper lumbar facet joints (T12-L2) were oriented closer to the midsagittal plane of the vertebral body (mean range, 26 to 34 degrees), whereas the lower facet joints tended to be oriented away from that plane (40 to 56 degrees). In the upper lumbar spine, approximately 80% of the facet joints are curved and 20% are flat. In the lower lumbar spine, these numbers are reversed.\textsuperscript{21} Studies by Grobler and colleagues\textsuperscript{23} and Boden and associates\textsuperscript{24} found a positive association between degenerative spondylolisthesis and more sagitally oriented lower lumbar facet joints. The inferior articular processes of L5 combine with the superior articular processes of the sacrum to form the L5-S1 facet joints. The dip in the sacrum immediately lateral to the superior articular process is termed the sacral ala.

Sensory innervation of the facet joints is derived from the medial branches arising from the posterior primary rami at the same level and the level above the facet joint.\textsuperscript{10,25} For example, the L4-5 medial branch receives its innervation from the L3 and L4 medial branch nerves. The medial branches of L1 to L4 run across their respective transverse processes one level below the named spinal nerve (e.g., L4 crosses the transverse process of L5) and traverse the dorsal leaf of the intertransverse ligament at the base of the transverse process. The nerve then proceeds along the junction of the superior articular process and the transverse process, courses underneath the mamilloaccessory ligament, and splits into multiple branches as it crosses the vertebral lamina (Fig. 61.4). Calcification of the mamilloaccessory ligament can be a source of nerve entrapment.\textsuperscript{26} This is most common at L5 (20%) but also occurs at L4 (10%) and L3 (4%). The nerve at L5 that is amenable to blockade is actually the dorsal ramus itself, which runs along the junction of the superior articular process of the sacrum and the sacral ala.\textsuperscript{27,28} Some authors have claimed that a branch from the S1 nerve root can run cephalad to supply a portion of the L5-S1 facet joint, although this point remains controversial.\textsuperscript{29,30}

**THORACIC FACET JOINTS**

The thoracic facets are the most vertically oriented joints, as noted in Figure 61.1, with the anterior portion of the joint located more cephalad,\textsuperscript{11,31,32} The frontal orientation permits more lateral flexion at the expense of axial rotation. In the low thoracic spine, the angle transitions from a predominantly frontal orientation to the characteristic sagittal orientation of the lumbar facets. This transition varies but generally occurs between T11-12\textsuperscript{11} and T12-L1.\textsuperscript{22} Unlike the lumbar facet joints, where tropism is unusual,\textsuperscript{10,33} asymmetry is the rule rather than the exception in the thoracic spine, with the right side generally oriented more vertically and frontally than the left.\textsuperscript{11}

Sensory innervation of the thoracic facets is comparable to that in the lumbar spine. At most levels, innervation is
derived from the medial branch from the same level and the level above. Exceptions to this rule sometimes occur at the uppermost thoracic z-joints, where the medial branches from C7 and C8 may travel caudad to levels as low as T3. In a cadaveric study by Chua and Bogduk, the authors showed that the thoracic medial branches assume different courses depending on the level. In the midthoracic levels, they do not run on bone but instead are suspended in the intertransverse space. Because the thoracic medial branches also swing laterally to circumvent the multifidus muscle, motor stimulation of the multifidus muscle cannot be used reliably to confirm needle placement during radiofrequency (RF) treatment as it can be in the lumbar spine. In none of the 84 medial branch dissections did authors find the nerve crossing the junction between the superior articular process and the transverse process, as occurs in the lumbar spine. Instead, the superolateral corner of the transverse process was noted to be a more accurate target point for diagnostic blockade and denervation (Figs. 61.5 and 61.6). A recent study suggests that the posterior rami in the thoracic spine may send a branch, termed the "descending branch," to the facet joint before the bifurcations of the medial and lateral branches.

**CERVICAL FACET JOINTS**

To facilitate the complex motions of the neck, the position and shape of the cervical z-joints change greatly from the base of the occiput to the cervicothoracic junction. The occiput sits on the C1 articular processes in an orientation nearly parallel to the axial plane. The superior articular process at C3 faces posteromedially, with a 70-degree angle in the sagittal plane and a 45-degree angle in the transverse plane. The relative position of the C2-3 facet inhibits rotation and serves to anchor the C2 vertebra as a rotational pivot for the atlantoaxial joint (C1-2). Between the C3-4 and C7-T1 facet joints, the orientation transitions to the consistent posterolateral position of the C7 superior articular process. The most frequent site of this transition is at the C5-6 joint. The position of the z-joints at this level allows flexion, extension, rotation, and lateral bending. Because of the enhanced mobility of this segment, the C5-6 level is also the most prone to facet dislocations and spondylosis. The C7 superior articular processes are oriented approximately 93 degrees to the sagittal plane and 65 degrees to the transverse plane. In addition, the shapes of the facet joints between C3 and C6 tend to be round and almost flat, whereas the C6-T1 z-joints are elliptical with a more concave surface. The combination of shape and orientation at the cervicothoracic junction is designed to maximize stability.

The innervation patterns of the cervical z-joints are slightly more complicated and varied than the lumbar and thoracic levels (Fig. 61.7). There are eight cervical nerve roots, the first seven of which exit the intervertebral foramen above the vertebral body of the same number. Similar to the lumbar and thoracic z-joints, the C3-4 to C7-T1 facet joints receive dual innervation from the medial branches of the posterior rami from the same level and one level above. The nerves curve around the waist of the articular pillars at their respective levels and then branch out to supply two joints. Tight fascia and the tendons of the semispinalis capitis muscle ensure that the medial branches cling closely to the periosteum, thereby making their position more predictable. On a lateral projection, the medial branches tend to lie in the center of the articular pillars.

The cervical facet joints above the C3-4 level are slightly more complicated. The C2-3 facet joint receives the majority of its innervation from the C3 dorsal ramus. The C3 dorsal ramus normally divides into two separate medial branches. The larger superior branch is better known as the third occipital nerve, and the inferior branch is conventionally termed the deep median branch. Some innervation of the C2-3 level is also derived from the C2 dorsal rami, which may form five distinct branches, the largest of which is the...
greater occipital nerve.42,43 Along with the upper cervical z-joints themselves, the dorsal rami and its branches can also be a source of cervicogenic headache.44,45

**MECHANISMS OF INJURY**

In the vast majority of cases, facet joint arthropathy is the product of years of repetitive strain, low-grade trauma, and stress from intervertebral disk degeneration. This is best demonstrated by the strong association between facet arthropathy and increasing age.46-51 Studies have demonstrated that intervertebral disk degeneration virtually always precedes facet changes in the lumbar spine.51 At the L4-5 and L5-S1 levels, some patients have facet degeneration without disk changes. In some cases an inciting event or pathology can be identified. This is especially true in trauma patients with whiplash injuries.41,45,52 In most patients, whiplash leads to chronic neck and shoulder pain. However, in some cases, rear impact injuries can result in radiculopathy from cervical facet dislocations or fractures or in spinal cord injury.53-61 In addition, high-impact trauma such as motor vehicle accidents (MVAs) or sports injuries may result in z-joint pain secondary to hyperflexion,62 rotation, and distraction injuries.63

**CADAVERIC AND LABORATORY STUDIES**

Cadaveric studies have shed some light on the mechanisms of z-joint movement and displacement. Ianuzzi and coworkers found that the joint moments occurring with any given motion are directly correlated with the magnitude of joint displacement and tend to be greatest at the L4-5 and L5-S1 joints.64 At the three most caudad joints (L3-S1), contralateral bending is associated with greater capsular strain than ipsilateral bending is (i.e., the left facet joints are most strained during right lateral flexion). In contrast, the L1-2 and L2-3 joints undergo greater strain during ipsilateral flexion. For the upper three facet joints, the maximum joint displacement and greatest strain are associated with lateral bending, usually to the right. For the two lowest joints, the greatest degree of strain occurs during forward flexion (Table 61.1).

Later work has provided evidence that fusion of two vertebrae can lead to accelerated degeneration at adjacent levels.65-69 Little and associates fixated human lumbar spine specimens with a single anterior thoracolumbar plate at L4-5 and measured capsular displacement and strain during a wide range of physiologic motions.69 Motion was increased at the level of fixation and at both adjacent levels. Fusion also increased intervertebral angulation at L3-4 and L5-S1, with decreased motion at L4-5. Although fusion relieved the anterior (ipsilateral) strain at L4-5, there was greater posterior strain at L4-5 and anterior and posterior strain at both adjacent levels.

The z-joints may respond to repetitive strain and inflammation by filling with fluid and distending, thereby stretching the capsule and causing pain.70 The pain from capsular inflammation can spread beyond the joint area due to compression of the exiting nerve root in the neural foramen or spinal canal, especially with foramina that are already narrowed by facet joint hypertrophy, osteophytes, or herniated intervertebral disks.71-74 Inflammatory cytokines released from facet joint tissue may also contribute to the radicular symptoms in patients with spinal stenosis.75 Facet joint pain can therefore be manifested in a radicular pattern. Irritation of the capsule may also cause reflex spasm of the erector spinae, multifidus, and other paraspinal muscles.71,76,77

The pathophysiologic basis for persistent lumbar facet pain was established in a series of elegant experiments conducted by Cavanaugh and colleagues,78 Yamashita and colleagues,79,80 and Ozaktay and colleagues81 on New Zealand white rabbits. These studies showed that injection
of proinflammatory and algic mediators into facet joints resulted in inflammatory changes, including vasodilation, venous congestion, and the accumulation of polymorphonuclear leukocytes. The associated inflammatory response led to sensitization and reduced the firing thresholds of both nociceptors and proprioceptive nerve fibers. The result was an increase in the discharge rate and recruitment of previously silent units. Persistent nociception is known to cause peripheral sensitization with the potential for subsequent central sensitization and neuroplasticity. Later work by Chen and colleagues showed the presence of C and Aδ fibers in the cervical facet joint capsules of goats. C fibers were more prevalent in the dorsolateral aspect of the z-joint capsule, where tendons and muscles attach. Even though animal research has played a critical role in improving our understanding of the pathophysiology of facet pain, there is a wide array of anatomic and functional differences between animals and humans. Rat models of facet pain have involved injection of monosodium iodoacetate into the facet joint; however, this led to mechanical hyperalgesia in the hind paw, which would not be expected in a model of axial spine pain. Therefore, caution should be exercised when extrapolating the results of animal studies to humans.

These preclinical data do indicate that chronic facet pain is likely to occur with repetitive chronic strain or, less commonly, following any acute event that stretches the joint beyond its physiologic limits. Clinical studies indicating a higher prevalence of facet arthropathy in the elderly and case reports of facet pain following high-energy trauma support these preclinical findings.
CHAPTER 61 — PATHOGENESIS, DIAGNOSIS, AND TREATMENT OF ZYGAPOPHYSEAL (FACET) JOINT PAIN

HUMAN STUDIES

In clinical studies, chronic facet pain has been associated with several conditions. In patients with LBP and asymptomatic individuals, sagittally oriented facet joints were associated with degenerative spondylolisthesis.\textsuperscript{23,24} In these patients, recurrent rotational strain results in a myriad of changes in the disks and paired facet joints, including loss of disk height, osteophyte formation, and degenerative joint hypertrophy.\textsuperscript{88,89}

The intervertebral disk and paired facet joints work in concert. Therefore, changes in any part of the three-joint unit will alter the motion and function of the others. Degenerative disk disease (DDD) has been shown to result in concomitant changes in the facet joints.\textsuperscript{90-92} In the reverse scenario, degeneration and motion abnormalities of the facet joints can induce and accelerate intervertebral disk degeneration.\textsuperscript{93-95} Multiple studies have examined the relationship between DDD and facet joint osteoarthritis (OA) and concluded that DDD generally precedes facet arthritis.\textsuperscript{51,96} In addition, facet arthropathy tends to be most pronounced at spinal levels with advanced DDD. DDD affects rotation and movement at the level of degeneration and neighboring levels.\textsuperscript{97} However, a clinical study investigating the relationship between injection-confirmed discogenic LBP and facet joint arthropathy yielded conflicting findings.\textsuperscript{98} Among 92 patients with axial LBP, 39\% had at least one positive diskogram with a negative control disk, and 9\% experienced concordant pain relief following a series of diagnostic facet blocks. Yet only 3\% of patients had both positive diskography and diagnostic facet blocks.

A number of other conditions besides OA may affect the facet joint, including inflammatory arthritides such as rheumatoid arthritis, ankylosing spondylitis, and reactive arthritis.\textsuperscript{99-102} In addition, synovial impingement, meniscoid entrapment, chondromalacia facetae, pseudogout, synovial inflammation, villonodular synovitis, and acute and chronic infection may cause facetogenic pain.\textsuperscript{102-107} Synovial pseudocysts within the facets can result in distension and pressure on adjacent structures and thereby lead to calcification and asymmetrical facet hypertrophy.\textsuperscript{108-113} Pseudocysts typically induce axial pain and radiculopathy but can also cause motor weakness, myelopathy, and cauda equina syndrome.\textsuperscript{112,113} A retrospective review of magnetic resonance imaging (MRI) findings in 303 consecutive patients with LBP found that 9.5\% of the patients had z-joint synovial cysts, with the majority being located posteriorly.\textsuperscript{114}

There are a number of reported cases of lumbar facetogenic pain secondary to traumatic dislocation from rapid deceleration injuries, mostly at L5-S1.\textsuperscript{62,63,115-119} The purported mechanism of injury in these cases was hyperflexion, rotation, and distraction. By itself, hyperextension rarely leads to facet fractures.\textsuperscript{62} Twomey and colleagues dissected the lumbar spines of 31 subjects who died of trauma (mostly MVAs).\textsuperscript{120} They found occult bony fractures in the superior articular process or subchondral bone plate in 35\% of subjects and facet capsular or articular cartilage damage (or both) in 77\% of cases. These findings indicate that occult bony and soft tissue injuries to the facet joints may be a source of LBP after trauma.

For chronic post-traumatic neck pain, the cervical z-joints have been estimated to account for upward of 60\% of cases.\textsuperscript{39,121} However, trauma is responsible for only a small percentage of chronic neck pain. An epidemiologic study conducted in patients with chronic cervical pain found trauma to be the precipitating event in only 13\% of cases.\textsuperscript{122} In patients with positive cervical facet blocks, the percentage of cases attributed to trauma varies significantly. In a small, controlled study evaluating RF denervation for cervicogenic headache, 5 of 12 patients reported a previous inciting event.\textsuperscript{123} However, in the largest cervical facet denervation outcome study, Cohen and colleagues\textsuperscript{124} found that only 23\% of the 92 subjects with a positive response to diagnostic z-joint blocks cited trauma as the principal cause. In rare instances, tumors may also cause facet joint pain.\textsuperscript{125,126
The prevalence of facet joint pain varies greatly throughout the literature. The lumbar facets are most commonly affected, followed in descending order by cervical and thoracic facet arthropathy.

### PREVALENCE OF LUMBAR FACET ARTHROPATHY

The cited prevalence rate of lumbar facet pain ranges from 5% to upward of 90% in the literature. Many of the studies investigating prevalence, however, have been flawed. Numerous reviews have found that diagnosis of facet joint pain via the history, physical examination, and radiologic findings is unreliable; the most reliable method to diagnose a painful joint is by image-guided medial branch blocks (MBBs) or intra-articular injections of local anesthetic (LA). Diagnostic facet blocks without controls have been associated with false-positive rates ranging from 25% to 41%. Although some consider positive MBBs to be "diagnostic," given their high false-positive rates, it is probably more appropriate to consider them as being prognostic of long-lasting treatments, such as RF ablation of the medial branch.

This high false-positive rate has led some experts to advocate controlled or comparative blocks as the only reliable method for diagnosing lumbar facetogenic pain. The reported prevalence of facet pain with single LA blocks has ranged from 8% to 94%. Although some consider positive MBBs to be "diagnostic," given their high false-positive rates, it is probably more appropriate to consider them as being prognostic of long-lasting treatments, such as RF ablation of the medial branch.

Larger epidemiologic studies by primary care physicians and spine surgeons have found much lower rates of lumbar facet pain. Newton and associates studied all cases of acute and chronic LBP in a large health maintenance organization population over a 9-month period and found a 6% prevalence of facet-mediated pain. The addition of placebo-controlled LA blocks decreases prevalence rates significantly to between 9% and 42% (Table 61.2). Not surprisingly, the estimated prevalence rates tend to increase with age.

Larger epidemiologic studies by primary care physicians and spine surgeons have found much lower rates of lumbar facet pain. Newton and associates studied all cases of acute and chronic LBP in a large health maintenance organization population over a 9-month period and found a 6% prevalence of facet-mediated pain. In a comprehensive epidemiologic study by Long and coworkers, spine surgeons from eight academic medical centers in the United States collected demographic and clinical information on more than 4000 patients with LBP over a 5-year period. Final diagnoses were based on the history and physical examination, radiologic and other diagnostic studies, and response to treatment or diagnostic injections (or both). The diagnosis of “facet joint arthritis” was made in 4.8% of the 2374 patients who completed the study.

<td>198 (50%) of pts obtained a (+) response to lidocaine blocks, with 124 reporting definite pain relief with bupivacaine, for a 31% prevalence rate.</td>
<td>FP rate, 27%. Mean age, 47 yr.</td>
</tr>
</tbody>
</table>

The false-positive (FP) rate, if not mentioned, was determined by dividing the number of patients who obtained pain relief with the lidocaine screening block but not with the confirmatory block by the total number of blocks.

LA, local anesthetic; LBP, low back pain; MBB, medial branch block; pts, patients; rec’d, received.
The more cephalad lumbar facet joints are infrequently found to be the main source of axial LBP. In descending order, the most frequently implicated painful facet joints are L5-S1, L4-5, and L3-4. The upper lumbar facet joints are far less likely to be the source of LBP independent of disease in the lower joints.

A number of factors make prevalence studies difficult to interpret. Most studies excluded patients with focal neurologic signs or symptoms, yet foraminal narrowing secondary to facet hypertrophy is a well-described cause of radiculopathy. A second confounding factor is that the best studies investigating the prevalence of facet hypertrophy used comparative MBBs. Although the medial branch is the largest branch of the primary dorsal ramus, the other two branches are the intermediate branch, which innervates the longissimus muscle, and the lateral branch, which supplies the iliocostalis muscle, thoracolumbar fascia, skin over the lower back and buttock region, and sacroiliac joint. The medial branches above L5 are most easily blocked at the superomedial border of the transverse process at its junction with the superior articular process. In these areas, LA will almost invariably block all three primary dorsal rami branches because of their close proximity. Although it is difficult to infer the precise prevalence of lumbar facet joint pain, based on the available literature the best estimate is that it affects approximately 10% to 15% of patients with LBP.

PREVALENCE OF CERVICAL AND THORACIC FACET ARTHROPATHY

Less is known about the prevalence of cervical and thoracic facet arthropathy, although a few prospective trials have been conducted. In one of the earliest cervical z-joint prevalence studies, April and Bogduk performed provocative diskography, intra-articular facet injections, or both in 318 patients with chronic nonradicular neck pain following injury. Based on concordant pain provocation to both sets of blocks, the authors estimated the prevalence of cervical z-joint pain to be 26%. In addition to not using the analgesic response to facet blocks as their primary diagnostic criteria, another flaw in this study is that only 52 of the 318 patients underwent diagnostic cervical facet blocks. In an observational study by Barnsley and colleagues involving 50 patients with chronic neck pain following whiplash injury, the authors found a prevalence rate of 54% based on double-blind, comparative LA MBBs.

In a prospective study of 500 patients with nonradicular neck pain (n = 255) and midback pain (n = 72) or LBP, Manchikanti and coworkers used a concordant response to LA MBBs done with 1% lidocaine and 0.25% bupivacaine to diagnose a painful thoracic or cervical facet joint. The authors found the prevalence of cervical facetogenic pain in patients with neck pain to be 55%, whereas patients with midback and upper back pain had a 42% prevalence of thoracic facet pain. The latter finding is consistent with a previous study done by the same group in which a 48% prevalence of thoracic facet pain was found in patients with midback and upper back pain. Bilateral involvement was present in 69% of the patients in the cervical spine, in 64% in the thoracic spine, and in 72% in the lumbar spine.

Based on studies using comparative blocks, the prevalence of cervical facetogenic pain in patients with chronic neck pain has been estimated to be between 27% and 63% (Table 61.3). The C2-3 and C5-6 levels were found to be the most prevalent levels in two studies of patients with chronic neck pain. The C2-3 facet joint was also found to have the highest rate of degenerative disease in a study of 196 excavated human skeletons from the sixth to eighth centuries AD from Germanic row graves in southwestern Germany.

The majority of well-designed cervical facet prevalence studies have been conducted in patients with whiplash injuries after MVAs, which makes it difficult to estimate the prevalence in patients with neck pain and no history of trauma. It is well known that cervical facetogenic pain accounts for a large percentage of cases of persistent whiplash injury. Based on the available literature, the prevalence of cervical facet pain is probably around 50% in patients with chronic neck pain. The prevalence of thoracic facet pain in patients with chronic axial midback pain is between 42% and 48% (see Table 61.3).

DIAGNOSIS

Despite years of research aimed at identifying clinical factors that can be used to predict responsiveness to facet interventions, there are essentially no elements of the history or physical examination, biomarkers, or radiologic findings that are sensitive or specific for responsiveness to facet interventions. A detailed history and physical examination can help exclude other potential pain generators and may build an overall clinical picture consistent with facet pain.

HISTORY

Some patient factors are associated with possible facet pain. The majority of investigations have focused on the lumbar z-joints, although some data are available for cervical and thoracic z-joint pain. With the exception of patients with a history of whiplash or trauma (including spine surgery), facet pain is often associated with older age. The direct association with age is consistent with the concept that facet pain is a chronic degenerative disorder that generally coexists with DDD rather than an acute inflammatory process. No self-reported patient complaints or activities, such as sitting, walking, standing, bending, twisting, or coughing, have consistently been found to be associated with responsiveness to facet interventions. Some studies have found that opioid use and previous spine surgery may be associated with poor outcomes after RF treatment, but lack of responsiveness to RF does not rule out facet pain.

PAIN REFERRAL PATTERNS

The distribution and radiation of pain from the facet joints have been derived from patient self-report of relief with LA blocks, direct pressurization of the facet joints, and direct stimulation of the medial branches innervating the specific joints. The majority of these studies have failed to demonstrate any reliable pain referral patterns.

These discrepancies between pain provocation patterns and pain mapping/historical findings are consistent with previous studies using sacroiliac joint and selective nerve root blocks.\textsuperscript{158,159} Since facet pain is a usually a chronic, degenerative process, attempting to simulate this pain with maneuvers that result in acute capsular pressurization may not result in accurate findings.

When the existing data are synthesized, however, certain pain patterns do emerge (Fig. 61.8). The joint capsule appears to be more likely than the synovium or articular cartilage to generate pain. A great deal of overlap between neighboring facet joints exists. All lumbar levels are capable of producing groin pain, although it is most common in the lower levels (Table 61.4).\textsuperscript{34,86,138,144,157,160-171} Pain from the upper lumbar facets tends to extend into the flank, hip, and upper lateral aspect of the thigh, whereas pain from the lower lumbar levels is likely to penetrate deeper into the thigh, usually in the lateral and posterior aspects. Infrequently, the L4-5 and L5-S1 facet joints can provoke pain in the lateral part of the calf and rarely in the foot. Patients with osteophytes, synovial cysts, or facet hypertrophy may also have radicular symptoms. Unilateral pain or pain in the paraspinal distribution is more likely to be associated with pain from the facet or sacroiliac joints than with discogenic or other causes of LBP.\textsuperscript{172} In addition, pain in the low back region and thigh, especially with increasing age, was found to be more predictive of facet pain than was pain emanating from the sacroiliac joint, intervertebral disks, and other sources based on a retrospective study of patients undergoing evaluation with structured diagnostic blocks.\textsuperscript{46}

Clinical studies have been conducted in both normal volunteers and patients with suspected cervical facet pain to determine pain referral patterns from the joints.\textsuperscript{173-175} The results of these experiments are strikingly consistent. From C2-3, the pain pattern generally extends rostrally to the upper cervical region and suboccipital area. Infrequently, symptoms will extend toward the ear or further up the scalp. From C3-4, pain is referred to the upper and middle posterior aspect of the neck, with occasional radiation to the lower occiput. From C4-5, the most common referral pattern is to the lower posterior cervical region, although in a significant percentage of people it extends to the middle posterior aspect of the neck and suprascapular region. Pain from C5-6 is typically distributed to either the suprascapular region or lower part of the neck but can sometimes extend to the shoulder joint or midposterior neck region. From C6-7, pain is usually referred to the upper scapula or lower neck area. Pain from the C7-T1 z-joint most frequently extends further down into the midscapular area. Later work by Windsor and colleagues\textsuperscript{176} indicated that the pain referral patterns elicited by cervical medial branch stimulation tend to be more contained and slightly different from those elicited by articular z-joint distention (Fig. 61.9).

Similar work has been done for the thoracic z-joints. Dreyfuss and coworkers\textsuperscript{177} mapped thoracic facet pain patterns based on intra-articular injections of contrast material into the T3-4 to T10-11 z-joints in nine asymptomatic volunteers (Fig. 61.10). Fukui and associates\textsuperscript{34} later investigated pain referral patterns during intra-articular injection of the upper- and lower-most thoracic z-joints. The resultant pain referral patterns were as follows: pain from the C7-T1 and T1-T2 z-joints typically radiates into the suprascapular region and superior angle of the scapula. Pain extending into the midscapular region may come from either C7-T1, T1-2, or T2-3, and pain from the T11-12 z-joint generally extends into the paravertebral region around the site of injection out to around the iliac crest area.

CHAPTER 61 — PATHOGENESIS, DIAGNOSIS, AND TREATMENT OF ZYGAPOPHYESAL (FACET) JOINT PAIN

PHYSICAL EXAMINATION

As with the history and pain referral patterns, physical examination has limited value in diagnosing facet pain and is more valuable in ruling out other common causes of similar pain complaints. Of the available physical examination findings, paraspinous muscle tenderness is probably the only one indicative of facetogenic pain. This finding is consistent with the self-reported patient complaints of paraspinous pain noted in the history section above.

Despite the limited value of physical examination in diagnosing facet pain, many research studies and clinicians still rely on provocative maneuvers to select patients for facet interventions. Early descriptions of physical examination findings thought to be consistent with facet pain came from retrospective studies. In a study by Fairbank and coworkers, low-volume, intra-articular bupivacaine facet blocks done on 41 patients with LBP with or without leg pain resulted in at least temporary pain relief in 14 of the 25 patients who completed the study. When compared with nonresponders, subjects who responded positively to the blocks tended to have pain localized to the back and thigh and worsening pain with forward flexion. The term “lumbar facet syndrome” was coined by Helbig and Lee in 1988 based on a retrospective study of 22 patients. Patients who responded to intra-articular injections were more likely to have back pain associated with groin or thigh pain, paraspinous tenderness, and reproduction of pain with extension-rotation maneuvers. Pain radiating below the knee was found to be a negative predictor.

Larger and more methodologically sound studies have failed to validate “lumbar facet syndrome” or the provocative maneuver commonly known as “facet loading.” Prospective studies of 390 and 176 patients with chronic LBP were unable to correlate any historical or physical findings associated with a positive response to facet injections. In both studies, only a small percentage (10% and 15%, respectively) of the patients responded to diagnostic blocks. A randomized, placebo-controlled study of 80 patients with chronic LBP by Revel and colleagues found seven factors to be associated with response to facet joint anesthesia: age older than 65 years and pain not exacerbated by coughing, not worsened by hyperextension, not worsened by forward flexion, not worsened when rising from forward flexion, not worsened by extension-rotation maneuvers, and well relieved by recumbency. Yet subsequent investigations also failed to corroborate these findings.

Very few studies have investigated the history and physical findings most consistent with cervical and thoracic facet pain. As noted in the last section, the prevalence of facet involvement in patients with chronic neck and thoracic pain is higher than that in patients with LBP. Therefore, prognostic factors may be somewhat less important. One study found that a blinded therapist specializing in manipulation was able to diagnose symptomatic cervical facet joint pain correctly in patients with positive diagnostic cervical MBBs by means of perceived passive displacement of the joint and its resistance to displacement. However, a subsequent study conducted using controlled blocks as the “gold standard” for cervical z-joint pain found that although manual examination had a sensitivity of 88%, low specificity (39%) precluded its use as a valid diagnostic tool. Lord and coworkers found that patients with chronic neck pain who had a positive response to diagnostic cervical facet blocks were more likely to be female, to be victims of a rear-end collision, and to have restricted neck movement, although the findings were not statistically significant. Another study showed a 94% correlation between lumbar and cervical facet pain in patients with confirmed lumbar facet pain who have concomitant neck pain. The majority of cervical facet prevalence studies have been conducted on whiplash victims, thereby making it difficult to draw conclusions on the association between neck pain in nontrauma patients and cervical facet disease.

RADIOLOGIC FINDINGS

The prevalence of facet joint disease as observed with radiologic imaging is dependent on the age of patients, presence
of symptoms, imaging modality used, and threshold used for designating an examination as “abnormal.” In LBP patients, the incidence of degenerative facet disease noted on computed tomography (CT) ranges from about 40% in some studies\textsuperscript{127,182} to upward of 85% in others.\textsuperscript{133} Some studies found MRI to be less sensitive than CT in detecting degenerative facet changes,\textsuperscript{133,183,184} whereas other studies involving LBP patients revealed MRI to be more than 90% sensitive and specific when compared with CT (Table 61.5).\textsuperscript{96,185}

In a study of 14 patients with DDD, those younger than 40 years showed minimal osteoarthritic changes of the lumbar facets.\textsuperscript{96} The prevalence of facet pathology increases significantly in patients older than 60 years; however, facet degeneration is not universal. In asymptomatic volunteers, the incidence of lumbar facet degeneration ranges from 8% to 14%.\textsuperscript{184,186,187} In a study involving 60 asymptomatic individuals aged 20 to 50 years, MRI was used to evaluate for degenerative disk changes, end-plate abnormalities, and facet OA by two independent radiologists. Although disk bulge (62%) and protrusion (67%) were frequently present, neither radiologist noted severe facet OA.\textsuperscript{184}

The use of radiologic imaging as a predictor of the response to diagnostic facet blocks has been conflicting at best. Even though some studies have found a positive association between CT, MRI, and other imaging and response to facet blocks,\textsuperscript{127,130,166,182,188} an equal number have not.\textsuperscript{49,86,133,158,163,189} In a study by Carrera and Williams, the response to high-volume (2 to 4 mL) diagnostic blocks was found to correlate with CT evidence of lumbar facet disease in 93 patients with LBP.\textsuperscript{182} However, a larger study by Jackson and associates involving 390 patients found no relationship between x-ray findings and response to lumbar z-joint blocks.\textsuperscript{86} Schwarzer and colleagues found no relationship between a concordant analgesic response to placebo-controlled intra-articular facet blocks and CT findings of z-joint OA in 63 patients with chronic axial LBP.\textsuperscript{138} In a recent multicenter study by Cohen and coworkers involving 192 patients who underwent lumbar RF denervation based on a positive response to a single MBB, the authors found no association between MRI evidence of facet hypertrophy or degeneration and 6-month outcomes.\textsuperscript{155} Finally, Kawaguchi and colleagues found no significant relationship between the degree of radiographic lumbar facet and LBP symptoms in a study of 106 patients with rheumatoid arthritis.\textsuperscript{190} In the cervical and thoracic regions, there is a paucity of data evaluating the ability of radiologic imaging studies to predict response to diagnostic facet blocks. In the largest cervical facet denervation study ever conducted in 92 patients who underwent RF lesioning based on a positive response to a single diagnostic MBB, Cohen and coworkers found no association between 6-month outcomes and MRI evidence of facet arthritis at three different hospitals.\textsuperscript{124}

In summary, the literature does not support the routine use of radiologic imaging as a means of diagnosing facet arthropathy. As with the history and physical examination, imaging is better used to rule out other disorders, such as corresponding neuroforaminal narrowing, spinal stenosis, vertebral fractures, and tumors. The lack of association between the degree of degeneration or damage in facet arthropathy and pain complaints and responsiveness to intervention has been used as proof against their use by those critical of facet interventions; however, the lack of an association between imaging findings and facet joint pain is consistent with virtually every pain disorder in which investigators have attempted to correlate radiologic findings with pain. The most robust example of this point lies in analyses of the most common cause of disability in the world, painful arthritis, especially knee OA. Despite well-defined grading systems for knee OA, there is no correlation between the severity of knee OA and complaints of pain, with 30% to 50% of patients with moderate to severe OA reporting no symptoms and 10% of patients with severe knee pain having normal radiographic findings.\textsuperscript{191,192} Psychological variables account for only a small proportion of this variance.\textsuperscript{193} Yet knee OA is a widely accepted pain diagnosis, and it is estimated that more than 1 million combined primary total knee arthroplasties and revisions are performed each year in the United States alone.\textsuperscript{194}

### Diagnostic Blocks

The poor correlation between historical and physical examination findings and zygapophysial pain has led to widespread acceptance of the use of diagnostic blocks to confirm the facet joint as a primary pain generator. Even though MBB and intra-articular injections are widely touted to be equally effective diagnostic tools,\textsuperscript{104,135,137,141} the evidence for this claim is based on two studies, neither of which used a crossover design or controlled blocks or prescreened patients for z-joint pain.\textsuperscript{169,195} Several factors undermine the diagnostic validity of MBB. In a cadaveric study done in the 1930s, Kellegren showed that injection of 0.5 mL of fluid spread into an area encompassing 6 cm\textsuperscript{2} of tissue.\textsuperscript{156} Cohen and colleagues demonstrated that a reduction in LA volume in cervical MBBs from 0.5 to 0.25 mL decreased aberrant distribution, including spread to the intervertebral foramen.\textsuperscript{197} Therefore, injection of low-volume LA is likely to block the lateral and intermediate branches in addition to the medial branch. Since these nerves supply afferent innervation to multiple potential pain-generating structures, including the paraspinal muscles, ligaments, sacroiliac joints, and skin, MBB can
relieve pain even in the presence of normal facet joints. False-positive rates have been found to be as high as 63% in the cervical region, 55% in the thoracic region, and 27% in the lumbar facet region.143 False-negative responses are also a concern and can be due to intravascular uptake of the LA or failure of patients to distinguish between procedure-related pain and their baseline pain. Given the low sensitivity of aspiration and intermittent fluoroscopy, some experts advocate using “real-time” fluoroscopy to detect intravascular uptake during MBB.198

Although intra-articular facet injections may inherently be more accurate in diagnosing facet pain, these blocks can be technically challenging and are fraught with limitations. Injection of 1 to 2 mL of fluid will probably rupture the joint capsule and lead to extravasation of LA onto other pain-generating structures. Depending on the point of rupture, these structures may include the epidural space, intervertebral foramen, ligamentum flavum, and paraspinal musculature.70,132,134,169

**MEDIAL BRANCH BLOCK VERSUS INTRA-ARTICULAR INJECTION**

Only three studies have compared MBB with intra-articular facet injections. In a prospective, randomized study by Nash, 67 patients with LBP were randomized in pairs to undergo either MBB with 2 mL of LA or intra-articular injections with 1.5 mL of LA and steroid.195 In the 26 pairs who completed the study, 12 reported MBB to be more beneficial at their 1-month follow-up, 11 reported intra-articular injection to be better, and 3 reported no difference between the two. Marks and coworkers randomized 86 patients with LBP to receive either intra-articular injections or MBB with 2 mL of LA and steroid.169 Although no immediate postprocedural difference was noted, patients in the intra-articular group experienced better pain relief at 1 month. At 3 months, however, no difference was noted. In the most recent study, Ackerman and Ahmad randomized 46 patients with axial LBP and a positive single-photon emission computed tomography (SPECT) scan to receive either intra-articular injections or MBB using 0.7 mL of LA and steroid. Twelve weeks after treatment, 61% of the intra-articular injection group experienced a positive outcome, which compared favorably with 26% in the MBB group.199

It is difficult to draw conclusions based on these comparative studies because of the multitude of design flaws, with the most prominent ones being the lack of a definitive diagnosis in the study populations and the fact that only one study195 evaluated immediate postprocedure pain relief. Studies investigating the prevalence and false-positive rates in chronic LBP patients (see Table 61.2) found comparable diagnostic value for MBB and intra-articular injection. Only one of three placebo-controlled studies evaluating the outcome of lumbar RF denervation after intra-articular injections to “confirm” the presence of facetogenic pain demonstrated positive outcomes.200,202 and the only study that screened patients with lumbar MBB showed a positive outcome.203 In a prospective, randomized study comparing lumbar facet cryodenervation success rates between patients who underwent medial branch and pericapsular lumbar facet screening blocks, Birkenmaier and associates204 found superior outcomes up to 6 months after the procedure in the MBB group. However, the excessive volumes used during both diagnostic procedures, the absence of controlled blocks, and the lack of proven validity for pericapsular injections all detract from the authors’ conclusions.

Intra-articular injections can be technically more challenging, especially in the steep, frontally oriented thoracic facet joints. In addition, MBB involves anesthetization of the nerves to be lesioned and hence may serve as a “dry run” before definitive treatment. Given the lack of evidence for intra-articular injections as a superior diagnostic tool and the technical ease of performing MBB, it seems logical to use MBB as a prognostic tool for subsequent denervation (Figs. 61.11 and 61.12).

**FALSE-POSITIVE BLOCKS**

Numerous studies have found a high false-positive rate for diagnostic facet blocks that appears to be unaffected by the type of block used (i.e., intra-articular or MBB). Rates have ranged from 25% to 40% in the lumbar spine,136,139,140,143 58% in the thoracic spine,150 and 27% to 63% in the cervical spine.41,143,151,181,205,206 Lord and colleagues conducted a randomized, double-blind study in which 50 patients with chronic neck pain following an MVA were evaluated with serial cervical MBBs using normal saline, lidocaine, and bupivacaine in random order.206 The authors found that the use of serial blocks with lidocaine and bupivacaine had a high degree of specificity (88%) but only marginal sensitivity (54%). Although high specificity will result in a low false-positive rate, the low sensitivity predisposes patients to false-negative diagnoses.

Reasons for false-positive facet blocks are multifactorial and include a placebo response (18% to 32%) to diagnostic interventions, use of sedation, liberal use of superficial LA, and spread of injectate to other pain-generating structures.207 Although some investigators have disputed this assertion,208,210 it is our belief that not only opioids but also
sedatives such as midazolam can lead to false-positive blocks by interfering with interpretation of the analgesic response (i.e., preventing patients from engaging in normal activities) and by virtue of their muscle relaxant properties.\textsuperscript{211} If sedation is used, stricter standards for a positive block should be applied. Manchikanti and coworkers\textsuperscript{210} showed that administration of midazolam or fentanyl for the diagnosis of cervical facet joint pain using a double-block paradigm could be a confounding factor when 50\% or greater pain relief is used as the cutoff for a positive response. However, when 80\% or greater pain relief was used as the threshold for a positive response, the effect of sedation on validity was low. A large multicenter study by Cohen and colleagues found no difference in outcomes of lumbar facet denervation between patients who obtained 50\% or greater and those who obtained 80\% or greater pain relief after a single diagnostic MBB.\textsuperscript{212} In a recent survey of 500 patients scheduled for facet blocks or epidurals at an outpatient spine center, Cucuzzella and associates found that only 17\% requested sedation.\textsuperscript{213}

Even in patients with symptomatology consistent with unambiguous pathology, diagnostic blocks may lack specificity. North and colleagues conducted a prospective study of 33 patients with L5 or S1 radiculopathy and radiologic evidence of ongoing nerve root compression.\textsuperscript{214} All patients underwent a battery of LA blocks that included selective nerve root block, sciatic nerve block, MBB, and subcutaneous control injections. The authors found that approximately 90\% of patients obtained almost complete pain relief following selective nerve root block, 70\% experienced almost complete relief after sciatic block, and a majority obtained at least 50\% pain relief after MBB. In contrast, the median degree of pain relief after subcutaneous injection was around 30\%. The authors concluded that uncontrolled LA blocks lack specificity in the diagnostic evaluation of referred pain syndromes.

Dreyfuss and associates used postprocedural CT scans following 120 fluoroscopically guided lumbar MBBs to assess specificity and spread of contrast material.\textsuperscript{28} Two target points were chosen, one at the superomedial border of the transverse process and a second lower site midway between the upper border of the transverse process and the mamillloaccessory ligament. In 16\% of injections, contrast material was noted to spread into the intervertebral foramen or epidural space, more commonly occurring at the cephalad lumbar levels. When the lower target point was used, spread into the adjacent neural structures occurred only when the needle was inadvertently placed too high. In all cases, distal spread into the cleavage plane between the multifidus and longissimus muscles was noted. The injectate volume of 0.5 mL bathed the target in every case. The authors concluded that lower volumes may be adequate for MBB and that using a more caudal target point may increase the specificity of lumbar MBB.

Following up on the Dreyfuss study, Cohen and colleagues\textsuperscript{215} sought to determine whether spread into the epidural space or intervertebral foramina could account for false-positive MBBs by examining the relationship between clinical signs of radiculopathy, diskographic findings, and RF outcomes in 78 patients with positive MBBs who eventually failed RF denervation. The authors found a negative correlation between discogenic pain and failed RF denervation and no association between radicular pain and RF treatment outcomes. In contrast, a trend was noted in which patients with failed back surgery syndrome experienced worse outcomes after facet denervation. The authors concluded that myofascial pain might be a significant cause of false-positive MBBs.

In a study of 24 patients undergoing cervical MBB, Cohen and associates investigated the spread of 0.5 versus 0.25 mL of LA mixed with contrast agent.\textsuperscript{197} MBBs were performed in either the prone (posterior) or lateral position. CT scans were conducted following the MBBs to assess for aberrant spread. Blocks performed in the 0.25-mL group resulted in aberrant spread to untargeted adjacent levels and into the intervertebral foramina less than half as often as those done with 0.5 mL (16\% vs. 38\%). There were a total of

![Figure 61.12](image_url) Figure 61.12 Anteroposterior (A) and lateral (B) fluoroscopic images demonstrating right-sided C4 and C5 medial branch blocks.
six “missed” medial branches in the 86 blocks performed, which were evenly distributed between the groups. These findings indicate that lower volumes may enhance specificity without negatively affecting sensitivity.

The evidence that inadvertent treatment of myofascial pain may be a significant cause of false-positive MBBs is circumstantial but multifaceted. In a large, multicenter epidemiologic study involving more than 2000 patients, Long and coworkers found myofascial pain to be the second most common cause of chronic LBP after herniated disks.131 Controlled studies conducted in chronic LBP patients have shown both muscle relaxants and low-volume botulinum toxin injections to be efficacious, as well as electromyographic evidence of increased paraspinal muscle activity when compared with matched controls.216-219 Finally, Ackerman and colleagues tested the hypothesis of whether myofascial pain could account for the high rate of false-positive facet blocks in a double-blind study conducted in 75 men with chronic LBP.220 Subjects received either intra-articular facet injections or MBB via two techniques: one in which LA was used to provide superficial anesthesia down to the target point and a second in which saline was injected as the needle was advanced. The authors found that the incidence of postprocedural pain relief was significantly higher in patients who had LA injected into their musculature than in those who received saline injected superficially, thus suggesting a higher false-positive rate. Injection of LA into the skin and soft tissues may also reduce LBP by means other than the inadvertent treatment of myofascial pain. In studies by Woolf and McMahon221 and Woolf and Wiesenfeld-Hallin,222 the authors found that the superficial injection of even small amounts of lidocaine reduced nociceptive behavior in animal models of neuropathic pain, a finding attributed to systemic absorption of the sodium channel blocker (Box 61.1).221,222

In an effort to reduce the amount of superficial anesthetic used for MBB, Stojanovic and colleagues introduced a single-needle technique whereby multiple medial branches are blocked via a single skin entry point.223 In a prospective crossover study comparing the single-needle and conventional multiple-needle techniques, the authors found that the single-needle technique required significantly less superficial LA, resulted in less procedure-related pain, and was quicker to perform than the multiple-needle approach (Fig. 61.13).224 With regard to final needle position, spread of contrast material, and postprocedural pain relief, no differences were noted between the two techniques.

**Box 61.1** Interventions That May Reduce the Incidence of False-Positive Lumbar Facet Blocks

1. Perform placebo-controlled blocks or, if not possible, comparative local anesthetic blocks.
2. Aim for a lower target point on the transverse process.
3. Reduce the injectate volume to 0.5 mL or less.
4. Be judicious with the use of superficial anesthesia.
5. Consider a single-needle approach.
6. Consider using guidance with computed tomography when doing intra-articular injections in patients with severe spondylosis.
7. Avoid the use of sedation or intravenous opioids.

![Figure 61.13](image-url) Anteroposterior fluoroscopic images showing spread of contrast material for L3 (left), L4 (middle), and L5 (right) medial branch blocks using the single-needle technique. The bottom figures show needle placement in an oblique fluoroscopic view for the same blocks.
FALSE-NEGATIVE BLOCKS

Similar to false-positive blocks, false-negative blocks may result from a multitude of factors. One study estimated the incidence of false-negative lumbar MBBs to be approximately 11%. However, this study attempted to elicit pain by facet capsular distortion following LA and control blocks in asymptomatic volunteers and hence would be unlikely to have significant clinical implications in patients. It suggests that some individuals may contain aberrant innervation from nerves other than the medial branches.

Venous uptake of LA was reported to occur in 8% of lumbar facet blocks in one study and 33% in another. In one of the studies, even after the needle was repositioned once venous uptake was detected, injection of LA failed to prevent pain from capsular distention in 50% of subjects. Therefore, some experts suggest that if aspiration is positive during diagnostic MBB, it is better to abort the procedure and repeat it later rather than risk a false-negative result. In a study of more than 1400 lumbar MBBs in 456 patients, Lee and coworkers found a 6.1% rate of uptake of LA, which was detected in 34% of the patients by aspiration and in 59% by spot fluoroscopy. Consequently, the authors recommended the use of continuous fluoroscopy during MBBs. One of the biggest causes of false-negative blocks is the failure of patients to properly distinguish procedure-related pain from their index pain, which underscores the need for proper education regarding the use of pain diaries.

**HOW MANY BLOCKS SHOULD BE DONE BEFORE RADIOFREQUENCY DENERVATION?**

Many experts and organizations advocate performing multiple diagnostic blocks to reduce the high false-positive rate. There are two problems with this argument. First, reducing the false-positive rate is important when trying to establish “efficacy” but may be counterproductive when one’s objective is “effectiveness,” which seeks to maximize outcomes under real-life conditions. To illustrate this point, many controlled studies evaluating RF denervation have screened hundreds of patients to enroll several dozen subjects. Although the results of the enrolled patients who received treatment are cited and again in systematic reviews and book chapters, the ultimate outcomes of the hundreds of patients excluded from participation remain unknown. Second, many of these “false-positive” blocks may actually include “false-negatives,” which can result from failure to discount procedure-related pain and discordant responses to either saline or LA, findings previously reported in clinical trials. Even though performing multiple blocks will invariably reduce the false-positive rate, it will inerredibly increase the false-negative rate, which translates to a safe and effective treatment being withheld from some individuals who will benefit. Undoubtedly, many of these patients eventually undergo surgery. Eliminating placebo responders may be not only impossible but also impractical since the benefits experienced by a “sham” intervention (e.g., pain relief, functional improvement) are indistinguishable from those experienced with a “true” intervention.

In an attempt to determine the ideal number of diagnostic blocks under “real-life” circumstances, Cohen and colleagues performed a randomized, comparative cost-effectiveness study in which 151 patients were allocated in an equal ratio to receive lumbar facet RF denervation without MBB, after a positive response to one MBB done with bupivacaine, or only after a concordant response to comparative blocks done in random order with lidocaine and bupivacaine. Predictably, a higher RF success rate was found in the double-block group, which is consistent with using this treatment paradigm in clinical trials that seek to determine efficacy. However, the overall number of patients who experienced a successful outcome at 3 months was significantly higher in the zero-block group \((n = 17)\) than in the single- \((n = 8)\) and double-block \((n = 11)\) groups. Moreover, the cost per effective treatment in the zero-block group was less than half that in the other two groups. The results of this study are bolstered by theoretical computations that have determined “double blocks” not to be cost-effective at current reimbursement rates. Similar comparative effectiveness studies have not been done for cervical facet joint pain; however, because the relative reimbursement rates between diagnostic blocks and RF denervation are comparable in the neck and because facetogenic pain accounts for a higher proportion of chronic neck pain than chronic LBP, it is likely that these results can be reliably extrapolated to cervical facet joint RF denervation. Currently, we believe that there is little basis for using double blocks, and the decision regarding whether to perform a single block or proceed straight to RF denervation should be made on a case-by-case basis (i.e., the risks of performing a diagnostic block might outweigh the benefits in a patient taking warfarin).

**TREATMENT**

**CONSERVATIVE TREATMENT AND PHARMACOTHERAPY**

A multimodal approach to the treatment of facetogenic pain is essential. Although many patients seen in interventional pain medicine clinics will receive a procedural approach to therapy, there is value in conservative therapy, medical management, and, when indicated, psychotherapy. Pharmacotherapy and noninterventional treatments of spinal pain have been investigated, but no study has evaluated these alternatives specifically in patients with facet pain. Tailored exercise programs and yoga have been shown to reduce pain and prevent relapses in patients with chronic LBP. Osteopathic manipulation has produced mixed results, with two studies indicating moderate relief of LBP and another showing no difference between true and sham manipulations. For subacute neck and back pain, a randomized study comparing conservative care (i.e., physical and pharmaceutical therapy) alone with conservative care and osteopathic manipulation three to four times per week found improved outcomes in the combined therapy group at 2 months but not at 6 months after the intervention. In addition, some randomized trials have found significant benefit with acupuncture and acupressure in patients with chronic LBP and neck pain. Similar to manipulation, however, one of the largest and most methodologically sound studies found no difference between true and sham acupuncture.
Nonsteroidal anti-inflammatory drugs and acetaminophen are widely considered first-line drugs for the treatment of LBP, with nonsteroidal anti-inflammatory drugs being slightly more efficacious than acetaminophen, which is devoid of anti-inflammatory properties. A comprehensive review of published clinical trials evaluating pharmacotherapy for LBP by Schnitzer and colleagues found evidence for the use of antidepressants for chronic LBP and muscle relaxants for acute LBP. However, more recent reviews have failed to find a significant benefit with antidepressants. In addition to LBP, skeletal muscle relaxants have also shown efficacy in controlled trials for neck pain. There is little doubt that untreated psychopathology can adversely affect back and neck pain treatment outcomes. In a study by Polatin and coworkers conducted in 200 chronic LBP patients, the authors found that 77% met the lifetime criteria and 59% demonstrated current symptoms for at least one psychiatric diagnosis, with the most common being depression, substance abuse, and anxiety disorders. Reviews demonstrate that neck and back pain are associated with depression and anxiety; however, this explains only a portion of the variance and cannot be considered the primary cause of the patient's symptoms. Lilius and associates found a strong correlation between a negative response to intra-articular and periarticular LA and steroid injections and inappropriate signs and symptoms. Wasan and colleagues found that depression and anxiety symptoms were associated with a negative response to intra-articular lumbar facet steroid injections. Some authors have postulated that depression and anxiety may be part of a broader phenotype of centralized pain, which may further explain the variance in outcomes described.

Optimal management of facet joint pain should encompass both noninterventional and interventional treatment, although clinicians are encouraged to exercise caution when extrapolating the results of studies conducted in patients with nonspecific back and neck pain to those with clear-cut z-joint pathology.

**INTRA-ARTICULAR STEROID INJECTIONS**

There is some controversy regarding the use of intra-articular LA and steroid injections for the diagnosis and treatment of facet pain. In uncontrolled studies, success rates in individuals undergoing intra-articular steroid injections range from 18% to 63%, with most of these studies being conducted in patients who did not undergo diagnostic screening blocks. Other studies have reported intermediate-term pain relief after intra-articular LA alone and with hyaluronic acid. The results of controlled trials have been mixed at best (Table 61.6). In a large study, Lilius and colleagues found no significant differences in the outcomes of 109 patients who received large-volume (8 mm) LA and steroid injected into two joints, the same mixture administered around the joints, or physiologic saline. In another study comparing intra-articular steroid and saline in 97 patients with chronic LBP, Carette and coworkers found a statistically significant benefit only at the 6-month mark in the steroid group. Although this was a large and methodologically sound study whereby patients were prescreened with diagnostic intra-articular LA blocks, the control group received intra-articular normal saline. Normal saline has been shown on multiple occasions to provide better pain relief than a true placebo for a variety of invasive procedures. Barnsley and associates randomized 41 patients with chronic neck pain following an MVA to receive 1 mL of either intra-articular bupivacaine or betamethasone under double-blind conditions. The median time to return of 50% of the patient's preinjection pain was 3 days in the steroid group and 3.5 days in the LA group, with less than half the patients reporting pain relief lasting longer than 1 week. All patients in this study were prescreened for cervical z-joint pain via comparative MBB. Wasan and colleagues found that psychopathology was associated with a negative response to intra-articular steroid lumbar facet injections in the 86 patients assessed. Even though responses were better in patients in the low- and moderate-psychopathology groups, the changes in average daily pain were only 23% and 6.1% 1 month after the block, respectively, and there were no improvements in pain interference, anxiety, or depression in any of the groups.

In six recent review articles, the authors have been evenly split on the efficacy of intra-articular steroids. Given basic science studies demonstrating inflammatory mediators around degenerated facet joints, we believe that intra-articular steroid injections may provide intermediate-term relief to a small subset of patients with an actively inflamed z-joint. Evidence to support this assertion is bolstered by several recent prospective and observational studies that evaluated low- to intermediate-volume (1 to 3 mL) LA and steroid intra-articular lumbar facet joint injections performed in more than 160 patients with axial LBP. These studies, patients with positive SPECT findings experienced dramatically better pain relief (>75% success rate) than did those with negative or no SPECT findings (<40% success rate) up to 3 months after injection. In the two studies that monitored patients for 6 months after injection, the beneficial effect wore off after the 3-month evaluation. These findings are supported by Ackerman and Ahmad, who randomized 46 patients with a positive scan and paraspinal tenderness to receive intra-articular injections or MBB with LA and steroids. Three months after the injection, the patients in the intra-articular injection group experienced better pain relief than did those who received MBB. Radionuclide bone scintigraphy is capable of depicting synovial changes caused by inflammation, degenerative changes associated with bone remodeling, and increased metabolic function. In addition to radiologic evidence of joint inflammation and degeneration, intra-articular steroid injections may be more effective in patients who obtain definitive pain relief following a diagnostic screening block and when LA is added to the injectate.

**THERAPEUTIC MEDIAL BRANCH BLOCKS**

In a series of prospective, randomized evaluations of repeated therapeutic MBB with LA, LA plus Sarapin, LA plus steroid, and LA plus steroid and Sarapin, Manchikanti and coauthors reported significant relief of lumbar, thoracic, cervical facet pain in more than 85% of individuals in all groups for up to 2 years. Patients were screened with comparative LA blocks, but the studies lacked a placebo or sham group. No differences were

</table>

The methodologic quality (MQ) score was based on the 5-point Jadad scale. A score of 3 or higher indicates high methodologic quality. HA, hyaluronic acid; LA, local anesthesia; LBP, low back pain; MBB, medial branch block; MVA, motor vehicle accident; NS, normal saline; pts, patients; rec’d, received; SPECT, single-photon emission computed tomography; z-joint, zygapophyseal (facet) joint.
found with the addition of either steroid or Sarapin to the LA. Even though some patients may derive long-term benefit from diagnostic MBB, either from a placebo response, from “breaking the cycle of pain,” or in rare instances from the anti-inflammatory effects of steroids on a medial branch trapped beneath the mamilloaccessory ligament, most studies have failed to corroborate these findings. The concept that blocking the medial branch with or without steroid would lead to sustained improvement in pain is analogous to the idea that serial blockade of the femoral nerve can successfully treat painful knee OA. Despite multiple publications reporting effectiveness by the same group of investigators, there is little supporting evidence for a prolonged benefit from MBB in most patients. Nevertheless, there is probably a small subset of patients who will experience sustained benefit following LA MBB.

PULSED RADIOFREQUENCY OF THE MEDIAL BRANCH

Pulsed radiofrequency (pRF) is a nonablative technique that has been used for the treatment of several chronic pain conditions. The conceptual appeal of pRF is that because it acts via the creation of an electrical field and enhancement of descending modulatory systems, it results in minimal nerve damage. Consequently, unlike conventional RF, which severs nerves that subsequently develop into neuromas, it is frequently used as a treatment of neuropathic pain, in which nerve damage is the underlying cause of the pain. The condition for which pRF is currently used most is chronic, refractory radiculopathy, and the dorsal root ganglion (DRG) is the target. Although pRF of the DRG may be efficacious, its efficacy for nociceptive pain conditions (e.g., facet joint pain) and its application to peripheral nerves, such as the medial branch, have not been demonstrated. In a retrospective study involving 118 patients who responded to diagnostic MBB, only 68 derived benefit from pRF, which lasted on average less than 4 months.

Two clinical trials compared conventional RF with pRF. Kroll and colleagues randomized 50 patients who obtained greater than 50% relief after two MBBS to continuous RF or pRF. Almost 50% of the patients were lost to follow-up. Although no significant differences between groups were found at the 3-month follow-up, a comparison of within-group differences revealed greater improvements in pain and disability in conventional RF patients. This study was underpowered to detect between-group differences.

In the second study, Tekin and coworkers randomized 60 patients with a positive response to a single MBB to either sham RF (LA only), pRF, or continuous RF. All groups, including the LA-only group, described improvements in pain and disability. However, the magnitude of improvement and the duration of benefit were significantly greater in the continuous RF group. In summary, the current state of evidence does not support the use of pRF of the medial branch for the treatment of facet pain.

RADIOFREQUENCY DENERVATION

The first description of percutaneous rhizotomy for the treatment of “intervertebral disk syndrome” was by Rees in 1971. Notwithstanding his greater than 99% reported success rate, it remains a subject of controversy whether his technique actually achieved “facet rhizolysis” since the instrument that he used may not have been long enough to accomplish anything more than a myofasciectomy. The technique of percutaneous RF lesioning is generally credited to Shealy, who was motivated by what he perceived to be an unacceptably high incidence of local hemorrhagic complications with the Rees technique. Subsequently, it has been used to treat different forms of spinal pain, including whiplash, sacroiliac joint pain, discogenic pain, and intractable sciatica. Many uncontrolled trials have touted the benefits of RF denervation for facet pain. For lumbar facet RF denervation, most studies report sustained relief in 50% to 80% of patients without previous back surgery, whereas 35% to 50% of subjects with failed back surgery syndrome obtain prolonged relief. In the only study comparing outcomes of cervical z-joint denervation in operated and nonoperated spines, Cohen and colleagues found no difference in success rates between patients with failed neck surgery syndrome and those who had never undergone surgery.

Seven placebo-controlled studies have evaluated RF denervation for lumbar z-joint pain (Table 61.7; Fig. 61.14). In the first study, King and Lagger randomized 60 patients with LBP and leg pain to receive empirical (without stimulation) RF denervation of the dorsal rami, an RF lesion made in the muscle, or a sham lesion after electrical stimulation. At their 6-month follow-up, 27% of patients in the facet denervation group experienced satisfactory pain relief versus 53% in the myotomy group and 0% in the sham group. The main criticisms of this study are that no diagnostic blocks were performed to screen people for lumbar z-joint pain and electrode placement was suboptimal based on subsequent anatomic studies. Almost 25 years later, Gallagher and coworkers randomized 41 patients to either sham or true denervation based on their response to diagnostic intra-articular blocks (equivocal or definitive response). A statistically significant difference in outcomes was observed at 1 month only between sham and true RF denervation in patients who obtained a “definitive” response to diagnostic blocks. This difference persisted for the duration of the 6-month follow-up period. In one of the most methodologically sound controlled trials, van Kleef and colleagues found a 46% reduction in pain in the RF lesion group versus an 8% reduction in the placebo group. At the 12-month follow-up, 7 of 15 patients in the treatment group continued to have a successful outcome versus only 2 of 16 in the sham group. In the only truly negative study, Leclaire and coworkers conducted a placebo-controlled study in 70 patients with a putative diagnosis of facet arthropathy. At their 4-week follow-up, the only outcome variable that favored the treatment group was an improvement in the mean Roland-Morris disability score. At 12 weeks, no difference in pain levels or any measure of functional capacity was noted between groups. The key flaws in this study are that the authors used “significant pain relief lasting > 24 h” after an intra-articular injection of LA and steroid as their main inclusion criterion, they failed to place the electrodes parallel to the nerves, and they screened only 76 patients to enroll their 70 study participants. In addition to being ambiguous, the 24-hour threshold is inconsistent with the

The methodologic quality (MQ) score was based on the 5-point Jadad scale. A score of 3 or greater indicates high methodologic quality. The clinical relevance (CR) score was based on patient selection parameters and description of the RF technique (0 to 9 scale) as described by Geurts and colleagues.
lesions. RF patients described higher self-reported improvement and significant improvements in back and leg pain, generalized pain, quality of life, and analgesic requirements when compared with the sham group.

A key flaw in many of these studies is the failure to select patients based on placebo-controlled or comparative LA blocks, which are now acknowledged to be inferior to placebo controls. Although double blocks are often impractical and will inevitably result in a lower overall success rate with higher total cost, elimination of “false-positive” responders is ideal for studies that seek to establish efficacy. In addition, electrode positioning was suboptimal in several studies, including the Leclaire and van Wijk trials. One final point that should be considered when screening patients is that all negative and equivocal studies used intraarticular injection rather than MBB to screen patients.

In an uncontrolled study designed to determine efficacy under ideal conditions, Dreyfuss and coworkers evaluated outcomes in 15 patients who underwent lumbar facet RF denervation. Their strict inclusion criteria and treatment parameters included 80% or greater relief with comparative MBB, elimination of patients with concomitant pain generators (e.g., discogenic pain), and the use of large-bore 16-gauge electrodes. They reported that 87% of 15 patients obtained at least 60% relief 12 months after RF denervation, with 60% of patients achieving at least 90% relief. Similar to the trial by Nath and colleagues, a large number of patients (N = 460) were screened to create the final group of 15 patients undergoing intervention. Although this may demonstrate efficacy using rigid selection criteria, it may not represent what occurs in normal clinical practice.

Even though some may construe these findings as evidence that RF denervation is a fundamentally flawed treatment, a more plausible interpretation is that they indicate a strong need to optimize RF denervation techniques and better identify candidates likely to obtain positive outcomes. Recent studies that have used appropriate technique and needle position have clearly demonstrated sustained improvements in pain and function. Several investigators have determined that placing the electrode parallel rather than perpendicular to the target nerve substantially increases the size of the lesion, thereby reducing the likelihood that the treatment will miss or only partially coagulate the target nerve. After a literature review and cadaveric study, Lau and coauthors concluded that the ideal electrode position is along the lateral neck of the superior articular process rather than at the groove between the angle of the superior articular and transverse processes, as was used in most studies. Other investigators found the maximal lesion size to be reached within 60 seconds of lesion time, independent of whether the system was temperature or voltage controlled. Studies conducted in human myocardium determined that irrigation fluid has either no effect or a slightly beneficial effect on lesion size. Consequently, the use of LA to prevent procedure-related pain or steroid to reduce the incidence of neuritis should theoretically have no adverse effects on the efficacy of RF denervation. In an ex vivo chicken model, Provenzano and colleagues found that injection of fluid before RF denervation actually increased lesion size. Ongoing studies by the same group are investigating the impact of the composition of various injectants on lesion size.
Only two randomized, double-blind trials have evaluated percutaneous RF denervation for cervical facet pain (Fig. 61.15). Lord and colleagues randomized 24 patients with whiplash injury following an MVA and a positive response to diagnostic, placebo-controlled cervical MBB to receive either cervical medial branch denervation or a sham procedure.154 Patients with pain stemming solely from the C2-3 facet joint were excluded. To establish a diagnosis of cervical facet pain, a series of three blocks were performed. The first block was done with either lidocaine or bupivacaine, the second block with either normal saline or the other LA, and the third block with the remaining agent. A block was deemed positive only if the patient had complete, concordant relief each time that an LA was used but no relief when normal saline was administered. Except for needle temperature, all therapeutic aspects of the procedures were the same in both groups. The mean time for return to 50% of baseline pain was 263 days in the RF group versus 8 days in the placebo group ($P = 0.04$). At 27 weeks, seven patients in the RF group and one patient in the control group remained pain free. Five of the patients in the RF group had numbness in the territory of the treated nerves, but none considered it troublesome.

In a more recent study, Stovner and coworkers randomized 12 patients in whom cervicogenic headache was diagnosed on the basis of clinical symptoms to receive either cervical facet RF denervation or a sham procedure.123 Although the authors performed medial branch and greater occipital nerve blocks, the results were not used to select patients. The study was halted early secondary to failure to enroll subjects. At their 3-month follow-up, four of six patients in the RF denervation group obtained a meaningful clinical response versus two of six patients in the sham group. At 6 months no differences were noted between groups. Two years after the procedure, patients in the sham group felt that they had more significant improvement than did those in the RF group.

The results of sham denervation in this study are comparable to those in a previous uncontrolled study that evaluated RF for cervicogenic headache in which patients reported a 34% reduction in symptoms.311 In an open-label prospective study comparing cervical z-joint RF results between litigant and nonlitigant patients with whiplash injuries, Sapir and Gorup found no significant differences between groups in 1-year outcomes.312 Potential reasons for limited RF success rates for chronic neck pain and cervicogenic headache include technical difficulty denervating the frequently affected C2-3 facet joint, concomitant sources of head pain, and lack of specificity for diagnostic injections. In an observational study conducted in 56 patients with post-traumatic neck pain, provocative diskography and MBB were positive at the same level in 41% of patients.313

Although only two placebo-controlled trials assessed cervical facet denervation, several uncontrolled studies deserve mention. McDonald and colleagues prospectively studied patients in whom cervical facet pain was diagnosed based on controlled diagnostic blocks and found that 18 of 28 patients obtained significant pain relief lasting at least 90 days.314 In patients with a positive response, the median duration of relief was 421.5 days. A later study by Barnsley measured the duration of pain relief following cervical facet denervation in patients with a positive response to controlled cervical MBB.315 In the 45 patients studied, 36 (80%) experienced significant relief for a mean duration of 36 weeks. In both studies, patients who experienced a good initial response to denervation obtained comparable relief following repeated procedures.

In an uncontrolled prospective study involving 40 patient with refractory thoracic pain, Stolker and associates obtained good results following thoracic medial branch denervation.316 Thoracic facet pain was diagnosed by clinical criteria and a positive response to diagnostic MBB. After 2 months, 47.5% of patients were pain free, 35% reported more than 50% pain relief, and 17.5% experienced minimal or no relief. At an average follow-up of 31 months (18 to 54 months), 44% of patients remained pain free, 39% continued to have more than 50% pain relief, and 17% had poor outcomes. Although these results are encouraging, the diagnosis of thoracic facet joint pain was made by using clinical predictors, which are inherently nonspecific, and by using single LA MBBs, which are known to carry a high false-positive rate.143 In addition, the long-term relief seen in many of the patients is beyond that typically observed in the cervical and lumbar spine.

The use of sensory stimulation to corroborate proximity to the targeted medial branch is another flaw of many RF studies. Generally, a threshold of 0.5 V or less is deemed to be sufficient to effect a lesion that encompasses the target nerve. Although sensory stimulation may indicate close proximity to the target nerve at this voltage, it is our experience that many patients perceive concordant stimulation at 0.5 V or less, even when the electrode is purposefully placed in muscle, as during a sham procedure. In a prospective study involving 61 patients, Cohen and colleagues...
found no correlation between the mean sensory threshold and lumbar RF denervation outcomes. Even though one might construe this to mean that sensory stimulation is not necessary, it should be emphasized that sensory thresholds in these patients were recorded only after repeated electrode adjustments. Consequently, a high sensory threshold (e.g., 0.8 V) might not afford the same likelihood of success when electrode manipulation could result in a lower threshold and consequently closer proximity to the target nerve.

An attractive alternative or addition to sensory stimulation in the lumbar and cervical spine regions is to attempt to elicit multifidus muscle contraction since the same medial branch that innervates the lumbar facet joint also supplies this large paraspinal muscle. Both studies in which the medial branch was identified by motor stimulation demonstrated positive outcomes.

**FACTORS ASSOCIATED WITH OUTCOME**

In a large, multicenter outcome study, Cohen and coworkers attempted to identify factors associated with successful RF treatment in 192 patients who underwent denervation at three teaching hospitals after a single positive MBB. Among the 15 variables analyzed for their association with treatment outcome, only paraspinal tenderness was found to predict successful treatment. Factors associated with failed treatment included increased pain with hyperextension and axial rotation (i.e., facet loading), duration of pain, and previous back surgery. The latter two variables have been associated with treatment failure not only for RF denervation but also for a host of other LBP interventions, as well as for epidural steroid injections and open surgery. A study performed on the cervical spine by the same group of investigators found similar results. The only variable associated with a positive outcome was paraspinal tenderness. Factors associated with a negative outcome included opioid use, radiation to the occiput, and pain worsened by extension-rotation maneuvers. When pain returns following RF denervation, which typically occurs between 6 months and 1 year, neurotomy can be repeated with similar efficacy, and small studies of RF denervation in the lumbar and cervical regions have demonstrated greater than 85% success rates.

**EFFICACY VERSUS EFFECTIVENESS OF RADIOFREQUENCY DENERVATION**

The efficacy of RF of the medial branch has been established in well-selected patients as noted in the earlier section on RF denervation. The studies that have established efficacy, however, have screened large numbers of patients and excluded most people, usually because of strict criteria for multiple MBBs. As described previously, Nath and colleagues enrolled approximately 10% of screened study candidates to demonstrate efficacy in the 40 patients randomized to RF or sham. Excluding such a high percentage of patients through rigid MBB response criteria (including exclusion of patients for longer than anticipated pain relief) will probably lead to a high success rate, but it does not represent what happens in clinical practice. In retrospective studies, failure to derive benefit from facet interventions (defined as 50% improvement at 6 months) is estimated to occur in 45% and 39% to 47% of patients after cervical and lumbar medial branch interventions, respectively. These studies were retrospective and intended to study predictors of failure, not the incidence of failure, so the failure rate data must be interpreted cautiously. Prospectively collected data on the effectiveness of facet interventions are incredibly limited, but such studies are ongoing.

Recently, there has been significant interest buoyed by the National Institutes of Health in comparative effectiveness research in which studies assess effectiveness, benefit, and harm relative to other treatment options. Unlike efficacy studies, which generally assess outcomes in comparison to placebo under ideal circumstances (i.e., stringent inclusion and exclusion criteria), effectiveness studies aim to measure treatment outcomes under “real-life” circumstances—often in comparison to the current standard treatment. Given the challenges in appropriately diagnosing facet pain, studying the comparative effectiveness of different interventions can be extremely challenging. Despite these challenges, there are ongoing studies evaluating comparative effectiveness for the treatment of presumed facet pain.

**SURGERY**

Surgery is occasionally performed to treat facet arthropathy despite a lack of evidence supporting fusion for degenerative spinal disorders. Not surprisingly, the results of studies evaluating the use of lumbar z-joint blocks to predict outcomes of lumbar arthrodesis are discouraging (Table 61.8). In the three studies that compared surgical outcomes between facet block responders and nonresponders, all three failed to show a difference between groups. Bough and associates conducted a retrospective review of 127 facet joints surgically removed from 84 patients in an attempt to correlate histologic evidence of facet degeneration with a provocative response to preoperative facet arthrography. Although the authors found the positive predictive value of concordant pain reproduction to be 85%, the negative predictive value was only 43%, which led them to conclude that provocative facet arthrography was of little value as a presurgical screening tool. In a prospective case series, Lovely and Rastogi found that 83% of 23 patients who responded to bracing and three successive facet blocks achieved 90% or greater pain relief after fusion surgery at the latest follow-up. However, the large volumes used per block, the failure to exclude placebo responders, and the lack of any comparison group undermine the conclusions that can be drawn. One reason that patients with lumbar z-joint pain might respond to arthrodesis is that some surgeons, either purposefully or inadvertently, perform medial branch rhizotomies during pedicle screw placement. More recently, some surgeons have proposed total posterior arthroplasty (TOPS) to treat the pain associated with lumbar stenosis, which frequently includes facet changes. The TOPS system has articulating components that are meant to allow motion while providing stability in patients appropriate for one- or two-level decompression. In a prospective pilot study involving 29 patients, TOPS was found to improve disability (measured by the ODI) and pain. No other data on this treatment are currently available, and this procedure is intended for spinal stenosis patients and is therefore probably not
generalizable to the larger facet arthropathy population. On a similar note, percutaneous fusion and open facet arthroplasty have recently been touted for treatment of facet joint pain, but there are no prospective outcome data for either procedure. In summary, there is no convincing evidence to support any surgical intervention for lumbar z-joint pain aside from that resulting from a traumatic dislocation.

**COMPLICATIONS**

Serious complications and side effects are extremely uncommon after facet interventions. The metabolic and endocrine sequelae of intraarticular depot steroids have not been studied, but by extrapolating from epidural steroid injections one would expect suppression of the hypothalamic-pituitary-adrenal axis for up to 4 weeks, depending on the depot steroid used and impaired insulin sensitivity manifested as elevated glucose levels for less than a week. Though rare, a host of infections have been associated with intra-articular injections, including septic arthritis, epidural abscess, and meningitis, but none have been reported following RF denervation. Case reports of spinal anesthesia and post–dural puncture headache have also been published.

A recently published study described the complications associated with more than 7400 patient encounters and more than 43,000 individual facet injections in the cervical, thoracic, and lumbar spine. There were no serious complications. Intravascular injection was detected in 11.4% of the patients overall, with the highest prevalence in the cervical region (20%). Local oozing was noted in 76.3% of patients, also more frequently in the cervical region. In less than 1% of cases, patients experienced vasovagal reactions, bruiising, and nerve root irritation. Catastrophic injuries have been reported, including a posterior circulation stroke during a C1-2 intra-articular steroid injection that was thought to be due to microvascular injury from accidental injection into the vertebral artery.

Numbness, dysesthesias, or both have been reported after RF denervation but tend to be transient and self-limited. Burns are rare with RF procedures and may result from electrical faults, breaks in the insulation of electrodes, and generator malfunction. The most common complication following facet joint RF is neuritis, with a reported incidence of less than 5%. In one study, administration of corticosteroid or pentoxifylline was found to reduce the incidence of postprocedural pain following RF denervation. There is also a theoretical risk for thermal injury.

to the ventral rami if an electrode slips ventrally over the lumbar transverse process.

CONCLUSION

Pain originating from the facet joints has long been recognized as a potential source of back and neck pain. Anatomic studies suggest that with aging, the lumbar facet joints become weaker and their orientation changes from coronal to sagittal positioning, thereby predisposing individuals to injury from rotational stress. The three most caudal lumbar facet joints, L3-4, L4-5, and L5-S1, are exposed to the greatest strain during lateral bending and forward flexion and are thus more prone to repetitive strain, inflammation, joint hypertrophy, and osteophyte formation. In patients with chronic neck pain, the C2-3 and C5-6 facet joints are most commonly affected. OA of the facet joints is frequently found in association with DDD. The exact prevalence of facet disease is unclear but may be as high as 10% to 15% in patients with axial LBP, 49% to 60% in patients with chronic neck pain, and 42% to 48% in patients with axial midback pain.

No discrete historical and physical findings are pathognomonic for lumbar, thoracic, or cervical facet arthropathy. Paraspinal muscle tenderness appears to be the only physical examination finding associated with a positive response to RF of the medial branch; however, its specificity is not known. Referral patterns for pain arising from the facet joints at different levels and from different structures (e.g., facet joints and disks) overlap considerably. In addition to axial LBP, pathology arising from the lower facet joints is associated with referred pain to the buttock, thigh, groin, and sometimes the lower part of the leg, whereas pain referred from the upper lumbar facet joints extends into the flank, hip, groin, and lateral aspect of the thigh. Cervical facet disease tends to refer pain to the neck, head, shoulders, and midback region. Reports on the correlation between CT and MRI evidence of facet arthropathy and the response to diagnostic lumbar facet blocks are conflicting. Since the facet joint is innervated by medial branches arising from the posterior rami of the spinal nerve at the same level and a level above the joint, LA blocks of these nerves have been advocated for diagnostic and prognostic purposes. Intra-articular facet injections with LA have also been proposed as an alternative method for diagnosing facet joint pain, although they may be technically more challenging and the existing data suggest that MBB may be a better predictive tool for RF denervation outcomes. Similar to other blocks, the potential for false-positive and false-negative results needs to be considered and steps implemented to reduce their incidence.

In addition to providing short-term and occasionally intermediate-term pain relief, diagnostic blocks are considered predictive of the potential usefulness of subsequent neurolytic procedures such as RF denervation. In carefully selected patients who fail conservative treatments, such as physical and pharmacological therapies, intra-articular steroid injections and RF denervation are treatment options. Studies evaluating the long-term outcomes of RF denervation have demonstrated efficacy in well-selected patients; however, there are limited data on the effectiveness of this procedure in clinical practice. The results of surgical therapies for facet arthropathy are discouraging.

ACKNOWLEDGMENT

The opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense. Dr. Brummett receives support from National Institutes of Health Grant RO1 AR060392, an American Society of Regional Anesthesia and Pain Medicine Chronic Pain Research Grant, the Michigan Genomics Initiative, and the Department of Anesthesiology at the University of Michigan. Dr. Cohen receives partial salary support from the Congressman John P. Murtha Neuroscience and Pain Institute, Johnstown, Pa, Pennsylvania, and the U.S. Army.

KEY POINTS

- The facet joints are a potential cause of axial neck and back pain.
- The most commonly affected lumbar facet joints are L3-4, L4-5, and L5-S1.
- The most commonly affected cervical facet joints are C2-3, C4-5, and C5-6.
- No pathognomonic historical, physical examination, or radiologic findings are sensitive or specific for facet pain.
- In patients who fail conservative therapies, minimally invasive facet interventions can be considered.
- Radiofrequency denervation of the medial branches in the affected area can provide pain relief for 6 to 12 months.
- Medial branch blocks are potentially prognostic of radiofrequency denervation outcomes.
- Intra-articular facet joint injections with local anesthetic and steroid may provide diagnostic value and short-term pain benefit in patients with acute inflammation.
- Surgery is not recommended for axial spine pain thought to be due to facet joint disease.

The use of electric current for pain management has a long history. As early as the second half of the 19th century, brain lesions were made in animals with the application of direct current, and empirical rules for quantifying lesion size based on current and time were developed. One of the first uses in humans was for the management of trigeminal neuralgia in 1931, when a direct current was delivered through a needle with a 10-mm uninsulated tip placed in the gasserian ganglion. This technique produced lesions with unpredictable size. The use of high-frequency electric current was later found to produce lesions with predictable size. Because frequencies of 300 to 500 kHz were also used in radio transmitters, the current was called radiofrequency (RF) current. Later, temperature monitoring was suggested to be the most important parameter to obtain a standardized lesion size.

In pain management, RF was first used for percutaneous lateral cordotomy to relieve unilateral pain in cancer patients. A few years later, RF treatment of trigeminal neuralgia was described. The first use of RF current for spinal pain was reported by Shealy, who performed RF lesioning of the medial branch for lumbar zygapophyseal joint pain. Another application for spinal pain was introduced by Uematsu, who described RF lesioning of the dorsal root ganglion (DRG).

At the end of the 1970s, percutaneous cordotomy and RF treatment of the gasserian ganglion were the only widely accepted RF procedures. A turning point came in 1980, when small-diameter electrodes, known as the Sluijter Mehta Kit (SMK) system, were introduced for the treatment of spinal pain. The system consists of a 22-gauge disposable cannula with a fine thermocouple probe inside for measurement of temperature. The smaller electrode size resulted in diminished discomfort during the procedure. Because there was less risk for mechanical injury to major nerve trunks, targets in the anterior spinal compartment were no longer off limits, and procedures such as RF lesions adjacent to the DRG (RF-DRG) and lesions of the communicating ramus and sympathetic chain became part of the treatment armamentarium.

Over the years the concept that the clinical effect of RF current was caused by the formation of heat had not been challenged. A selective effect of heat on thin nerve fibers was thought to interfere with the conduction of nociceptive stimuli.

There were several reasons why the role of heat was finally questioned. First, the classic concept presupposes a strict configuration: the RF lesion must be made in between the nociceptive focus and the central nervous system (CNS). Yet RF lesions were also successful when not performed between the nociceptive focus and the CNS. For example, in the treatment of acute radicular pain from a herniated disk, the electrode is placed distal to the nociceptive focus. Second, RF-DRG induces only transient sensory loss, which is possibly heat related, whereas the pain relief may be of much longer duration. Finally, the role of heat was also questioned by the publication that no differences in outcome were noted when two different tip temperatures (i.e., 40°C and 67°C) were applied. It is against this background that pulsed radiofrequency (PRF) treatment was developed. PRF delivers strong, fluctuating electric fields while the temperature effects are kept to a minimum. PRF was conceived as a novel, potentially safer mode of administration of RF energy. It can be specifically useful for treatments in which RF lesioning is not indicated, such as peripheral neuropathies, arthrogenic pain, painful trigger points, and application to the DRG in patients with neuropathy or radicular pain.

**RADIOFREQUENCY GENERATOR SYSTEM**

A modern RF lesion generator has the following functions:

- Continuous online measurement of impedance
- Nerve stimulation
- RF delivery mode
- Pulsed current delivery mode
- Monitoring of voltage, current, and wattage during the RF procedure
- Temperature monitoring

Electrical impedance is measured to confirm continuity of the electrical circuit. After placement of the needle under fluoroscopic control, nerve stimulation is performed to confirm proper position of the electrode. Stimulation is carried out at 50 Hz to ensure proximity of the electrode to sensory fibers; 2-Hz stimulation is performed to detect muscle contractions, which indicate that the position of the needle is too close to motor fibers. If an electrode is actually resting on a nerve, the minimum stimulation level required to produce a discharge is 0.25 V. At a distance of 1 cm from the nerve, 2 V would be required; thus the stimulation threshold is an indicator of the distance of the electrode from the nerve. Temperature is measured with a thermocouple electrode. A thermocouple electrode consists of a junction of two dissimilar metal elements and produces a voltage that is proportional to temperature.

**THEORETICAL ASPECTS OF RADIOFREQUENCY TREATMENT**

**CONTINUOUS RADIOFREQUENCY TREATMENT**

The generator establishes a voltage gradient between the (active) electrode and the (dispersive) ground plate. RF
current flowing through the tissue results in an alternating electric field. This electric field creates an electric force on ions (electrolytes) in the tissue that causes the ions to move back and forth at a high rate. Frictional dissipation of the ionic movement within the fluid medium results in tissue heating. RF heat is therefore generated in the tissue and the electrode is heated by the tissue. The size of the lesion depends on the temperature of the tip of the electrode, and tip temperature depends on the amount of power delivered. There are also other factors that influence lesion size, for instance, heat and the type of tissue. Heat is removed from the lesion area by conductive heat loss and by blood circulation (heat “washout”). The larger the heat washout, the smaller the lesion will be for a given tip temperature. Tissue factors influence heat washout. For example, bone is an effective heat insulator, and for this reason, RF lesions close to bone will have less washout. Similarly, segmental blood vessels, which lie in close relationship to the DRG, may cause more heat washout and thereby reduce the size of the lesion.22

PULSED RADIOFREQUENCY TREATMENT

The treatment effect of PRF is based on the dual effect of exposure of the tissue to RF fields (Fig. 62.1). Besides the ionic friction that causes the production of heat, there is an independent, electric field effect. The mechanism of this electric current effect is thought to be an alteration in synaptic transmission in a neuromodulatory type of effect.18,19,23 Trans-synaptic induction of gene expression in the dorsal horn has been found in both the short and long term.24

PRACTICAL CONSIDERATIONS

It may be wise to avoid ultralow sensory thresholds (<0.05 V) because such values may reflect intraneural electrode placement.22 In a small proportion of procedures the mean tip temperature exceeds 42° C at some point during the PRF procedure. In this case, power output should be decreased as a precaution. This can be done by lowering the voltage or by decreasing either the duration of the active cycle (typically 20 to 30 msec) or the frequency of the cycle (typically 2 Hz).

It is undesirable to adjust the voltage during a PRF procedure to reach the mean tip temperature since the mean tip temperature does not affect the outcome of the procedure.26 Because there is a large variation in heat washout, large and unpredictable variations in voltage will occur.

INDICATIONS FOR AND CONTRAINDICATIONS TO RADIOFREQUENCY TREATMENT

RADIOFREQUENCY TREATMENT PROCEDURES ON THE HEAD

TRIGEMINAL NEURALGIA

Patients with trigeminal neuralgia have brief episodes of sharp, shooting pain in one or more of the trigeminal divisions that are typically provoked by touch. This so-called trigger area need not be in the division where the patient experiences pain. Many patients with pain in the first division, for example, have the trigger zone in the second division. In the classic case the patient is free of pain between episodes. However, residual pain has been reported in 42% of cases.27 These patients were described as having a combination of trigeminal neuralgia and atypical facial pain. Some of these patients even had a continuous type of pain before the onset of trigeminal neuralgia. Trigeminal neuralgia predominantly occurs in older age groups (50+ years), although it may occasionally be seen in very young patients. It is thought to be caused by vascular compression of the trigeminal root. In patients with multiple sclerosis it occurs frequently and may indeed be the first symptom of the disease. In a study evaluating the clinical characteristics of patients with trigeminal neuralgia, 22 had multiple sclerosis. Six of them had atypical trigeminal neuralgia and 16 had signs of brainstem involvement.28 It is not clear whether the pain is caused by plaques in the CNS in these patients, but clinically there was no distinction between patients with and without brainstem involvement. Trigeminal neuralgia may also be caused by a primary brain tumor (acoustic neuroma), which should always be excluded before symptomatic treatment is considered (red flag).

Treatment

In younger patients, posterior fossa craniotomy with microvascular decompression is the treatment of choice.29 This treatment has a high rate of success and avoids the sensory loss that is one of the consequences of thermocoagulation of the ganglion. This procedure has a low complication rate. When complications do occur, they are mostly serious neurologic deficits.30 In patients with multiple sclerosis the procedure should be combined with partial sectioning of the trigeminal nerve.31 This could be an indication for...
a more central mechanism in these patients. Pain relief is substantially longer after microvascular decompression than after thermocoagulation of the ganglion. If the pain recurs, recurrent vascular compression is seldom found during reoperation. In such cases, partial sectioning of the nerve could be performed. However, other forms of treatment such as thermocoagulation are generally recommended because the incidence of complications is distinctly higher after reoperation. The outcome of thermocoagulation is less favorable, though, in operated patients. The choice between microvascular decompression, a major operation with potentially longer effect, and RF treatment of the gasserian ganglion is a clinical decision in which age, physical condition, and personal preference of the patient have to be taken into account.

**Evidence**

There is extensive experience with RF treatment of trigeminal neuralgia. A review of 25 years’ experience in 1600 patients undergoing percutaneous RF trigeminal rhizotomy for idiopathic neuralgia indicated acute pain relief in 97.6% and continued complete pain relief at 5 years’ follow-up in 57.7%. Comparisons with other techniques are based mainly on retrospective evaluations.

The effectiveness of PRF for trigeminal neuralgia is still under debate. One prospective randomized study demonstrated that PRF is not an effective method of treating pain in patients with idiopathic trigeminal neuralgia.

**Procedure**

The technique for placing a needle (preferably an SMK-C10) in the gasserian ganglion is as follows:

The oval foramen is visualized first by using a tunnel view technique. To do this the direction of the x-rays should be reversed from the normal configuration because the image intensifier is too bulky to avoid contact with the patient’s chest. The position of the C-arm should be adjusted until the oval foramen is identified just medial to the mandibular processes and just lateral to the maxilla.

The shape of the foramen varies with the angle of the x-rays in the horizontal plane. A more vertical direction will transform the foramen into a round, almost circular shape. A more horizontal direction will make the foramen flat, like a split. The C-arm should be adjusted so that the foramen really has its oval shape. If the skin entry point is now marked over the target point, it will be seen that variation from patient to patient, in relation to the corner of the mouth, is considerable. The entry point may be just superior to the mandible, but it also may be much more superior, close to the maxilla.

The division of the trigeminal nerve that is the target for treatment also determines the choice of entry point. For the first division, the end position must be made medial and more superior.

**Adverse Events and Complications**

The procedure is associated with very low morbidity and virtually no mortality. Reports vary considerably regarding recurrence of pain. This may be due to variations in technique. If a dense sensory loss is produced, there is a lower incidence of recurrence. However, loss of facial sensation and the accompanying paresthesia account for 80% of the side effects of the procedure. If RF treatment with a less intense lesion is performed, it might be associated with a lower incidence of paresthesia but potentially earlier recurrence. Other complications involve masseter weakness and paralysis (4.1%), anesthesia dolorosa (1%), keratitis (0.6%), and transient paralysis of cranial nerves III and IV (0.8%).

![Figure 62.2](image-url)
A much less frequent complication is permanent palsy of the abducens nerve.  

**CHAPTER 62 — RADIOFREQUENCY TREATMENT**

**CHAPTER 62 — RADIOFREQUENCY TREATMENT**

RADIOFREQUENCY TREATMENT OF THE PTERYGOPALATINE (SPHENOPALATINE) GANGLION

The pterygopalatine ganglion is a parasympathetic ganglion located in the pterygopalatine fossa just beneath the maxillary nerve. It is in or close to the foramen that connects the pterygopalatine fossa to the nasal cavity. Preganglionic fibers reach the ganglion from the facial nerve through the greater superficial petrosal nerve and the nerve of the pterygoid canal. There are also connections through the deep petrosal nerve that joins with the greater superficial petrosal nerve to form the vidian nerve (Fig. 62.4). Many afferent fibers originating from the nasal mucosa, the soft palate, and the pharynx cross the ganglion on their way to the maxillary nerve and eventually to the gasserian ganglion.

**Treatment and Evidence**

The rationale for RF treatment of cluster headache is based on the parasympathetic symptoms that occur during an attack. Treatment of atypical facial pain in the second division of the trigeminal nerve has also been described. A case report on PRF treatment of the pterygopalatine ganglion for post-traumatic headache described 17 months of pain relief. Analysis of PRF treatment of the pterygopalatine ganglion in 30 patients suffering from chronic head and facial pain showed complete relief of pain in 21% and mild to moderate relief in 65%. No side effects or complications were mentioned. Evidence for the use of PRF is weak, but given the safe character of this treatment, the authors recommend the use of PRF for these conditions.

**Procedure**

The patient is placed in supine position with the head immobilized. The pterygopalatine fossa is identified on the lateral fluoroscopic image, and a line overlying the fossa is drawn on the skin. The intersection of this line with the inferior edge of the zygomatic arch is the entry point. After anesthetizing the skin, a 10-cm SMK cannula with a 5-mm active tip is inserted at this point and then carefully advanced under lateral fluoroscopic control in a superior and anterior direction to enter the pterygopalatine fossa (Fig. 62.5). As soon as the fossa is entered, the cannula contacts with the maxillary nerve, and the patient reports a paraesthesia, 1 to 2 mL of 2% lidocaine is injected. The cannula is advanced further until the tip reaches the pterygopalatine ganglion. The pterygopalatine ganglion is located in the anterior superior corner of the fossa. It is important for the tip to actually pass the rim of the fossa to prevent damage to the maxillary nerve during the lesion.

The C-arm of the image intensifier is then placed in the anteroposterior (AP) position. The tip of the cannula
should now be projected over the lateral wall of the nasopharynx (Fig. 62.6).

The stylet is removed and replaced with a thermocouple RF probe. The position of the electrode is verified by electrical stimulation at 50 Hz, and this usually results in paresthesia inside the nose at 0.2 to 1.0 V. Paresthesia occurring at the outside of the cheek or upper lip indicates stimulation of the maxillary nerve and thus that the tip of the needle is too far lateral. If the patient reports paresthesia in the palate, the cannula is advanced a few millimeters. Treatment consists of three consecutive lesions performed at 70° C to 80° C for 60 seconds. In between these lesions the cannula is slowly advanced (1 to 3 mm).

**Adverse Events and Complications**

Total destruction of the pterygopalatine ganglion causes dryness of the eye, an “open nose” because the mucosa has less inclination to swell, and numbness of the soft palate. Following a heat RF lesion, dryness of the eye is unusual. Numbness of the soft palate does occur, but the condition is usually temporary, with gradual recovery occurring over a period of 4 to 6 weeks. Sometimes loss of taste can be permanent.

**RADIOFREQUENCY TREATMENT PROCEDURES ON THE CERVICAL SPINE**

**CERVICAL FACET (ZYGAPOPHYSEAL) JOINT PAIN**

The most common symptom associated with pain arising from the cervical facet joints is unilateral pain that does not radiate past the shoulder. Pain emanating from the cervical facet joints can be referred to the occiput, the interscapular region, or the shoulder girdle regions, depending on which cervical facet joint is involved. Pain from the higher cervical facet joints may be the origin of cervicogenic headache. Physical examination of the cervical spine usually shows paravertebral tenderness and limitation of rotation and retroflexion. Computed tomography and magnetic resonance imaging may reveal morphologic abnormalities of the facet joints. However, degenerative changes of the cervical spine are present in asymptomatic patients, thus supporting the lack of correlation between radiologic findings and pain.

Indications for RF treatment of the medial branches that innervate the cervical facet joints are degenerative and post-traumatic neck pain (i.e., whiplash-associated disorders). The anatomy of the cervical spine is illustrated in Figure 62.7. RF treatment of the cervical medial branches is aimed at reducing nociceptive signals from the spinal facet joints and shows some promise for the treatment of cervicogenic headache. RF facet joint treatment is usually performed at two or three segmental levels.

**Evidence**

Percutaneous RF treatment of cervical facet–mediated pain has been studied intensively. The data from original articles were summarized in systematic reviews. Only one randomized controlled trial (RCT) has evaluated RF treatment of the ramus medialis (medial branch) of the ramus dorsalis in patients with whiplash-associated disorders. The effectiveness of RF treatment of degenerative neck pathology was shown in observational studies. A retrospective chart analysis of the effect of repeated RF facet treatments illustrated that the mean duration of effect of the first intervention was 12.5 months. The procedure can be repeated when pain recurs, with similar success. Patients who respond positively to the first intervention received up to six additional interventions. After each RF intervention more than 90% of the patients had satisfactory pain relief, and the duration of effect was between 8 and 12 months.

Van Suijlekom and coworkers evaluated the effect of RF lesioning of the medial branch of the dorsal ramus at the C3-4 levels for the treatment of cervicogenic headache. In this study the postural lateral approach was used. They demonstrated that RF cervical facet treatment leads to a significant reduction in headache severity, number of days with headache, and analgesic intake in patients with cervicogenic headache diagnosed according to the criteria of Sjaastad and colleagues. In a randomized, double-blind, sham-controlled study on RF treatment of facet joints C2-3 for the treatment of cervicogenic headache, 12 patients were included and monitored for 24 months. A slight improvement was noted in the RF group at 3 months, whereas no differences were seen during the remaining follow-up period. In contrast, Haspeslagh and associates could not find evidence that RF treatment of the cervical facet joints is better than injection in the greater occipital nerve. However, definite conclusions on the clinical efficacy of the procedure can be drawn only from an RCT with a greater number of patients.

**Procedure**

Several approaches can be used to reach the medial branch of the dorsal ramus at the upper and middle cervical area. We use the posterolateral technique, which was first described with a three-quarter projection of the C-arm. Since this technique is difficult to perform because it is...
not a tunnel view technique, we developed a new approach with a lateral projection. For this technique the patient is positioned supine on the operating table.

For treating the upper cervical levels, the domelike structure between C1 and C2 should be aligned without any double contours. Usually, the facet joint space of C3-4 is clearly visible, also without double contours. Adjustments of the C-arm are often necessary for the C4, C5, and C6 levels, with alignment of the facet joint spaces and the facetal column needed every time. In this position the anterior and posterior tubercles of the neuroforamen can be seen projected over the vertebral body. The medial branch runs just above the posterior tubercle, midway between the facet joints. Needle entry points should be at the dorsal side of the facetal column in a virtual vertical line exactly between the facet joint spaces. Under fluoroscopic guidance the needle electrode is carefully placed in a slightly anterior horizontal direction until contact is made with the facetal column (Fig. 62.8). The tip of the needle should be at or just above the posterior tubercle, midway or slightly rostral between the facet joint spaces. To confirm that the tip of the needle is close to the segmental nerve but not in the neuroforamen, the C-arm is placed in an approximately 30-degree oblique position in such a way that the projection of the contralateral pedicles is 50 degrees anterior to the vertebral body (Fig. 62.9). This position is sometimes preferred for
treatment of the C6 and C7 levels because of overprojection of the shoulders on the lateral view.

Positioning the C-arm in the AP direction should confirm the position of the tip of the needle adjacent to the concavity ("waist") of the articular pillars of the cervical spine at the corresponding level (Fig. 62.10). When optimal anatomic localization of the needles is achieved, an electrical stimulation is performed to confirm correct needle position. An electrical stimulation rate of 50 Hz should elicit a response (tingling sensation) in the neck at less than 0.5 V. Stimulation at 2 Hz is performed to confirm accurate needle position. Contractions of the paraspinal muscles will be noticed. Muscle contractions in the arm indicate placement of the needle too close to the exiting nerve. In this case the needle should be repositioned more posteriorly. Once proper positioning of the needle is confirmed, the medial branch of the dorsal ramus is anesthetized with 1 to 2 mL of local anesthetic solution (1% or 2% lidocaine). An 80° C RF thermal lesion is made for 60 seconds at each level.

Another method is a posterior approach to the facet joint. This was first introduced by Lord and associates in 1995. For this technique the patient is positioned prone on the operating table with the head flexed (about 5 to 10 degrees) and the face resting on a padded ring. The electrode is introduced twice for each nerve: once along a parasagittal path to reach the nerve as it crosses the lateral aspect of the articular pillar and again at a 30-degree angle to the sagittal plane to reach the nerve over the lateral aspect of the articular pillar.

**Adverse Events and Complications**

Complications are rare. Nevertheless, one should be aware that the vertebral artery may be punctured if the needle is pushed too far anterior into the foramen intervertebral. The position of the tip of the needle should be verified with AP fluoroscopy to prevent intrathecal injection of the local anesthetic. In an observational study the incidence of inadvertent intravascular penetration for medial branch blocks at a cervical level was reported to be 3.9%, comparable to the incidence at a lumbar level (3.7%). Some patients experienced short-term vasovagal reactions. Intravascular uptake of local anesthetic and contrast solution was thought to be responsible for the false-negative diagnostic blocks. No systemic effects were reported. Monitoring of the saturation level and availability of resuscitation equipment are essential. Infections have been described, but the incidence is unknown and probably very low.

Other potential complications of facet joint interventions are related to needle placement and drug administration; they include dural puncture, spinal cord trauma, spinal anesthesia, chemical meningitis, neural trauma, pneumothorax, radiation exposure, facet capsule rupture, and hematoma formation. After RF treatment, burning pain is regularly reported postoperatively, but this pain disappears in 1 to 3 weeks. There are no incidence data on side effects and complications following cervical RF treatment of the ramus medialis (medial branch) of the ramus dorsalis. At the lumbar level the incidence of complications was lower than 1%.

**CERVICAL RADICULAR PAIN**

Cervicobrachialgia is a common pain syndrome. Bland estimated that 9% of all men and 12% of all women experience this pain at some time in their lives. Later, in 1994, Radhakrishnan and associates published a population-based survey. This epidemiologic survey found the annual incidence of cervical radiculopathy to be 83.2 per 100,000 population between 13 and 91 years of age.

The pain in cervicobrachialgia is described as a continuous, dull aching pain in the neck (most commonly localized in the mid and lower cervical area) that radiates beyond the shoulder into the arm with referral to a particular spinal...
Segmental pain in the upper extremity can be related to disk pathology, such as cervical disk protrusion with irritation of the spinal nerve. Spinal nerve irritation can also be caused by narrowing of the intervertebral foramen by spondylosis. The most common levels involved are C6, C7, and to a lesser extent, C5. Involvement of the C4 and C8 levels is uncommon. The involved spinal level can be estimated by the dermatome in which the pain is radiating and can be confirmed by diagnostic nerve blocks. Diagnosis of cervical radicular pain and radiculopathy requires complete history taking and clinical diagnosis using standardized methods of physical examination, medical imaging, electrophysiologic investigation, and selective nerve root blocks.

Evidence

In 1991, Vervest and Stolker published a retrospective study of 53 patients with prolonged cervical pain radiating to the occipital region, head, shoulder, or arm that did not respond to conservative treatment. If the patient had local tenderness at the facet joints, a percutaneous cervical facet joint treatment was performed. If this treatment was not successful and there was cervical pain with referral to the occipital region or arm, indicative of segmental nerve irritation, diagnostic segmental nerve blocks were performed. A positive diagnostic block was followed by RF-DRG. The results were good to excellent in more than 80% of treatments. Even after a follow-up of 1.5 years, more than 80% still had satisfactory pain relief.

In an open prospective study of 20 consecutive patients with chronic intractable pain in the cervical region and referral to the head, shoulder, or arm, RF-DRG provided pain relief in 75% at 3 months and in 50% at 6 months. These results indicate acceptable initial pain relief but a tendency for recurrence of the pain at 3 to 9 months. A prospective double-blind, randomized, sham-controlled trial of RF lesions adjacent to the cervical DRG for the management of chronic cervical radicular pain showed a positive outcome during the first 8 weeks after the procedure. In a double-blind, randomized study with 3 months’ follow-up, Slappendel and colleagues found that RF treatment adjacent to the cervical DRG at 40°C is as effective as treatment at 67°C.

Despite these encouraging results, Geurts and associates in a systematic review concluded that there is limited evidence that RF-DRG is more effective than placebo for chronic cervicobrachialgia. In their systematic review Niemisto and coworkers came to the same conclusion.

In 2003, Van Zundert and colleagues published a clinical audit of 18 patients with cervicogenic headache or cervicobrachialgia who failed conservative treatment and underwent PRF treatment adjacent to the cervical DRG. Seventy-two percent of the patients had a minimum reduction in pain of at least 50% at 8 weeks. At 1 year, 33% of the patients continued to rate the treatment outcome as good or very good. No neurologic side effects or complications were observed. These results were later confirmed in an RCT in which PRF appeared to be more effective than placebo 3 months after treatment. In addition, 6 months after treatment there was a positive trend for PRF treatment, but in this study the outcome fell short of statistical significance. The need for pain medication was significantly reduced in the PRF group after 6 months. No complications were observed during the study period.

There is limited evidence that PRF treatment of the DRG (PRF-DRG) on a cervical level is as effective as RF-DRG. However, PRF-DRG is safer and has fewer side effects. Therefore, the authors suggest that cervical radicular pain be treated with PRF-DRG and not with RF-DRG.

Procedure

To perform a diagnostic segmental nerve block, a viewing technique is used in which the C-arm is positioned so that the x-rays are parallel to the axis of the intervertebral foramen. This axis points 25 to 30 degrees anteriorly and 10 degrees caudally. With the C-arm in this position, entry is determined by projecting a metal ruler over the caudal part of the foramen. A 50-mm, 22-gauge neurography needle is carefully introduced parallel to the beam of the x-rays. The direction of the x-rays is then changed to the AP position and the cannula is introduced further until the tip is projecting just lateral to the facial column. After the segmental nerve has been identified with 0.4 mL of iohexol contrast medium, 0.5 mL of 2% lidocaine is slowly infiltrated around the nerve. The resultant radiopaque mixture is closely observed during injection so that accidental overflow into the epidural space can be avoided.

For the RF procedure, the same viewing technique is used. The entry point is found by projecting the metal ruler over the caudal and posterior parts of the foramen. The cannula (SMK-C5 with a 2-mm exposed tip) is introduced parallel to the beam of the x-rays, and if necessary, the approach is corrected while still in the superficial layers until the cannula is projected on the screen as a single dot (Fig. 62.11). In practice this dot should lie directly over the

![Image](image.png)

Figure 62.11 Radiofrequency lesion adjacent to the dorsal root ganglion in a 20-degree oblique, 10-degree cranio-caudal projection. The needle is positioned in the posterior aspect of the fossa at the junction of the middle and caudal third part. It is projected as a dot in tunnel vision.)
dorsal part of the intervertebral foramen at the transition between the middle and most caudal third. This dorsal position is chosen to avoid possible damage to the motor fibers of the segmental nerve and to the vertebral artery that runs anterior to the ventral part of the foramen. The direction of the x-rays is then changed to AP and the cannula is further introduced until the tip is projected over the middle of the facet column (Fig. 62.12).

The stylet is now replaced with the RF probe. After checking the impedance, electrical stimulation is started at a rate of 50 Hz. The patient should feel a tingling sensation between 0.4 and 0.65 V. The frequency is then changed to 2 Hz and the patient is observed for muscle contractions. These contractions should not occur below a voltage of 1.5 times the sensory threshold. One-half milliliter of iohexol is injected to exclude accidental intradural positioning of the electrode, followed by 2 mL of 2% lidocaine. RF current is then passed through the electrode to increase the temperature of the tip to 67°C. This temperature is maintained for 60 seconds.

**Adverse Events and Complications**

A side effect that is often seen (40% to 60%) is a mild burning sensation (some deep neck soreness) in the treated dermatome, but it subsides spontaneously after 1 to 3 weeks. Some sensory changes such as slight hypoesthesia may occur but invariably disappear within 3 or 4 months. Known complications of blockade of a cervical segmental nerve are epidural, intrathecal, or intravascular injection of local anesthetic. During this procedure, injectant can be placed in the adjacent venous plexus, in the vertebral artery, or even in the carotid artery. Because of the proximity of the higher cervical levels to the brain, there is a risk for local anesthetic CNS toxicity (seizure), although only a low volume of local anesthetic is used.

**RADIOFREQUENCY PROCEDURES ON THE THORACIC SPINE**

Thoracic pain accounts for approximately 5% of all referrals to a pain clinic. Thoracic pain may have many causes, from cardiac to lung pathology, in addition to pain referred to the chest from other affected organs (upper abdominal organs such as the gallbladder and pancreas). Pain in the lower thoracic region must be differentiated from renal pathology. Thoracic pain may have an underlying pathology such as disk herniation, aneurysms, tumors, postoperative sternal wound infection, trauma, old fractures, herpetic infection, and stress fractures in athletes. Chronic postsurgical pain has been described after many different operations, most notably thoracotomy, mastectomy, and coronary artery bypass grafting. However, in most cases, thoracic pain is judged to be of spinal origin and emanating from nociceptive nerve endings in the periosteum, ligaments, disks, or joints.

Thoracic pain can be divided into thoracic mechanical joint pain and thoracic segmental pain. The thoracic spine is a relatively immobile section. The range of motion in both flexion and extension is on the order of 10 degrees, and lateral flexion is almost impossible. Rotation is the only meaningful movement of the thoracic spine.

Thoracic mechanical pain is characterized by pain in both thoracic facet joints, as well as the thoracic disks. Pain emanating from thoracic facet joints is usually related to degenerative processes, vertebral collapse, and continual mechanical strain. The problem can be in the facet joint but may be manifested elsewhere in the spine. There are no specific pathognomonic criteria whereby thoracic facet joint pain can be diagnosed from a patient’s history and physical examination. A diagnosis of thoracic facet joint pain can be based on the similarity of the symptoms to lumbar and cervical facet syndromes. Extensive examination should be performed to rule out any pathology as a primary cause of the symptoms and signs.

When thoracic spinal pain becomes chronic and resistant to conservative treatment modalities such as physical therapy, pharmacologic therapy, and transcutaneous electrical nerve stimulation, minimally invasive treatment modalities, including RF lesioning of the facet joints, can be considered.

The thoracic facet joints are more vertically oriented than the lumbar facet joints and lie almost parallel to the coronal plane (Fig. 62.13). They are oriented perpendicular to the sagittal plane and face directly anterior. The thoracic facet joints are innervated by medial branches of the posterior primary rami of the segmental nerves. Each thoracic facet joint is bisegmentally innervated by the medial branch of the same level and the medial branch of the level above. The thoracic medial branches pass through the intertransverse space and touch the superolateral corner of the transverse process. They then run medially and inferiorly across the posterior surfaces of the transverse processes before entering the posterior compartment of the back and innervating the multifidus muscles. In this location they send ascending articular branches to the facet joint. An exception to this pattern occurs at the midthoracic levels (T3-8). Although the curved course remains essentially the same, inflection occurs at a point superior to the superolateral corner of the
transverse process. This course is different from that seen with the lumbar medial branches, which are fixed at the junction of the superior articular process and the transverse process. The T11 and T12 medial branches have the same course as the lumbar medial branches.105

Evidence

Stolker and coworkers evaluated 40 patients with thoracic facet syndrome who underwent percutaneous facet joint treatment: 24 left sided, 21 right sided, and 6 bilateral. Seven study patients underwent two sessions, and two patients had three facet joint denervation sessions; 82% of the patients experienced 50% to 75% relief of their pain at 2 months. Four patients were lost to long-term follow-up (18 to 54 months, mean of 31 months), 44% of the study patients were free of pain, and 39% had a 50% or greater reduction in their pain.103 In line with these criteria being non-specific for thoracic facet syndrome, all patients in this study had positive diagnostic blocks performed before RF ablation. Stolker and coworkers attributed their results to the consistent course of the medial branch of the dorsal rami of the thoracic spinal nerves as they leave the intertransverse space; however, the anatomic target point (junction between the superior articular process and the transverse process) that they used in their study is at variance with the anatomic course of thoracic medial branch described by Chua and Bogduk.104 They reported that the medial branch crosses the superolateral corners of the transverse processes and then passes medially and inferiorly along the posterior surfaces of the transverse processes before ramifying into the multifidus muscle that it supplies.104 Bogduk and Long stated that a double-blind, controlled clinical trial of Stolker and colleagues’ approach to thoracic facet nerve denervation or modification of their procedure was needed to be concordant with the surgical anatomy of the thoracic medial branches.105

In another study by Tzaan and Tasker in 2000 in which 17 patients with thoracic facet syndrome were evaluated, 15 had satisfactory pain relief at follow-up, with 2 patients having their procedure repeated.106

Procedure

The patient is placed in the prone position. Obtaining a fluoroscopic view is quite difficult for a variety of reasons. In this region one has to contend with overprojection of the ribs, a prominent transverse process that is directed slightly cranial and markedly posterior, and the size and orientation of the pedicles, which can make them difficult to visualize. In addition, the orientation of the thoracic facet joints impedes the operator’s ability to differentiate between the superior and inferior articular processes.

In contrast to a diagnostic thoracic intra-articular block, which has been well described,107 expert opinion varies on RF lesioning of medial branches in the thoracic vertebrae. Nonetheless, we describe how to perform an RF lesion of the medial branches at the thoracic level. Although we embrace this technique, some authors have suggested that the tip of the needle is actually “too far anterior” to the medial branch to result in denervation. Using the junction between the superior articular process and the superior border of the transverse process as a target point for thoracic medial branch neurotomy, Stolker and colleagues reported that the medial branch of the dorsal ramus was never within reach of the electrodes.108 The C-arm is positioned in the axial plane, and an external radiopaque object such as a clamp is used to identify the proper level. A straight AP view of the vertebra at the anticipated target level is obtained. The end plates of the vertebra should be parallel without any visible double contours. The C-arm is then rotated slightly obliquely. This should facilitate access to the target point, which is the junction of the superior articular process and the transverse process. A proposed entry point is marked on the skin and local anesthetic (1% lidocaine) is injected with a 23-gauge needle. The RF needle is then inserted parallel to the angle of the C-arm beam until contact is made with bone at the junction of the superior articular process and the transverse process (Fig. 62.14A).

Subsequently, the needle is redirected slightly more cranially and laterally until it just loses osseous contact. Needle position is then checked on the lateral view. The tip of the needle should be just posterior to a line connecting the posterior aspects of the neuroforamina (see Fig. 62.14B).
Stimulation at 50 Hz is now performed. A paravertebral tingling sensation should be perceived with a current of less than 0.5 V. Next, stimulation at 2 Hz should provoke paravertebral muscle contractions at 1 V or less. Stimulation should be negative for anterior nerve root stimulation, which would be perceived as muscle contraction or pain in the anterior chest wall or abdominal region, depending on the level undergoing RF treatment. When proper needle position has been confirmed with fluoroscopic imaging and electrical stimulation, 0.5 mL of 1% or 2% lidocaine is administered at each level. After the local anesthetic has taken effect, lesioning is conducted for 60 seconds at 20 V. We typically perform RF treatment of three levels because of the multisegmental innervation of the facet joints.

**Adverse Events and Complications**

As with any RF procedure there is always the possibility of postprocedure exacerbation of pain. A complication unique to the thoracic region is pneumothorax. Proper technique and the use of fluoroscopic guidance for placement of the needle will minimize the risk for this complication. The patient must be warned of the possibility of the development of pneumothorax and should return to the hospital if shortness of breath or pain with inspiration develops.

**THORACIC RADICULAR PAIN**

Thoracic segmental pain syndromes have many causes, including disease or lesions of ribs, disorders of the thoracic skeletal spine (fractures, arthritis, metabolic disorders, and tumors), or neuropathies originating from the spinal roots, spinal nerves, or intercostal nerves.101 Some thoracic segmental pain syndromes are iatrogenic, such as post-thoracotomy and postmastectomy syndromes, as well as incisional pain after upper gastrointestinal surgery.99,100,109

Percutaneous thoracic sympathectomy is considered the most efficacious for sympathetically mediated pain, Raynaud’s syndrome, hyperhidrosis, and vasculopathy.103 Percutaneous RF treatment adjacent to the thoracic DRG has been described for segmental nerve pain related to intercostal pain, rib tip syndrome, 12th rib syndrome, vertebral collapse, and segmental peripheral neuralgia.

In the higher thoracic segments it is difficult to reach the DRGs because of overlying anatomic structures. Among the obstacles are the wide facet column, articulations of the transverse processes with the ribs, and most importantly, the lungs. The pulmonary structures prevent adopting a very lateral approach, which would have been ideal to allow one to get under the posterior osseous barriers. In successive lower thoracic segments, the anatomy gradually resembles that of the lumbar spine. This change creates an opportunity for a lower thoracic DRG to be reached as though it were a lumbar DRG.

**Evidence**

RF treatment adjacent to the thoracic DRG was evaluated in 45 patients who underwent 53 PRF-DRG procedures, 37 patients at one level, 1 bilaterally at one level, and 7 at two levels unilaterally. Clinical diagnoses included intercostal neuralgia, post-thoracotomy pain syndrome, postmastectomy pain syndrome, 12th rib syndrome, rib resection, osteoporosis, vertebral metastasis, and traumatic collapsed vertebra. At first follow-up 2 months after the procedure, 66.7% were pain free, 24% obtained greater than 50% pain relief, and 9% obtained no pain relief. Four patients were lost to long-term follow-up or died of their malignant disease. After a follow-up period of 13 to 46 months (median, 24 months), 49% were pain free, 37% had good pain relief, and 14.6% had no pain relief.108

The authors of this study advocated prognostic blockade as being essential to (1) confirm the diagnosis of segmental pain, (2) determine the appropriate level of treatment, and (3) assess the potential benefit of percutaneous RF-DRG.

In a similar study, van Kleef and Spaans110 evaluated the effects of single-level RF-DRG for thoracic segmental pain.
In this study, 43 patients with a minimum of a 6-month history of unilateral thoracic segmental pain unresponsive to conservative therapy were evaluated. Twenty-seven of the patients had pain in the distribution of only one or two segments (group 1), whereas 16 patients had pain at more than two segmental levels (group 2). Short-term analysis 8 weeks after the procedure showed that 52% of the patients in group 1 were pain free or had good pain relief whereas only 18% in group 2 were pain free or had good pain relief. Long-term follow-up (36 to 168 weeks, mean of 99 weeks) illustrated that 37% of the patients in group 1 were pain free or had good pain relief whereas only 18% of those in group 2 had such a positive outcome at long-term follow-up (40 to 60 weeks, mean of 128 weeks).

**Procedure**

Two or more diagnostic blocks at different levels must be performed to identify the segment involved because of frequent overlapping of thoracic segmental pain from one segment to another. An intercostal block can be used as a test block of a thoracic segmental nerve. The level that provides the best temporary reduction in pain is then selected for RF-DRG treatment. As described, in the upper thoracic spine the classic approach (posterolateral approach) is not possible because the foramina face more anteriorly and accurate positioning of the needle is hindered by the angle of the ribs. Therefore, an alternative technique is used to reach the DRG of T7 and above. The patient is placed in the prone position and a dorsal approach is used. The target point is the craniodorsal part of the intervertebral foramen and is thus the same as the target point in the classic dorsolateral approach. The entry point is the midpoint of the pedicle on the AP view (Figs. 62.15 and 62.16).

This entry point is checked on a lateral view, where it should be aimed at the superior dorsal quadrant of the foramina where the DRG is supposed to be lying. Under local anesthesia a small hole is drilled with a 16-gauge Kirschner wire through the lamina of the vertebra under fluoroscopic guidance in the AP view. A potential danger is piercing of the facet joint. The RF cannula is inserted through the hole into the proper position, which is checked on the lateral view and should be in the craniodorsal part of the intervertebral foramen (Fig. 62.17).
The stylet of the cannula is replaced with an RF probe, and stimulation at 50 Hz is carried out. The patient should feel tingling sensations in the selected dermatome when a 0.4- to 1.0-V stimulus is used. Stimulation at 2 Hz should not produce contractions of the intercostal muscles at a stimulation threshold below 1.5 times the sensory threshold. After satisfactory placement is achieved, 0.4 mL of iohexol contrast medium is injected to exclude intradural or intravascular spread. When correct position has been confirmed, 1 to 2 mL of 1% or 2% lidocaine is injected, and a 60-second 67°C lesion is made.

At the lower thoracic levels, the same approach can be used as at the lumbar level. The needle position, stimulation, and lesion parameters are identical. This technique is described later under RF-DRG treatment in the lumbar region.

A 10-cm SMK 22-gauge cannula with a 5-mm active tip and an RF probe can be used. This needle can be manually curved to perform the parasagittal approach. For the dorsal approach, a 16-gauge Kirschner wire can be used to make a bur hole in the lamina.

**Adverse Events and Complications**

One of the most important complications is the possibility of damage to the nerve root or spinal cord during placement of the needle. Another common complication is neuritis. Again, there is a slight possibility of pneumothorax and hemotherax. These particular complications should be described in detail to any prospective candidate for RF lesioning at the thoracic level. Other possible complications include infection, increased pain, bleeding, and bruising. It cannot be overemphasized that the occurrence of pneumothorax should be excluded clinically. If any doubt remains, radiographs are mandatory.

**Conclusion**

The data on RF facet and RF-DRG at the thoracic levels published in the years 1994 to 1996 were all collected retrospectively. For this reason the level of evidence for the different procedures is low. In the case of thoracic segmental radicular pain, for which treatment of the DRG might be considered, we prefer PRF-DRG as the first step; this is in line with policy on the cervical level. There is no formal evidence for RF or PRF, but PRF is safer on this level. When PRF-DRG on the thoracic level has a temporary effect, RF-DRG can be considered.

**RADIOFREQUENCY TREATMENT PROCEDURES ON THE LUMBAR SPINE**

The annual incidence of low back pain was found to be 18.6% in an adult population. The prognosis for this low back pain is not as good as we once believed. Spitzer and colleagues stated that 92% of these patients recover 6 months after onset of the low back pain. However, recent reviews indicate that approximately 62% of patients with low back pain still experience pain after 12 months. At this time there are few interventions with long-term effect on chronic low back pain. However, there are some evidence-based interventions with minimal clinical short-term effect, such as behavioral therapy, back schools, manipulation, and cyclooxygenase inhibitors. The minority of patients with low back pain have specific causes of their pain, such as a herniated disk, spondylolisthesis, diskitis, or fractures. Most have undiagnosed low back pain. In such patients the back pain may emanate from potential painful structures, including the lumbar facet joints, the intervertebral disks, or the sacroiliac (SI) joints. The anatomy of the lumbar spine is illustrated in Figure 62.18.

**LUMBAR ZYGAPOPHYSEAL (FACET JOINT) PAIN**

The prevalence of facet joint pain in an adult population with low back pain was found to be 15% to 32%. Patients with lumbar facet joint pain may exhibit paramedian pain (one or both sides), absence of exacerbation by coughing ($P \leq 0.07$), absence of exacerbation by forward flexion and rising from forward flexion ($P \leq 0.002$), absence of worsening by hyperextension, and pain immediately on standing and walking ($P \leq 0.001$). The diagnosis is confirmed by at least a 50% reduction in pain after a diagnostic local anesthetic nerve block of the medial branch of the dorsal ramus.

**Evidence**

Technically, two prerequisites for success of RF facet treatment are identifying the painful facet joints with a diagnostic block and precisely localizing the nerve of the targeted facet joints. Techniques for RF facet treatment vary nevertheless.
